DICTIONARY OF APPLIED PHYSICS

— A —

Abbé Autocollimating Eyepiece. See "Goniometry," § (1).

Abbé Refractometer: an instrument for the rapid determination of refractive indices, principally of liquids. See "Spectroscopes and Refractometers," § (14).

Abbé Spherometer. See "Spherometry," § (3).

Abbé Theory of Microscopic Vision. See "Microscope, Optics of the," § (23).

Abbé's Autocollimating Spectroscope: a spectroscope for the determination of refractive indices of solids requiring the use of a minimum of material. See "Spectroscopes and Refractometers," § (12).

Abbé's Crystal Refractometer: an instrument primarily intended for the measurement of refractive indices of crystals, but suitable also for other substances. See "Spectroscopes and Refractometers," § (15).

Abbé's Method of adjusting Rangefinders. See "Rangefinder, Short-base," § (14).

Aberration, Spherical, stated by Lord Rayleigh to be unimportant when it nowhere exceeds a small fraction of the wavelength. See "Optical Parts, The Working of," § (3).
  General Theory of, for Lenses. See "Optical Calculations," §§ (8), (21), (22); also "Lens Systems, Aberrations of," § (5) (iv.).

Aberration of Camera Lenses, Spherical and Chromatic. See "Camera Lenses, Testing of," §§ (2), (3), and (11).

Aberration of Lenses. See "Optical Calculations," § (8); also "Telescope," § (3); "Lens Systems, Aberrations of," § (5); also "Photographic Lenses," § (8).

Aberrations, Measurement of. See "Objectives, Testing of Compound," § (3).
  Hartmann's method. See *ibid.* § (3) (iii.).
  Microscope method. See *ibid.* § (3) (i.).
  Shadow method. See *ibid.* § (3) (ii.).

Aberrations of Oblique Pencils in Microscope Systems. See "Microscope, Optics of the," § (19).

Aberrations of Telescopes, Practical Treatment of. See "Telescope," § (4).
  Von Seidel's Five Aberrations. See *ibid.* § (3).

Abrasion, Characteristic Features of. See "Optical Parts, The Working of," § (6).

Absorption Coefficients of X-rays. See "Radiology," § (17).

Accommodation: the process by which the eye adapts its focus to varying distances. See "Eye," § (20).

Achromatism of Telescope Lenses. See "Telescope," § (9).

Acoustics, Architectural: Jaeger's Treatment. See "Sound," § (22) (iii.).
  Marage's Work on halls in Paris. See *ibid.* § (22) (i.).
  Sabine's Work. See *ibid.* § (22) (i.).
  Watson's Investigations. See *ibid.* § (22) (iv.).

Active Deposit: a term used in radioactivity to denote the deposit of active matter on the surface of bodies which have been exposed for some time to the emanations from radio-elements. See "Radioactivity," § (18).

Acuity, Visual, the clearness with which the eye can see detail. See "Eye," § (28).

Adaptation, Dark: the highly sensitive condition of the eye when kept in darkness for some time. See "Eye," § (15).

Air, Dust-free, Experimental Observation of Scattering of Light by. See "Scattering of Light by Gases, etc.," § (3).

Aldis Spherometer. See "Spherometry," § (4).

— B —

BIPRISM, FRESNEL'S: an experimental arrangement for the production of interference fringes, using refraction through a biprism to form two adjacent virtual images of a source of light. See "Light, Interference of," § (4) (iv.).

BIQUARTZ: the name given to a device for measuring the rotation of the plane of polarisation of light by a substance; the device consists of two semicircular discs of quartz, 3·75 mm. thick, between parallel nicols, one half being right-handed quartz and the other left-handed quartz. See "Polarimetry," § (2).

BLACK BODIES AND RADIATION. See "Radiation Theory," § (4).

BLOCH'S METHOD OF CALCULATING AVERAGE ILLUMINATION. See "Photometry and Illumination," § (70).

BLONDEL'S PHOTOMETER: a photometer for the determination of average candle-power. See "Photometry and Illumination," § (43).

"BOILING" TUBE: an X-ray "gas" tube in which the anticathode is kept at a constant temperature by boiling water. See "Radiology," § (12).

BOLOMETER: an instrument for investigation of the infra-red spectrum; the temperature of a very fine strip of metal is measured in terms of the change of its electrical resistance, the strip being heated by radiation. See "Wave-lengths, The Measurement of," § (7).

BOMBARDON, BB♭ Monster: a brass wind instrument with valves. See "Sound," § (44).

E♭: a brass wind instrument with valves. See *ibid.* § (44).

BORIC ACID, renders glass resistant to water attack. See "Glass, Chemical Decomposition of," §§ (1) and (2).

BORIC OXIDE, USE OF, IN GLASS MANUFACTURE. See "Glass," § (11).

BOSANQUET'S CYCLE OF FIFTY-THREE: a particular musical temperament which gives as near an approach to just intonation as could be demanded from any instrument with fixed keys. See "Sound," § (6) (i.).

BOUGIE DÉCIMALE: a French standard of light. See "Photometry and Illumination," § (14).

BRACE SPECTROPHOTOMETER. See "Spectrophotometry," § (12).

BRACE'S POLARIMETER. See "Polarimetry," § (11) (iii.).

BRASHEAR'S OR SUGAR METHOD OF SILVERING MIRRORS; details of solutions and process. See "Silvered Mirrors and Silvering," § (2) (ii.).

BRASS BAND, VALVED INSTRUMENTS OF. See "Sound," § (44).

BREWSTER'S LAW. If light be incident upon the surface of a transparent body in such a direction that the tangent of the angle of incidence is equal to the refractive index of the body, then the reflected ray is plane polarised. The angle of incidence is in this case called the polarising angle. See "Polarised Light and its Applications," § (2).

BRIGHTNESS: used to denote the total visual effect of a light independently of its colour or purity. See "Eye," § (8).

Measured by the amount of light emitted by a surface per unit of projected area. See "Photometry and Illumination," § (2).

BROWNIAN MOVEMENT, use of ultramicroscope in study of. See "Ultramicroscope and its Application," § (2).

BUBBLES AS USED IN SPIRIT LEVELS. See "Spirit Levels," §§ (2), (3).

BUNSEN (GREASE-SPOT) PHOTOMETER: one of the early forms of photometer head still in current use. See "Photometry and Illumination," § (15).

β-RAYS, General Properties of. See "Radioactivity," § (13) (i.).

Magnetic spectrum of. See *ibid.* § (13) (ii.).

Scattering of, by matter. See *ibid.* § (13) (iv.).

— C —

CALIBRATION OF RANGE-SCALES OF RANGEFINDERS. See "Rangefinder, Short-base," § (15).

CAMERA, AERIAL. See "Photographic Apparatus," § (12).

Copying: a type of camera used for the photography of flat surfaces. See *ibid.* § (3).

Field or Portable. See *ibid.* § (2) (i.).

Hand: a general term for cameras devised especially for exposures of brief duration. See *ibid.* § (11).

Panoram: a type of camera used to photograph a large angular "stretch" of country. See *ibid.* § (7).

Photographic: in essential, a chamber for the purpose of exposing sensitive plates to the action of luminous images formed by optical means. The three main classes of cameras are (1) Stand Cameras, (2) Hand Cameras, (3) Aerial Cameras, and these again are classified into subgroups. See *ibid.* § (2).

Studio. See *ibid.* § (2) (ii.).

CAMERA LENSES, THE TESTING OF

The general problem of the testing of compound objectives is dealt with elsewhere.[1] The optical data that have to be determined in the case of photographic objectives are, generally speaking, more numerous than in the case of telescope objectives, and special methods of testing camera lenses have therefore been devised.

An idea of the general performance of a camera lens may be obtained by setting up an object, consisting of a network of straight lines on a white background,[2] and taking a photograph of it. The plate, after development, may then be examined by means of a microscope. In this way any distortion of the image may be detected and measured. The method, however, only gives a qualitative idea of any want of focus that may be present at any part of the plate.

A more accurate method is to make use of a specially designed lens bench, such as the one manufactured by Messrs. R. & J. Beck, Ltd. The principal features of this bench are illustrated in *Fig.* 1, which is reproduced from a photograph taken from the side, looking down at one end at an angle of about 45°. The various appliances for holding the lens, etc., slide on a steel dovetail-shaped bar B_1 which is supported on two struts (one of which is shown at *St*) provided with levelling screws. The lens L is screwed into one of a series of adapters held in a collar *Co* which revolves on ball bearings in the framework F_1. A clamping device *Cl* is provided for fixing the collar in any desired position. The framework can be moved along the slide S_1 by means of a rack and pinion actuated by the head H_1. This slide S_1 can be rotated about a vertical axis, the amount of rotation being measured on a scale Sc_1 on the platform Pl_1, which can be clamped to the bar B_1 at any convenient position. The framework F_2 can be moved along a slide S_2 by means of a rack and pinion actuated by the head H_2, the slide being fixed to the platform of the framework F_1. A bar B_2 is fitted at one end to a small carriage C_1 which can slide along the groove *Gr* in the framework F_2. This bar is constrained to move along the axis of the system between adjustable rollers R attached to the platform Pl_2, which can be clamped to the bar B_1 at any desired position. The observing microscope M can be moved along the axis relative to the bracket Br_1 (which is fixed to the bar B_2) by means of a rack and pinion actuated by the head H_3, the motion being registered by a scale and vernier. A vertical metal plate P, having a circular hole concentric with the axis of the system, is fixed to the small carriage C_1. When the lens holder, together with the framework F_2, is swung about the vertical axis of rotation, the plate remains parallel to the groove *Gr* and therefore normal to the axis of the lens. The distance between the axis of rotation and the plate P is measured by means of a millimetre scale Sc_2, one end of which fits into a bracket Br_2, so that the zero of the scale is always opposite the axis of rotation. A

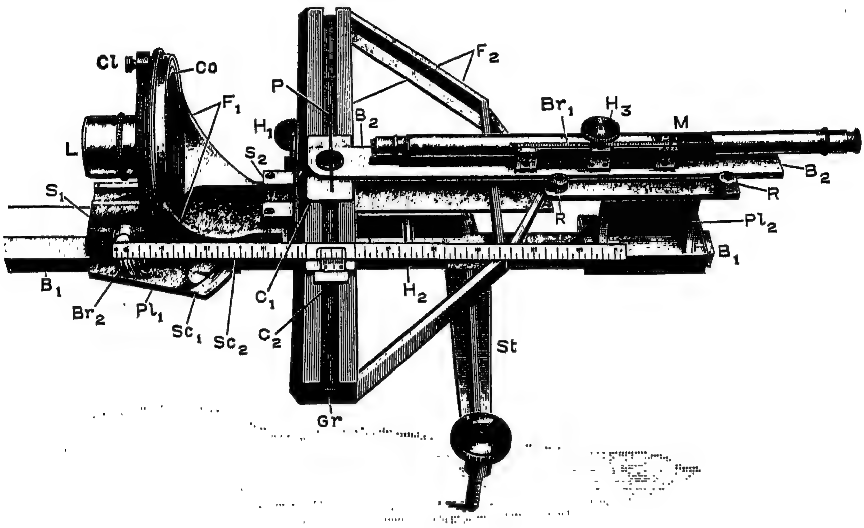

Fig. 1.

[1] See article on "Objectives, The Testing of Compound."

[2] See *Photographic Lenses*, by Conrad Beck and Herbert Andrews.

vernier is fixed to a small carriage C_2 which slides in the groove *Gr*, the vernier zero being in the plane of the left-hand surface of the plate P.

The optical data of a camera lens are determined as follows.

§ (1) Focal Length.—A piece of ground glass is held with its ground surface against the left-hand surface of the plate P and the observing microscope M is focussed on the ground surface. The framework F_2, carrying the microscope, is then moved along the slide S_2 by turning the head H_2 until the image of a distant object[1] is brought into the focal plane of the microscope.[2] The lens holder, together with the framework F_2, is next moved along the slide S_1 by turning the head H_1 until there is no lateral displacement of the image when the system is rotated through a small angle about the vertical axis. When this is the case, the vertical axis passes through a point, called the nul point, which divides the distance between the nodal points into parts whose ratio is equal to the lateral magnification. If the incident light is parallel, the nul point coincides with the second nodal point; the focal length is then given by the distance between the vertical axis and the focal plane, its value being read off on the scale Sc_2. When one is dealing with an object at a finite distance, the nul point is the point at which a line joining non-axial conjugate points in the object and image planes cuts the axis of the lens. In such a case it is advisable to make a separate determination of the position of the second nodal point by using parallel incident light. The back focal length is given by the distance between the last surface of the lens and the plate P.

§ (2) Spherical Aberration.—This is measured by placing a series of concentric stops in front of the aperture of the lens and measuring the movement of the microscope which is necessary to bring the image into focus for different zones of the lens. It is advisable to insert a colour filter between the microscope eyepiece and the observer's eye in order to eliminate the effects of chromatic aberration.

§ (3) Chromatic Aberration.—A series of colour filters, giving monochromatic regions more or less evenly spaced throughout the spectrum, is placed in turn behind the eyepiece of the microscope and the movements of the microscope necessary for bringing the different coloured images into focus are measured. It is sometimes advisable to stop out certain zones of the lens in order to eliminate the effects of spherical aberration.

§ (4) Coma.—A collimator, with an illuminated pinhole at its focus, is mounted on the axis of the system and the image of the pinhole is examined at different angles of rotation about the vertical axis. The dimensions of the comatic figure may be measured by means of a scale in the focal plane of the microscope eyepiece.

§ (5) Flare Spot.—The same arrangement is used as in the previous case, and the positions of flare-spot images are noted; such images do not give trouble unless they are in the neighbourhood of the focal plane of the lens.

§ (6) Astigmatism and Curvature of Field.—The system is rotated about the vertical axis, on which the second nodal point lies, through angles of 5°, 10°, etc., up to the maximum semi-angle that the lens is designed to cover, and at each angle (on either side of the axis) the positions of the microscope are determined for best focus of horizontal and vertical lines. The differences between these positions and the normal position of focus, that is, the focus for the centre of the field, give the distances of the positions of astigmatic foci from the plate (measured along the rays) at different parts of the field. The mean values of the distances of the foci for horizontal and vertical lines give a measure of the curvature of the field.

§ (7) Distortion.—The system is rotated as in the previous case, and the horizontal displacement of the image of a vertical line is measured for each angle by means of a horizontal graduated scale in the focal plane of the microscope eyepiece, the microscope being kept in the normal position. The horizontal displacement divided by the magnification of the microscope then gives the distortion in the plane of the plate.

§ (8) Effective Apertures of Stops.—The microscope is removed and a small pinhole, mounted in the plane of the plate P, is illuminated from behind. A piece of ground glass is held against the front of the lens mount and the diameters of the illuminated areas, corresponding to the different stops, are measured.

§ (9) Illumination at the Corners of the Plate.—The same arrangement is adopted as in the previous test, and the boundary of the illuminated portion is traced on the ground glass when the system is rotated through an angle corresponding to the semi-diameter of the plate to be covered by the lens. The area of this portion divided by the area of the unobscured aperture and multiplied by 100 and by the fourth power[3] of the cosine of the

[1] Either a set of suitable cross-lines at the focus of a well-corrected collimator objective mounted on the axis of the system, or a series of horizontal and vertical lines (black on white background and white on black background) at some considerable distance from the apparatus, may be used.

[2] On rotating the system about the vertical axis the left-hand surface of P moves in a plane which is equivalent to the plate of the camera.

[3] If the vignette is measured in a plane normal to the axis of the bench, the cube of the cosine is to be used.

angle then gives the percentage illumination at the corners of the plate relative to that at the centre; the loss of light due to oblique reflections and absorption further reduces the percentage illumination at the corners.

In addition to these measurements the relative centering of the components of the lens may be tested by using a small retinoscope for throwing a beam of light along the lens axis and examining the alignment of the images of the retinoscope hole, through which the observer looks. The number of glass-air surfaces in the lens may be determined by counting the number of these images. The presence of visible defects, such as striae, veins, etc., in the glass of the lens may be detected by mounting an illuminated pinhole at some distance from the lens and placing one's eye at the conjugate point. The aperture of the lens will then appear illuminated and any defects that may be present will be noticeable, especially if the image of the pinhole is partially obscured by a diaphragm.

§ (10) Definition.—It is customary to determine what is the largest stop for which the definition is satisfactory over the entire plate. In estimating the definition of a given lens it is advisable to compare with it the definition of a standard lens of similar dimensions.

§ (11) Photographic Methods.—The aberrations of a camera lens may be measured by a simple photographic method, which is employed at the Reichsanstalt.[1] The principle of the method is illustrated diagrammatically in *Fig.* 2. A slit S, illuminated by a bright source, such as a mercury vapour lamp, is placed at the focus of a collimator objective O. The camera lens L forms an image of this slit at S′, and a photographic plate P is mounted at S′ in such a position that it makes a small angle with the axis of L, the plane containing the slit and the optical axis being normal to the plate. The plate can be moved in its own plane at right angles to the axis of L, so that a series of exposures can be made for different zones of the lens and different wave-lengths. The various positions of foci are then determined by finding on the developed plate the places where the bundles of rays have the minimum breadths. In this way the spherical and chromatic aberrations of the lens may be determined. If the lens and the plate are rotated through different angles about an axis passing through the second nodal point of the lens, and a series of exposures made, the astigmatism, curvature of field, and distortion may similarly be determined. An estimate of the amount of coma present may be obtained from the degree of sharpness of the outer edge of the bundle of rays at the position of minimum breadth.

Another photographic method, which is applicable to the case of camera lenses, is the Hartmann method, particulars of which are given in the article "Objectives, The Testing of Compound."

The methods that have been described are not applicable to the case of process lenses, since these are specially designed for near work. In order to test such a lens a suitable object is mounted near the lens in such a way that it can be moved into different positions in a plane at right angles to the axis of the bench. The image is then examined with a microscope which can be moved parallel and at right angles to the bench axis and also about a vertical axis.

Crova's Spectrophotometer. See "Spectrophotometry," § (12).

Crystal Elements and Constructional Axes. See "Crystallography," § (4).

Crystal Faces, Miller's Method of distinguishing: a method of defining the relative positions of crystal faces in which the faces of a crystal are treated as a series of planes and any three of these, no two of which are parallel, are taken as planes of reference to which the positions of the other faces may be referred. See "Crystallography," § (3).

Crystal Structure, modern work on, based on the fact that the structure of a crystal is fundamentally that of a space-lattice, a three-dimensional trellis-work. See "Crystallography," § (11).

Analysis of, by X-rays: Laue's method, depending on the reflection and diffraction of X-rays by the molecules of a crystal, which are arranged on a space-lattice. See *ibid.* § (14).

Crystalline Lens: the lens of the eye. See "Eye," § (2).

CRYSTALLOGRAPHY

§ (1) Introduction.—The study of crystals can never be a matter of indifference to the physicist, for Crystallography is essentially the Physics of Solids. The higher branches of Optics deal very largely with crystals, and it is a crystal, tourmaline or calcite, that affords the best means of producing plane polarised light. Rock crystal, quartz, is the material of the best lenses employed by the optical investigator; a train of lenses and prisms of rock salt crystals are essential in the study of radiant heat; and the phenomenal progress which has recently been made in our knowledge of X-rays and of the ultimate structure of matter—the special domain of the physicist—is being very materially assisted by the use of crystals, the most perfectly organised form of solid matter. Yet the science of Crystallography has in the past been as strangely neglected by physicists as by chemists, to

whom the subject is likewise proving of prime importance, and has been left in the hands of a very few specialists, and regarded as a side issue chiefly connected with Mineralogy, oppressed by a forbidding kind of Mathematics and by a weird nomenclature. It will be the task of this brief summarised account of the subject to dispel this illusion, and to show how fascinating and intrinsically valuable it really is to the physicist.

Crystallography is essentially practical when its study is undertaken in a sensible manner. A few hours with a good crystal on a reflecting goniometer will bring out the chief properties of crystals and the laws of Crystallography so that they can never be forgotten, and will render the subject at once plain and simple. The goniometer, of which the best form is shown in *Fig.* 1, is nothing but the physicist's spectrometer, but with a small crystal, preferably no larger than a very small pea, as the object of study at the centre instead of the usual spectroscopic prism, and with a more delicate and convenient adjusting and centring apparatus. Also, instead of an ordinary parallel-jawed slit one is used which is expanded at its two ends, so that its image reflected from a crystal face exhibits a fine central part for accurate adjustment to the vertical cross spider-line, and broader ends which are brilliantly illuminated. It is surprising how brilliant such slit images are as seen in the telescope, when reflected from even the minutest faces, almost points, if the crystals are normally well developed.

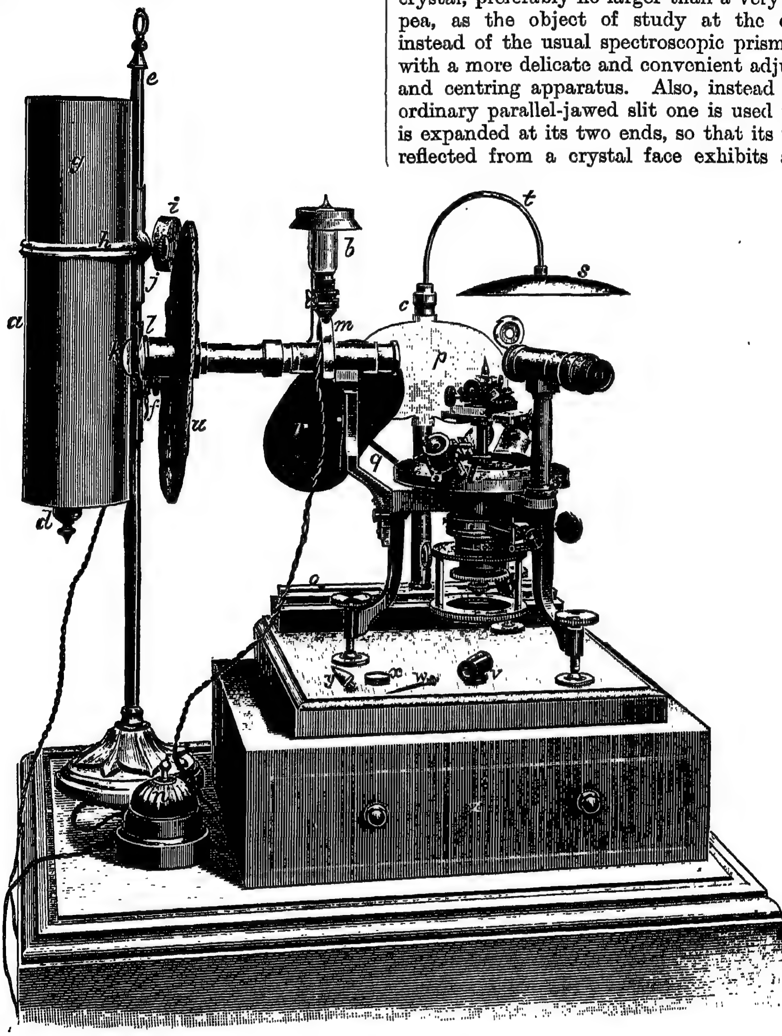

FIG. 1.—The Reflecting Goniometer in Use.

§ (2) NATURE OF CRYSTALS.—The first facts obviously and unmistakably impressed by such a practical investigation of a series of

well-developed crystals, of the same and of different substances, on the goniometer, are the following:

(*a*) Crystals are naturally formed solid polyhedra bounded by plane faces meeting in straight edges.

(*b*) These faces on the best crystals are true planes, highly polished and affording brilliant and sharp reflections of the goniometer signal-slit.

(*c*) The faces are inclined to each other at angles which usually display among themselves more or less symmetry, and are constant in value for the same substance; these particular values are thus characteristic of the substance, the only exception being when the symmetry is at its maximum, in the cubic system, when this perfect symmetry itself fixes the angles.

(*d*) The faces are arranged in zones, each zone being composed of faces parallel to a common axis, to which all their edges of intersection are also parallel. When this axis is set parallel to the axis of the goniometer, all the faces of the zone are automatically adjusted, so as to reflect the signal-image from every face in turn to the cross-wires of the telescope when the goniometer axis and crystal are rotated.

(*e*) When the signal-image from each successive face is adjusted to the cross-wires and the circle reading taken, the differences between the readings are the angles between the face-normals, and these are most conveniently considered as the interfacial angles; they are arranged in accordance with the symmetry developed.

§ (3) Miller's Method of distinguishing Crystal Faces.—A method of defining the relative positions of crystal faces by means of a compact symbol now universally adopted is due to W. H. Miller, Professor of Mineralogy at Cambridge from 1832 to 1881.

The faces of a crystal are a series of planes, and any three of these, no two of which are parallel, may be taken as planes of reference to which the position of the other faces may be referred.

(i.) *Axes of Reference.*—Consider then three planes passing through a point O which we take as origin and drawn parallel to any three faces of the crystal; these planes intersect in three straight lines OX, OY, OZ (*Fig.* 2); these lines we take as axes of reference.

The planes may be parallel to any three faces, but it will usually be possible to find three which, from the regularity of the crystal with regard to them, are clearly of importance in its construction, and in a number of cases two or more planes can be found mutually at right angles.

Any fourth plane will cut the axes in points A, B, C, and its position can be defined by the lengths of the intercepts OA, OB, and OC—or rather, since we are not concerned with the actual location of the face, which depends on the size and not merely the form of the crystal—by the ratios OA : OB : OC of the three intercepts, which thus fix a series of parallel planes. It is now a universal (international) convention for the description of crystals that the axis OY (and its intercept OB) shall run from left to right, and the OX axis (OA intercept) from front to back.

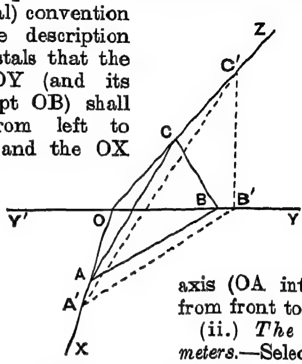

Fig. 2.

(ii.) *The Parameters.*—Select then any such plane and let the lengths of the intercepts be a, b, c respectively. We define this as a parametral plane, and the values of a, b, c measured in any convenient unit as the parameters. It will usually be found that there is a plane, developed as a prominent face, for which some simple relations exist between a, b, and c, *e.g.* all three parameters are equal, or two of them are equal and differ from the third; it is convenient but not essential to select such a plane as the parametral plane.

(iii.) *The Indices.*—A plane parallel to any other face of the crystal will cut the axes in three points, A′, B′, C′ say.

Then it is found by observation that the intercepts OA′, OB′, OC′ are proportional respectively to a/h, b/k, c/l, where h, k, l are in all cases small whole numbers—including zero—in few cases so great as 6. These numbers are called the indices of the plane, and if we know in any case the position of the axes and the values of the parameters the position of any other plane is defined by its indices and is denoted by the symbol $(h\,k\,l)$.

This implies that if the known parameters be a, b, c, and we cut off on the axes lengths proportional to a/h, b/k, and c/l, the face in question will be parallel to the plane so defined.

The relative positions of the axes are fixed by the angles between them. If we put $YOZ=\alpha$, $ZOX=\beta$, $XOY=\gamma$, we see that the position of any face is determined by the values of the three parameters a, b, c, the three angles α, β, γ, and the three indices h, k, l; moreover, in all cases h, k, l are small integers including possibly zero.

A face may of course cut the axes on either the positive or the negative side of the origin, *i.e.* either between O and X or on the side of O remote from X. This will be indicated by giving a negative sign to the corresponding index, which becomes $-h$ or, as it is usually written, $\bar{h}$. Again, if one of the indices, say h, is zero, the corresponding intercept is $a/0$ or infinity. This indicates that the axis OX is parallel to the face in question.

Again, since we are only concerned with the ratios $a:b:c$ we may take any one of these quantities to be unity and refer the others to it; it is usual to select b as unity, so that the ratio becomes $a:1:c$.

§ (4) CRYSTAL ELEMENTS—CONSTRUCTIONAL AXES. — These axes are spoken of as the constructional axes of the crystal, and the various systems of crystals are grouped according to the values of the parameters a, b, c, expressed as $a:1:c$, and the angles α, β, γ, between the constructional axes. These quantities are known as the crystal elements.

§ (5) CRYSTAL SYSTEMS.—These are seven in number. Each system contains a number of classes characterised by a common set of constructional axes, *i.e.* common type of crystal elements, and certain common features of symmetry.

§ (6) ELEMENTS OF SYMMETRY. — The elements of symmetry which belong to a crystal are two in number; it may possess a plane or planes of symmetry or it may be characterised by an axis or axes of symmetry, or by both elements.

(i.) *Plane of Symmetry.*—Imagine a crystal to be divided into two portions, A and B, by a plane which we suppose capable of producing a reflected image of A; let B′ be this image. In general there will be no resemblance between B and B′, but if it should happen that each face of B′ coincides with or is parallel to a face of B, then the crystal has been divided into two symmetrical portions by the plane, the plane is a plane of symmetry.

(ii.) *Axis of Symmetry.*—Imagine now a line in a crystal possessing the property that if the crystal be rotated about this line through some definite angle each face is brought into a position either coincident with or parallel to that occupied by some other face before the rotation took place. The crystal is said to be symmetrical about the line, and the line is an axis of symmetry. If the crystal were mounted on a goniometer with the axis of symmetry coincident with the axis of the goniometer it would not be possible to infer from the readings of the instrument that the crystal had been moved. Thus, for example, in a cube each of the faces of the cube is a plane of symmetry and each of the edges an axis of symmetry; a cube, however, has many more planes and axes of symmetry than these. Or consider a crystal bounded by two regular figures, ABCDE, A′BCDE (*Fig.* 3), having the rectangular face BCDE in common, and the eight triangular faces equal; the face BCDE is clearly a plane of symmetry, and the line AA′ which is perpendicular to it is an axis of symmetry.

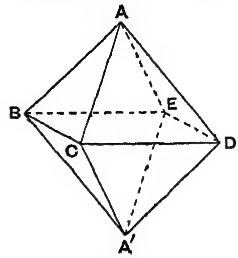

FIG. 3.

The angle through which rotation takes place in order to bring the crystal into a symmetrical position is in all cases some submultiple of 360°, corresponding to division of the whole circle by two, three, four, or six. If the rotation be through 180°—360°/2—the symmetry is *digonal*, for 120°—360°/3—it is *trigonal*, for 90°—360°/4—it is *tetragonal*, and for 60°—360°/6—the symmetry is *hexagonal.*

In some crystals a more complicated type of symmetry exists in which we can bring the crystal into the symmetrical position by supposing (1) that it is rotated about an axis, and (2) that each face is displaced as it would be if reflected in a plane; we have to consider the combined effect of an axis of symmetry and a plane of symmetry.

Thus consider a crystal of which a section is given by ABCD (*Fig.* 4), a quadrilateral figure in which

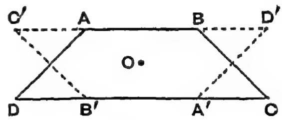

FIG. 4.

AB and CD are parallel and BC and AD equally inclined to AB. On rotating this through 180° about an axis through O, the mid point of the bisector of the two parallel sides, perpendicular to the paper, we get A′B′C′D′, which has not all its faces parallel to those of the original crystal, but by supposing B′C′ reflected in a plane through the middle point of AD perpendicular to the paper, and A′D′ similarly reflected in a plane through the mid point of BC, we recover the original crystal.

§ (7) THE SEVEN SYSTEMS OF CRYSTALS.—Before discussing the types of symmetry which characterise the various systems of crystals each of which has its own type of crystal elements defined by the parameters a, b, c, and the angles α, β, γ, of the constructional axes, it will be useful to give in a schedule the relations between these quan-

tities for each of the seven systems, which are named as shown in Table I.

TABLE I

SYSTEMS OF CRYSTALS

Name.	Parameters.	Interaxial Angles.
i. Triclinic . .	$a \gtrless b \gtrless c$	$\alpha \gtrless \beta \gtrless \gamma$
ii. Monoclinic .	$a \gtrless b \gtrless c$	$\alpha = \gamma = 90°$ $\beta \gtrless 90°$
iii. Rhombic . .	$a \gtrless b \gtrless c$	$\alpha = \beta = \gamma = 90°$
iv. Tetragonal .	$a = b \gtrless c$	$\alpha = \beta = \gamma = 90°$
v. Hexagonal .	$a = b \gtrless c$	$\alpha = \beta = 90°$ $\gamma = 60°$ and $120°$
vi. Trigonal . .	$a = b = c$	$\alpha = \beta = \gamma \gtrless 90°$
vii. Cubic . .	$a = b = c$	$\alpha = \beta = \gamma = 90°$

§ (8) CLASSES OF SYMMETRY. — Each of these seven systems includes crystals of various classes of symmetry, in all thirty-two in number, which are built up from the elements of symmetry—the plane of symmetry and the axis of symmetry—already described.

(i.) The *Triclinic System*, which is the least symmetric, comprises two classes. The three axes are unequal and unequally inclined. Class 1 has no symmetry whatsoever, every face being a "form" unto itself, that is, it has no fellow or fellows of like relation to the constructive axes about which the crystal can be imagined to be erected. Class 2, however, is symmetrical about the centre; thus the crystal is composed of parallel faces, each pair of which is a form in the sense just alluded to. One of the best-known triclinic substances is copper sulphate, $CuSO_4 . 5H_2O$, a crystal of which is shown in *Fig.* 5.

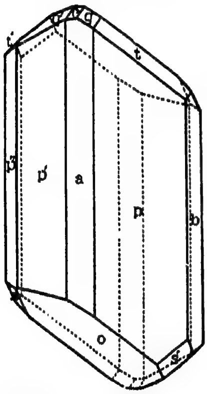

FIG. 5.—A Crystal of Copper-sulphate.

(ii.) The *Monoclinic* or *Monosymmetric System* comprises three classes. The three axes are unequal, two being inclined to each other at an angle other than 90°, while the third, always chosen as the *b* axis, is normal to their plane. Two real elements of symmetry are now possible, a plane of symmetry, that containing the inclined axes, and a digonal axis of symmetry perpendicular thereto and identical with the normal construction axis. Class 5 possesses both these elements of symmetry, while Class 3 is endowed with the plane of symmetry only, and Class 4 with the digonal axis only. An excellent example of full monoclinic Class 5 symmetry is potassium nickel sulphate, $K_2Ni(SO_4)_2 . 6H_2O$, a typical crystal of which is shown in *Fig.* 6.

(iii.) The *Rhombic* or *Orthorhombic System* includes three classes. The three axes are unequal but are arranged at angles of 90° to each other. One class, No. 8, possesses all the six elements of symmetry which now become possible, namely, three planes of symmetry, which are also the three constructional axial planes, and three digonal axes of symmetry, identical with the three rectangular axes and the intersections of the planes. Potassium sulphate, K_2SO_4, is a common substance crystallising in this Class 8, and a characteristic crystal is represented in

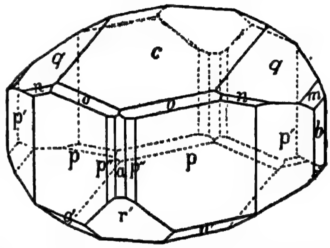

FIG. 6.—A Crystal of Potassium Nickel Sulphate.

Fig. 7. Class 6 possesses the three axes of symmetry only, and Class 7 possesses two of the planes and one axis of symmetry, the axis in which the planes intersect.

(iv.) The *Tetragonal System* goes a step further in degree of symmetry. Two of the axes are of equal length, the third being unequal; the angles are all equal to 90°. In describing or setting up the crystal the unequal axis is made vertical. No less than seven classes are now possible, all of which possess the systematic characteristic, a tetragonal axis of symmetry which is identical with the vertical constructional axis. Class 9 possesses this symmetry element alone, but Class 15, the highest of the system, is also endowed with four symmetry planes intersecting each other at 45° in the tetragonal vertical axis, an equatorial symmetry plane perpendicular to the vertical axis, and four digonal axes of symmetry lying in that

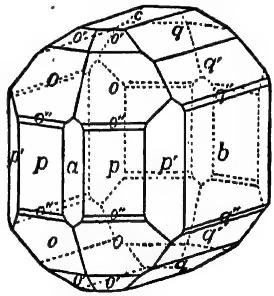

FIG. 7.—A Crystal of Potassium Sulphate.

equatorial plane. Zircon, silicate of zirconium, $ZrSiO_4$, crystallises with the symmetry of this class, and a typical zircon is portrayed in *Fig.* 8. Between this "holohedral" class (of full symmetry) and Class 9 are five other classes possessing various combinations of some of these symmetry elements but always including the tetragonal axis, the essential symmetry element of the tetragonal system.

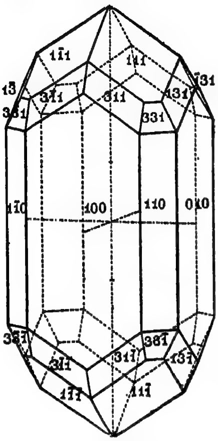

FIG. 8.—A Zircon Crystal.

(v.) The *Hexagonal System* is similar in many ways to the tetragonal, but the equal axes are inclined to each other at 60° instead of 90°; it is characterised by a hexagonal vertical axis of symmetry. There are five classes in the system, the simplest, Class 23, possessing only the essential hexagonal axis of symmetry; but the most symmetrical, the holohedral Class 27, has six planes of symmetry intersecting each other at 30° in the hexagonal axis, and an equatorial plane of symmetry with six digonal axes of symmetry lying in it at 30° from each other, a total of fourteen elements of symmetry. Beryl, $Be_3Al_2(SiO_3)_6$, the beautiful gemstone known as aquamarine when pale green in colour and emerald when dark green, is an excellent example of Class 27, and a typical beryl crystal in shown in *Fig.* 9.

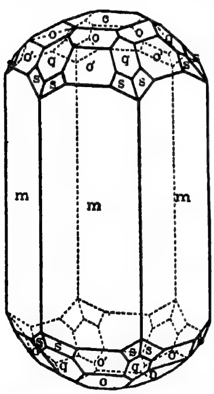

FIG. 9.—A Beryl Crystal.

(vi.) The *Trigonal System* has three equal and equally inclined axes, generally at other than 90°. The axes, indeed, are the edges of a rhombohedron, which resembles a cube compressed or extended along one diagonal, and this diagonal is the vertical axis of trigonal symmetry and not a construction axis; it is the essential element of symmetry of the system, which includes seven classes, the simplest, Class 16, having this as its only symmetry element. The most symmetrical, the holohedral Class 22, possesses in addition three symmetry planes intersecting at 60° in the trigonal axis, an equatorial symmetry plane, and three digonal axes lying therein at 60°. No well-known substance exhibits this full trigonal symmetry, although two rarer substances, including the gemstone benitoite, $BaTiSi_3O_9$, belong to the class. But two very important minerals, calcite, $CaCO_3$, and quartz, SiO_2, belong to Classes 21 and 18 respectively, and figures of typical specimens of calcite and quartz crystals are shown in *Figs.* 10, 11, and 12. *Fig.* 10 also shows the three constructional rhombohedral axes, and the vertical trigonal axis. This Class 21 only differs from the holohedral Class 22 by having no equatorial plane of symmetry. The actual crystal shown in *Fig.* 10 is a combination of the rhombohedron, with edges parallel to the constructional axes, and the hexagonal prism parallel to the vertical axis.

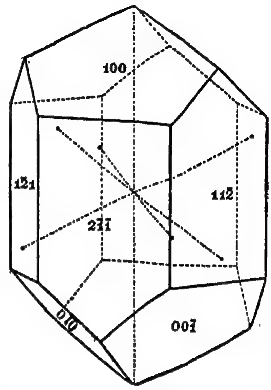

FIG. 10.—A Crystal of Calcite.

The Quartz Class 18 has all the four axes of symmetry (three horizontal and one vertical) of the system, but no symmetry planes. Now it is an interesting and highly important fact that all the classes of symmetry, and there are eleven of them, which possess no plane of symmetry are distinguished by the property of right- and left-handedness, or, as it is termed, "enantiomorphism." Two varieties of crystals, one the mirror image of the other, right- and left-handed like a pair of gloves, are not only possible but are often found developed, and two such crystals of quartz are portrayed in *Figs.* 11 (left-handed) and 12 (right-handed). Moreover, to enhance the interest, it is just this remarkable property which is possessed by the crystals of all substances which rotate

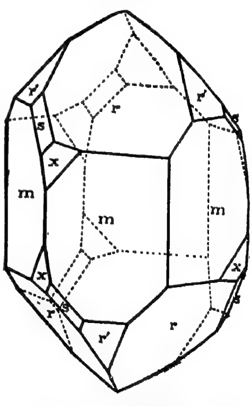

FIG. 11.—A Left-handed Crystal of Quartz.

the plane of polarisation of plane-polarised light, and if a section-plate were cut out of each of the two crystals shown, perpendicularly to the vertical axis, it would rotate the plane of polarisation to the left in case of *Fig.* 11 and to the right in the case of *Fig.* 12.

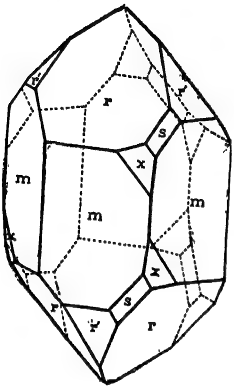

FIG. 12.—A Right-handed Crystal of Quartz.

(vii.) The *Cubic System* of highest symmetry is typified by the cube itself, the three constructional axes being parallel to the cube edges, equal in length and all mutually at right angles. There are five classes comprised in the system, the least symmetric, Class 28, possessing three rectangular digonal axes of symmetry coincident with the constructional axes, and four trigonal symmetry axes equally inclined to the former. But the most symmetric, the holohedral Class 32, possesses no less than twenty-two elements of symmetry, namely, the three already mentioned as digonal axes but which are now tetragonal ones, and the four trigonal axes also already referred to, and in addition six digonal axes bisecting the angles between the tetragonal axes, three planes of symmetry (the cube planes) perpendicular to the tetragonal axes, and six other symmetry planes bisecting the angles between the three just

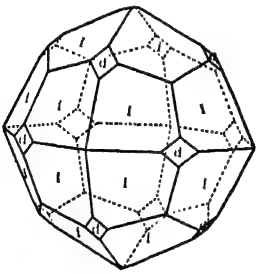

FIG. 13.—A Crystal of Garnet.

mentioned. The ancient Greeks may well have taken the cube as their symbol of perfection, their geometricians having understood the immense possibilities of symmetry incipient within it. Garnet, the beautiful yet very common silicate of the general composition $R''_3R'''_2(SiO_4)_3$, in which R'' stands for calcium, magnesium, ferrous iron, or manganese, and R''' for aluminium, ferric iron, or chromium, crystallises in this Class 32 of maximum symmetry, and a typical red garnet measured by the writer is shown in *Fig.* 13. The cubic system is unique in that all the faces,

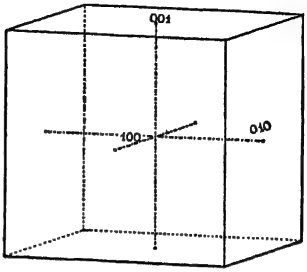

FIG. 14.—The Cube.

and they are exceedingly numerous, possible to be developed on the crystals conforming to the system are inclined at angles absolutely fixed by the symmetry and invariable. Its three

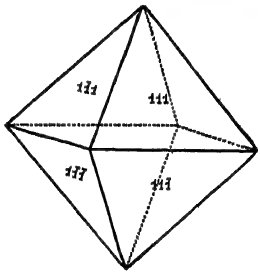

FIG. 15.—The Octahedron.

simplest forms, the cube, octahedron, and rhombic dodecahedron, represented in *Figs.* 14, 15, and 16, are also unique in that there can be only one cube, one octahedron, one rhombic

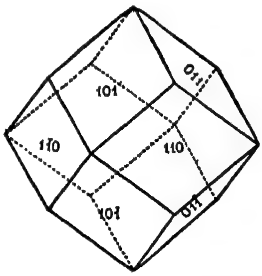

FIG. 16.—The Rhombic Dodecahedron.

dodecahedron. But there are four other holohedral cubic forms, the hexakis octahedron, the icositetrahedron, the triakis octahedron, and the tetrakis hexahedron, represented by

the next four figures, *Figs.* 17, 18, 19, and 20, which may have several representatives, the commonest of which are specified in (§) 10, yet each of which has its own definite angles fixed

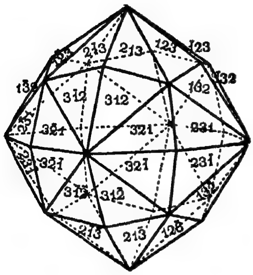

FIG. 17.—The Hexakis Octahedron.

by the symmetry. Also, there are ten other polyhedra characteristic of the cubic classes of lower than the holohedral symmetry, of which two may be taken as examples, the tetrahedron and the pentagonal dodecahedron,

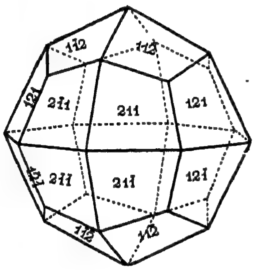

FIG. 18.—The Icositetrahedron.

shown in *Figs.* 21 and 22. The tetrahedron is a form of both Class 31 and Class 28, the former class being produced when the three axial planes are no longer planes of symmetry and the six digonal axes are no longer operative.

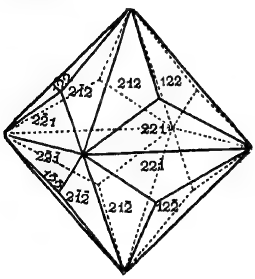

FIG. 19.—The Triakis Octahedron.

The pentagonal dodecahedron is most characteristic of Class 30 (in which iron pyrites, FeS_2, crystallises), which is formed when the six diagonal planes of symmetry are eliminated, the three cubic planes being operative; the form occurs, however, also in Class 28. The

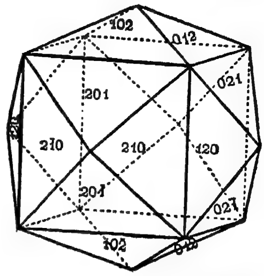

FIG. 20.—The Tetrakis Hexahedron.

polyhedron represented in *Fig.* 17, the hexakis octahedron, possesses the large number of 48 faces. It is the solid produced by the operation of the whole 22 symmetry elements when a single face inclined unequally to all three cubic axes is taken as the start.

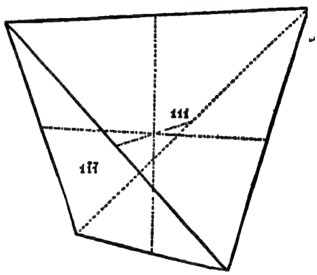

FIG. 21.—The Tetrahedron.

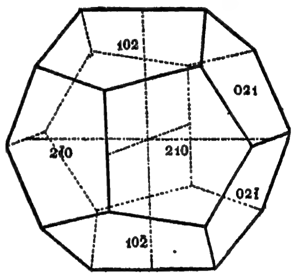

FIG. 22.—The Pentagonal Dodecahedron.

§ (9) THE REAL ELEMENTS OF SYMMETRY.—It has been essential to refer to these geometrical details concerning the seven systems of crystal architecture, and the 32 classes of symmetry combinations which they comprise, in order to render quite clear one of the greatest advances of the last third of a century. Previous to that the existence of classes of less than the full "holohedral" systematic symmetry had been accounted

for by assuming that the half or three-quarters of the full number of faces corresponding to the holohedral class were suppressed, or latent. For instance, the suppression of alternate faces of the octahedron was supposed to give the tetrahedron; and the elimination of half of the faces of the tetrakis hexahedron to give the pentagonal dodecahedron. These classes were therefore denominated "hemihedral" or "tetartohedral," according as one-half or only one-fourth of the full number of faces were present. But the work of Victor von Lang, von Groth, Story Maskelyne, and Viola effectually eliminated this feeble and very unscientific supposition, by showing that there are certain definite elements of symmetry, relatively few in number—those in fact which have been specified in § (6)—and that each crystal class of the 32 is endowed with its own invariable and fixed number and character of symmetry elements, and that all of them are active, the crystal being the outcome of the operation of all the symmetry elements specified as governing and forming the class.

§ (10) The Law of Rational Intercepts or Indices.—When we proceed to determine the indices of the other forms besides the primary, or parametral, and their individual faces on the crystal, we are saved from complicated figures and fractional or decimal values by a most remarkable law, already mentioned, which has proved to be the key to crystal structure. When we have made the comparison and got out our indices, they all prove to be simple integers. That is, the faces developed on crystals by Nature are only such as have rational, integral, intercepts, whole numbers only, and usually very low ones such as 2, 3, 4, 5, or possibly 6, and but very rarely higher numbers. In other words, we have not to deal with faces of every possible angle, but only with faces having angles arranged at definite intervals. Moreover, if symmetry be present, as is usual, the faces will form the natural groups or "forms" already referred to, for which the index numbers are the same, all these faces of any one form having the same relation to the symmetry developed. We have seen that in the system of highest symmetry, the cubic, for which the parameters are all equal, the general (faces inclined to all three axes) form, the hexakis octahedron, has no less than 48 faces, all represented by the same form symbol, {321} for instance. The kind of bracket just used is, in fact, reserved to enclose a "form" symbol, the indices given as representing the form being those of a face in the top right front octant. At the other extreme, in Class 1, possessing no symmetry, every face is a form unto itself.

The regular octahedron, of 8 faces as its name implies, is {111}. The rhombic dodecahedron is {110}, as each face is parallel to one cubic axis and cuts off equal intercepts from the other two axes; it possesses 12 faces as again implied by its name. The cube is {100}, for each face is parallel to two axes; (100) is the front face, (010) the right face, and (001) the top face. The ordinary form of simple bracket here used is that reserved for the symbol of a face. The other four forms represented in *Figs.* 17 to 20 are known to have several representatives, the commonest being, for the hexakis octahedron {321}, shown in *Fig.* 17, and {421}, all three indices being always different; for the icositetrahedron of 24 faces {211}, shown in *Fig.* 18, and {311}, two indices being always equal and less than the third; for the triakis octahedron also of 24 faces {221}, shown in *Fig.* 19, and {331}, the two equal indices being always greater than the third; and for the tetrakis hexahedron {210}, shown in *Fig.* 20, and {310}, every face of the 24 which it possesses being parallel to one axis and differently inclined to the other two.

In no other system than the cubic are the whole of the angles determined by the symmetry itself, and able to be calculated directly therefrom by spherical trigonometry. In the other systems the angles not fixed by the symmetry require to be determined by goniometrical measurement, from the results of which the crystal elements can be directly calculated. The occurrence of the faces in zones is a great help, especially as most faces lie at the intersection of two or more zones. Indeed the position of the faces can be located on a sphere directly from the measurements of the angles in the various zones; and by a very simple construction, the points where normals to the faces from the common centre of crystal and sphere cut the sphere can be projected on to a plane, the eye being supposed to be at the north or south pole and the plane of projection to be the equatorial plane. Such a projection on paper, the Stereographic Projection, affords us a concise and invaluable plan of the crystal, and the spherical triangles on it indicate to us the obvious course of the calculations, by which the crystal elements and the interfacial angles themselves can all be computed, provided one, two, three or five (according to the degree of symmetry) "basal" angles are measured as the basis of calculation.

Thus *Fig.* 23 represents the stereographic projection of a crystal of topaz $(AlF)_2SiO_4$, which is orthorhombic, of the holohedral Class 8. Every zone is represented by a circular arc or straight line, and in the case of the zone of faces parallel to the vertical axis, by the outer complete circle. The points on each zone represent the positions of the

various faces indicated by the Millerian indices. The projection is that of the upper hemisphere, but as the plane of the paper is a plane of symmetry of this rhombic crystal the poles on the lower hemisphere are identically placed. The two vertical planes of symmetry are represented by the two diameters parallel to the page edges. The symmetry of the crystal is thus clearly and fully indicated by the stereographic projection.

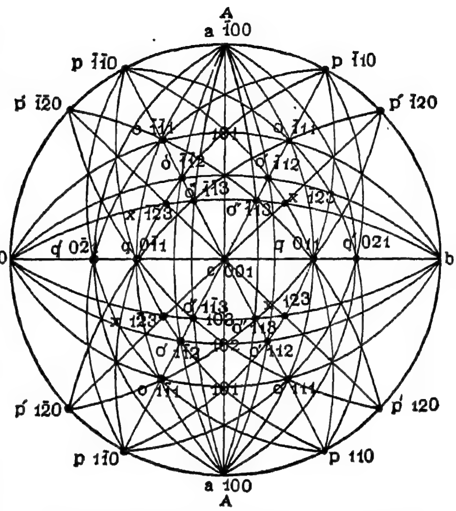

FIG. 23.—The Stereographic Projection of Topaz.

§ (11) CRYSTAL STRUCTURE.—Now the limitation of the number of possible forms to such as have rational indices is of prime importance with regard to the structure of crystals. For it means that the crystal is built up of units of definite appreciable size, the "bricks" of the crystal edifice. The Abbe Haüy, who first recognised the law at the time of the French Revolution, imagined them as "molécules intégrantes," and since his time the idea has developed, very slowly for many years, but lately much more rapidly, until a geometrical theory of crystal structure has been evolved which has probably now reached finality, having been confirmed in a remarkable manner by the new X-ray analysis of crystals presently to be referred to. Its essence is as follows:

Considering the elementary atoms composing the crystal substance as points, the crystal structure is that of a homogeneous arrangement of points. There are 230 modes of arranging points in a homogeneous structure, such as is possible to crystals, having regard to all the limitations which are imposed by the law of rationality and the fact that crystals have plane faces. Of these, 65 are point-systems of the simpler kind, involving geometrical "space operations" of only the first order (rotations about axes only). They were first described by L. Sohncke. The remaining 165 more complicated point-systems involve space operations of the second kind (reflections over planes). These were recognised and described simultaneously by E. S. Fedorov, A. Schoenflies, and W. Barlow. Fundamental to the whole 230, however, are 14 space-lattices defined by Frankenheim and Bravais, and many of the 65 Sohncke systems reduce to these space-lattices when groups of the points are considered as units, or are replaced each by a single point; in a few cases the space-lattices are special cases of the point-systems.

We thus come to the basal fact that the structure of a crystal is fundamentally that of a space-lattice, a three-dimensional trellis-work. Three of these space-lattices are of cubic symmetry, the points being arranged as the simple cube, the centred cube, and the face-centred cube. They are shown in *Figs.* 24, 25, and 26. Two others are tetragonal, four are rhombic, two monoclinic, one triclinic, one is hexagonal, or trigonal-prismatic, and another is rhombohedral-trigonal. In the crystals of very simple chemical compounds, and of the chemical elements themselves, the space-lattice is directly formed by the chemical atoms. In the more complicated crystalline substances, when more atoms go to the molecule, the space-lattice points are surrounded or replaced by groups of atoms. In any case, the structure is that of one of the 230 systems of points, according to which

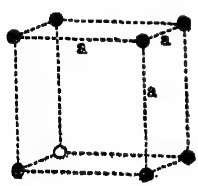

FIG. 24.—The Cubic Space-lattice.

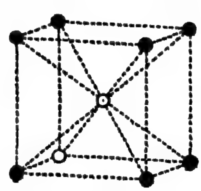

FIG. 25.—The Centred Cube Space-lattice.

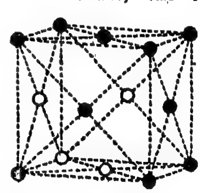

FIG. 26.—The Face-centred Cubic Space-lattice.

alone homogeneous crystal structures must be arranged, or is a special and very simple case of one of them. The crystal faces are parallel to the various planes of atoms of the space-lattice. Any three adjacent points of the lattice of course determine a face. It is, indeed, only these possible planes of atoms, the nodes of the space-lattice, corresponding to all the possible combinations of three adjacent atom-nodes, that are possible faces, and this is the very simple explanation of the law of rational indices or intercepts. In short, the parallelepipeda formed by joining the rows of points of the trellis by straight lines, along the three dimensions of space, the unit blocks of the three-dimensional lattice, are the "bricks" of the crystal edifice. Further, the Cleavage Planes of crystals are those along which the atomic points or nodes are most densely packed; for obviously in the perpendicular direction the cohesion must be less, the atomic attractive points being further apart, and the crystal is more readily torn asunder by a force thus perpendicularly directed. A very simple and rational explanation of the very important property of cleavage, which so many crystals exhibit, is thus afforded.

§ (12) Relative Measurement of Space-lattice Cells in similarly constructed Crystals.—The points at the corners of the unit parallelepipedon of the space-lattice may be either the atoms themselves (simple cases), or the representatives of groups of atoms; or we may regard them as representing the chemical molecules or small groups of molecules (not usually more than four, but occasionally as many as eight) which form the complete point-system of the structure, and thus we come to regard the parallelepipedon as the cell or habitat of such molecular or polymolecular structural unit. Now in a series of substances crystallising similarly—those known as "isomorphous"—in which the only chemical difference is that one chemical element is replaced by another belonging to the same family group of the periodic system, it must be obvious that the structure is a strictly analogous one, belonging to the same crystal-class and exhibiting the same "forms," and only differing in the dimensions of its parallelepipeda. It was suggested by F. Becke in the year 1893 that a relative measure of these cell dimensions might be obtained by combining the crystallographic axial ratios with determinations of the density of the crystals. For the latter divided into the molecular weight of the substance affords the Molecular Volume of Kopp, and this may be regarded as the volume of the cell. Combination of this with the axial relative lengths should therefore yield us the relative edge dimensions of the cell. The suggestion was taken up practically by Muthmann and by the writer simultaneously and independently in the year 1894, and applied by the former to the case of the rhombic permanganates of the alkalies, the crystals of which he had measured and submitted to density determinations, and by the latter to the rhombic sulphates and selenates of potassium, rubidium, caesium, and ammonium, as well as to a large number of the double sulphates and selenates of the well-known monoclinic series with six molecules of water of crystallisation, of which these alkali salts are the dominating constituents. The new Space-Ratios thus obtained were called "Topic Axial Ratios" by Muthmann (from τόπος, space), and "Distance Ratios" by the writer. Now the interesting result was obtained that these relative space-ratios indicated a regular increase in the space-lattice cell volume and edge dimensions, as the atoms of potassium were replaced by the heavier atoms of rubidium, and these in turn by the still heavier ones of caesium. The actual values will be found given in § (17) (iv.), for the simple rhombic sulphates of the alkalies. It was further indicated that the volume and edge dimensions of the cells of the analogous ammonium salt were almost exactly identical with those of the corresponding rubidium salt, the intermediate member of the group of salts. It has to be remembered that the atomic weight (84·9) and atomic number (37) of rubidium are practically exactly midway between these constants for potassium (38·9 and 19) and caesium (131·9 and 55). Hence, the crystals of these ammonium and rubidium salts are essentially isostructural.

Now these interesting results were in keeping with those derived from the writer's previous researches. For it had been shown that the interfacial angles and elements of the crystals of these isomorphous series exhibit a similar progression, corresponding to the advance in atomic weight and atomic number, and in a long series of subsequent memoirs (just completed, 1922) it has been proved conclusively that this is a general law for all the crystal properties, morphological, optical, and thermal, of these important rhombic and monoclinic series of isomorphous salts. The volumes and edge dimensions of their space-lattice cells thus conform to the general law of progression which the writer has now established for these series.

§ (13) Final Proof of Haüy's Law of Constancy of Crystal Angles.—Incidentally this result has also definitely settled the long-argued contradiction between the view of Haüy—that every chemical substance was characterised by its own crystalline form—and the principle of isomorphism of Mitscherlich, who in first putting forward his discovery of the principle in its cruder form

held that isomorphous substances are equiangular, and therefore that quite a large number of similarly constituted substances had not only the same form but also the same angles. But the results of the writer's work prove that there are small but very real differences in the crystal angles, rarely reaching 3° and often less than 1°, as well as in every other property, and that consequently, even in these cases of great similarity, Haüy's law is strictly true. The only cases excluded are cubic crystals, for which the symmetry fixes the angles. But even in these cases all the other properties show progressive differences.

§ (14) Analysis of Crystal Structure by X-rays (Laue).—At this point the writer was eagerly looking for a means of converting into absolute measures these relative dimensions of the space-lattice cells, afforded by the space-ratios. For so far only strictly related compounds, such as those of isomorphous series for which the structures were certainly analogous, were strictly comparable. One step forward had been made, however, for from the evidence of the production of excellent mixed crystals and parallel growths it had been proved that rubidium and ammonium sulphates were also strictly comparable, and their isostructure rendered certain; for closeness of structural dimensions is a condition for such productions. But at this moment, in the year 1912, M. von Laue of Munich made his epoch-making suggestion, that if the atoms or molecules of a crystal are in truth arranged in a space-lattice, they ought to be capable of reflecting or diffracting the exceedingly minute electro-magnetic waves of the X-rays, for the order of dimensions of atoms and of the wave-lengths of X-rays is approximately the same, about 10^{-8} cm. The planes of atoms of such a space-lattice ought, in short, to behave much as a diffraction grating does towards ordinary rays of light. His colleagues, W. Friedrich and F. Knipping, tried the experiment with a crystal of zinc blende, and found it to succeed perfectly, the crystal diffracting the incident beam of X-radiation into a number of diverted beams, each of which made an impression on a photographic plate which developed as a spot, and the whole series of spots formed a pattern—the now well-known Laue radiogram—which exhibited the cubic symmetry of the crystal, each plane of atoms of the space-lattice producing its own spot. The writer was fortunate in seeing these historic first Laue radiograms in the Munich laboratory on a visit just afterwards. One of them, for zinc blende, is reproduced in *Fig.* 27.

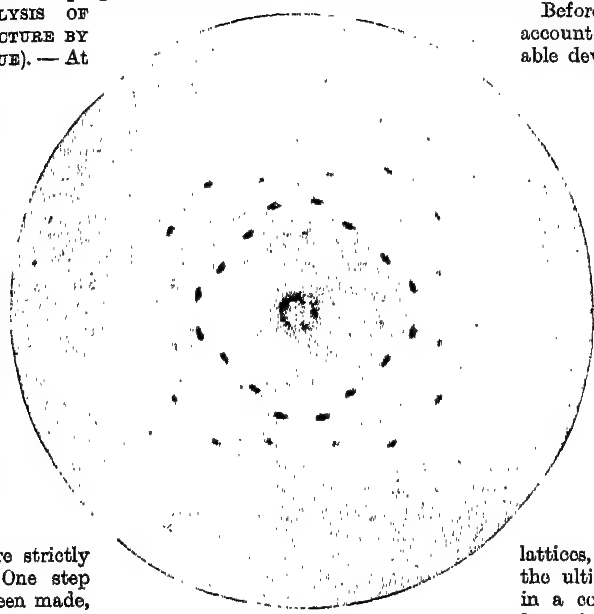

Fig. 27.—Reproduction of original Laue Radiogram of Zinc Blende.

Before giving a brief account of the remarkable development which has followed from this new mode of attack, it may be said at once that the results have fully confirmed the conclusions of crystallographers above described. They prove beyond a shadow of doubt that crystals are built up on the principle of point-systems and space-lattices, the atoms being the ultimate units, and in a considerable number of cases of simple chemical compounds the absolute dimensions of the space-lattice cells have been determined. In the particularly important case of the sulphates of potassium, rubidium, and caesium, for which the relative cell dimensions had been given by the writer as explained in a previous section, the absolute values now obtained by X-ray analysis have proved to possess precisely these relations, the correspondence being of a most satisfactory and even surprising closeness. The actual figures are given and more fully referred to in § (17).

§ (15) The X-ray Spectrometer (Bragg).—Shortly after the publication of the memoir of Laue, Friedrich, and Knipping, a new method of procedure[1] was devised by Sir William H. Bragg, and a fuller explanation was given of the Laue radiograms by his son, Prof. W. L. Bragg, who has also used with

[1] See "X-Rays," §§ (6)-(9), Vol. II.

conspicuous success the method of his father. This consists in mounting the crystal on a spectrometer-goniometer, replacing the ordinary collimator by two successive slits in leaden screens (lead being impervious to X-rays), and the telescope by an ionisation tube, the diffracted or reflected X-rays passing within the latter and ionising the vapour of methyl bromide or gaseous sulphur dioxide contained therein, the electrical effect being communicated to an electroscope and measured as to its intensity. It was found that reflection of the X-rays at any plane of atoms (really a large number of parallel planes inside the crystal having the same relations to the crystal symmetry) occurred only at certain specific glancing angles, the facts being expressed by the following equation, which is of similar kind to that governing the action of a diffraction grating toward light waves:

$$n\lambda = 2d \sin \theta,$$

where n is the order of X-ray spectrum, λ the wave-length of the X-rays (the Braggs using "monochromatic" X-rays instead of the more general X-radiation employed by Laue and his colleagues), d is the "spacing" of (distance between) the parallel planes of atoms affording the reflection, and θ is the glancing angle of reflection (that is, the angle from the plane, not from the normal to the plane). Knowing the wave-length of the X-rays employed—and Sir William Bragg had determined this with considerable accuracy for the rays from certain specific anticathodes, notably those of palladium—it is obvious that this important equation affords us, in the value of d, the absolute distance between the planes of atoms, and between the atoms themselves when planes normal to all three directions of space are investigated; indeed it gives us the absolute lengths of the edges of the space-lattice cells.

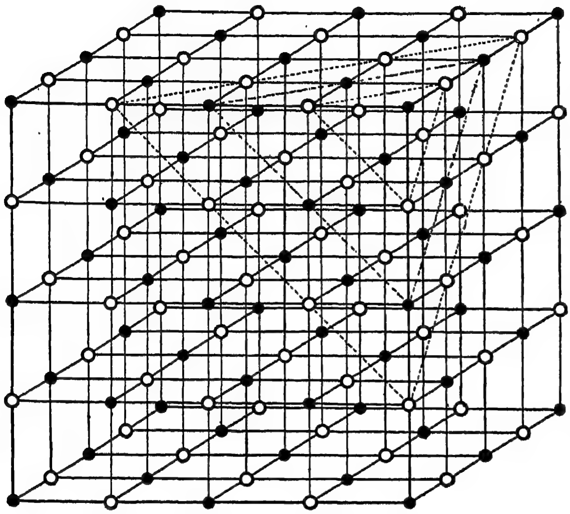

FIG. 28.—The Structure of Sylvine and Rock-salt.

Really satisfactory results, consisting of a definite determination of the positions of all the atoms, have only so far been obtained with substances of relatively simple chemical composition. They are divisible into two very distinct types: (1) those in which the positions of all the atoms are fixed by the symmetry, by the nature of the space-lattices or other point-systems present, which are clearly recognised by the X-ray analysis; and (2) those in which only the atoms of one or more of the dominating elements present—the metal, for instance, in a salt or binary compound—are thus fixed, while the atoms of another element or other elements are permitted some latitude within certain limits, the exact positions being determinable by the X-ray analysis. Three instances of the former fixed type are: (*a*) many native metals, copper for instance, the structure of which is simply that of the face-centred cube lattice already illustrated in *Fig.* 26; (*b*) potassium or sodium chloride, KCl (sylvine) or NaCl (rock-salt), shown in *Fig.* 28; and (*c*) zinc blende, ZnS, portrayed in *Fig.* 29.

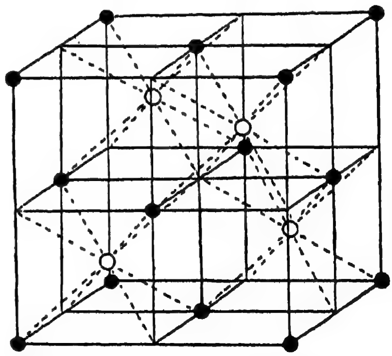

FIG. 29.—The Structure of Zinc Blende.

Two instances of the latter type, with one or more variables, are iron pyrites, FeS_2, and calcium carbonate, $CaCO_3$, the positions of the sulphur and oxygen atoms being allowed a certain choice of position along particular lines; these positions have been exactly determined by quantitative X-ray analysis.

The structure of iron pyrites is shown in *Fig.* 30, which is the reproduction of a photograph of a model. The case of calcium carbonate is more complicated, as the structure appears to be built up of calcium atoms and of CO_3 groups, in which the oxygen and carbon atoms

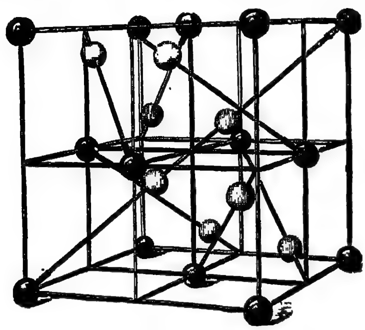

FIG. 30.—The Structure of Iron Pyrites.

are very closely bound together, for a reason to be presently explained (the sharing of certain electrons in common).

In the case of copper crystals the atoms are all alike, being those of the element copper, and their arrangement is that of the face-centred-cube space-lattice. In the cases of the chlorides of sodium and potassium, however, two kinds of atoms, those of the alkali metal and of chlorine, are present. Now the Bragg method has revealed another important and very helpful fact, that the intensity of X-ray reflection from a crystal face (really from the planes of atoms within the crystal parallel to the face) is proportional to the mass of the atoms composing it, and the atomic weight or atomic number may be taken as representing the mass of the atom. Hence, as potassium possesses the atomic weight 39 and chlorine 35·5 the masses of the atoms in sylvine are nearly alike. But as sodium has the much lower atomic weight, 23, there is a distinct dissimilarity in the masses of the two kinds of atoms composing rock-salt. The effect of this is curious. Referring to *Fig.* 28, it will be seen that the cube planes (100) are all composed of equal numbers of metallic and chlorine atoms, while the octahedral planes (111), shown in dotted lines, are alternately composed all of chlorine and all of metallic atoms. The effect in the case of rock-salt is as if there were two interpenetrating space-lattices of the face-centred cube, of different reflecting power, composed solely of sodium and of chlorine respectively, each of double the spacing; the first order spectrum becomes consequently weakened, while the second order is abnormally strong, the third order nearly disappears, but the fourth order reflection is quite good. On the other hand potassium chloride (sylvine) crystals behave as if the structure were of one kind of atom only, and the space-lattice is that of the simple cube, the small cubes of *Fig.* 28.

§ (16) DEBYE AND SCHERRER.—Yet a third method of X-ray analysis has been devised and most successfully used by P. Debye and P. Scherrer, and independently by A. W. Hull, in which the crystal is pulverised and the powder compressed into a rod, placed in the axis of a cylindrical photographic film and subjected to "monochromatic" X-rays. Characteristic interference curves are shown on development of the film, afforded by such particles (and among the infinite variety of orientations of the particles some such are bound to be present) as are correctly orientated to give the reflections from their planes of atoms. These three methods, the Laue radiographic, the Bragg spectrometric, and the Debye and Scherrer powder-method, of X-ray analysis, most wonderfully confirm and supplement one another.

Sir William Bragg has since shown that the powder method may be adapted for use with the X-ray spectrometer, it being only necessary to paste the powder on the flat surface of a holder placed on the spectrometer instead of the crystal.

§ (17) STRUCTURE AS DETERMINED BY X-RAYS.—Careful examination of the reflections of X-rays at the various glancing angles corresponding to the different orders of spectra (n), as regards both the determination of the exact angle and of the relative intensity, has enabled the structure of a large number of substances of more or less simple character to be determined and their cell dimensions to be measured.

(i.) *Zinc Blende, Diamond, and Fluorspar.* —That of zinc blende, ZnS, is shown in *Fig.* 29. The zinc atoms occupy the corners and centres of the large cube faces, but the sulphur atoms occupy the centres of alternate small cubes. Moreover, if we replace both zinc and sulphur by carbon atoms we have the structure of the diamond. Again, if the zinc atoms be replaced by calcium atoms, and the centres of all the cubelets (not only alternate ones) be filled with fluorine atoms, we have the structure of fluorspar, CaF_2. In all these cases the structure-lattice itself fixes the positions of all the atoms.

(ii.) *Iron Pyrites.* — In the case of iron pyrites, shown in *Fig.* 30, only the iron atoms are fixed by the lattice itself, of which they form the corners, like the zinc and calcium atoms of zinc blende and fluorspar. The sulphur atoms, however, in iron pyrites are not at the centres of the cubelets, but each is moved along one of the diagonals (a trigonal axis), chosen complementarily as shown in

the figure, to a position the exact location of which has been determined with great accuracy; as no iron atom is present at the corner near which the sulphur atom is arranged, its next neighbour will be another sulphur atom, as shown about the central corner in *Fig.* 30.

(iii.) *Carbon and its Compounds.*—The structure of diamond has already been given in (i.); that of the other form of carbon, graphite, has been determined by the powder method, by Debye and Scherrer, by Hull, and by Sir William Bragg, and found to be, as expected, that of a trigonal space-lattice. Now it is particularly interesting that the two structures, of diamond and of graphite, correspond to two different arrangements of the four valency bonds of carbon. Those of diamond (cubic) are arranged tetrahedrally, each carbon atom being attached to four others situated at the corners of a tetrahedron (of which it forms the centre) resting on one of its faces, one bond being thus upright and the other three radiating and slanting downwards like a tripod. In graphite there are three principal valencies in a plane, which is puckered according to Hull, and a fourth feebler one perpendicular to the plane. Further, Sir William Bragg has shown that the same puckered planes exist in both diamond and graphite, and that their repetition in the structure results in the formation of six-carbon-atom rings. Moreover, if we take two such layers of a diamond structure model and remove one of them further away from the other while at the same time giving it some rotation, we produce a model of graphite. The greater separation of the planes is also accompanied by some tightening up of the atoms in the puckered plane, and the two occurrences together determine that graphite has great cohesion in the plane and very slight at right angles to the plane; hence, it cleaves parallel to the plane so readily as to be actually soft enough to act as a lubricant. On the other hand, diamond is the hardest substance known.

Most interesting of all, however, is the fact brought to light by Sir William Bragg, that these hexagonal six-atom rings persist as such in the aromatic carbon compounds. Benzene itself, C_6H_6, has not yet been investigated as the crystals melt at 6° C. But there is good ground for believing that it consists entirely of such hexagonal carbon rings with attached hydrogen atoms. Naphthalene, however, $C_{10}H_8$, which has two benzene rings in its constitution, two carbon atoms being common to the two rings, crystallises well, and anthracene, $C_{14}H_{10}$, well enough for the powder method, this hydrocarbon having three benzene rings with four carbon atoms in common. On analysis by the X-ray spectrometric method it was found that the monoclinic space-lattice cells of each substance contained two molecules of the hydrocarbon, and their absolute dimensions were determined. The corners of the cells, and also the centres of their basal plane faces, are each occupied by the double benzene ring of naphthalene or the triple one of anthracene, each acting as an entity, the hydrogen atoms being accommodated in the spaces left around these structures. Further, the double benzene rings were also found to remain intact in the derivatives of naphthalene, the particular ones studied being acenaphthene, the α- and β-naphthols, and α-naphthylamine. The cell dimensions of these substances were determined in absolute measure, and the cells found to contain four molecules of the substance in all four cases.

In these remarkable organic structures it is clear that the molecules persist in the crystalline state, and a clear case is afforded which should check the tendency to conclude, from the early X-ray results with very simple binary compounds, that atoms alone need be considered in the crystalline state, and that molecules no longer persist. Such a conclusion was in any case premature, and there are many reasons why it was difficult to believe. For saturated—indeed supersaturated—solutions, and not dilute, are concerned in crystallisation, so that ionic dissociation is excluded; and the molecules which deposit themselves in orderly fashion in forming the crystal are reproduced, or others indistinguishable from them, when the crystal edifice is taken down again by solution or fusion.

(iv.) *Alkali Sulphates.*—As an example coming under the writer's own personal observation, of the highly satisfactory manner in which these results confirm the work of crystallographers, the case of the rhombic alkali sulphates may be quoted. The sulphur atoms were found to be located at the corners and face-centres of the unit rectangular prism, practically like *Fig.* 28, except that the rectangular spacings (edges of the prism-cell) were not equal, the block or cell being not cubic but rectangular rhombic. The metallic atoms, of potassium, rubidium, or caesium, are arranged hexagonally, which is in remarkable accordance with the well-known closeness of potassium sulphate and its isomorphs to hexagonal symmetry, the angles in the prism zone being only a few minutes removed from exactly 60° and 30°. The table on following page shows the writer's published values for the molecular volumes and topic axial ratios (the relative dimensions of the space-lattice cells) for the four salts of the series, and also the absolute dimensions and volumes as determined by means of X-rays with the same crystals (grown and measured by the writer) by Prof. Ogg and

Mr. F. L. Hopwood in Sir William Bragg's laboratory. The correspondence is striking, indeed if the writer's relative values be multiplied by 10^{-7} and considered as centimetres the absolute values as fixed by X-ray reflection are practically reproduced. Moreover, the almost perfect isostructure (equality of cell dimensions) of the rubidium and ammonium salts is fully confirmed. Incidentally, this is a fact which clearly shows the fallacy of the Pope and Barlow valency volume theory, which would require that the volume of the ammonium salt should be twice as great as that of rubidium sulphate, the respective valency volumes of the two salts being 24 and 12.

a periodic one like that just referred to, with the electro-positive alkali metals at the summits of the periods and the halogens and other electro-negative elements at the depressions; it is shown in *Fig.* 31. The sphere of which this "atomic diameter" is the diameter is the limit of approach to that of any other atom, and in the simplest structures, the crystals of the elements themselves, it is the actual distance of separation of the centres of the atoms from one another. The law is proving very helpful in elucidating further more complicated crystal structures; for no two atoms can occupy, or be assigned, closer positions than the sum of their two radii.

COMPARISON OF MOLECULAR VOLUMES AND SPACE-RATIOS WITH ABSOLUTE DIMENSIONS OF SPACE-LATTICE

§ (18) THE LAW OF ATOMIC DIAMETERS.—Another remarkable principle has more recently been deduced by Prof. W. L. Bragg from a consideration of all the X-ray analyses obtained up to the beginning of the year 1920. It is that the atoms of each chemical element possess the same diameter (regarding the atom as a sphere) in all the compounds of that element studied, and these fixed and definite diameters are related, not as the valencies of the elements (as they are supposed to be in the Pope and Barlow theory), but in a manner reminiscent of the relations of their atomic volumes, as shown in the well-known curve of Lothar Meyer. The curve is

§ (19) X-RAY CRYSTAL ANALYSIS AND ATOMIC STRUCTURE.—Finally, X-ray analysis in the hands of the Braggs is now affording some indication also of the structure of the atoms composing the crystal structure. It appears quite likely that the sphere just referred to as representing the limiting surface of the atomic domain is the outer shell of electrons. More careful study of the intensities of the reflections of the various orders of X-ray spectra from the diamond (from the tetrahedron planes of atoms), and from fluor-spar, are affording indications of something—probably connecting electrons—dispersed tetrahedrally in the case of the diamond, and

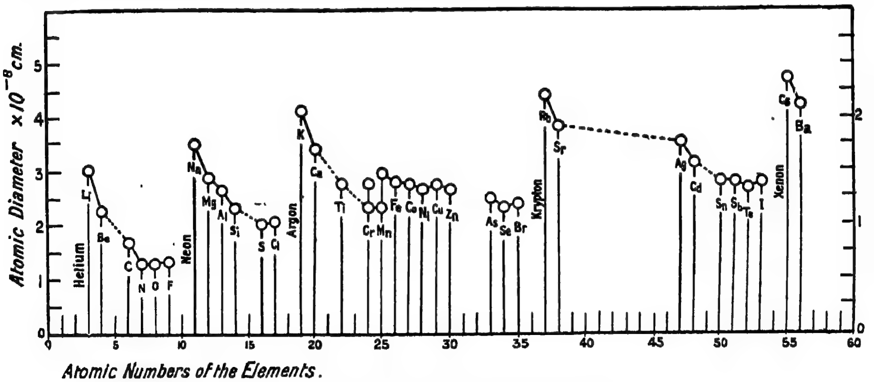

FIG. 31.—The Curve of Atomic Diameters.

one-third to one-quarter of the way between the calcium and fluorine planes in the case of fluorspar. Also by using X-rays rendered more strictly monochromatic by preliminary reflection from rock-salt, much more accurate determinations of intensity have been obtained, such indeed as can be expressed by a definite mathematical formula. Among the various factors which make up this formula there is one which relates to the positions of the electrons of the outer shell, and this again assists in obtaining indications of the positions of these electrons. Hence, it is probable that further researches will afford us not only accurate X-ray analysis of crystal structure, but also of atomic structure.

The results so far are more in unison with the Lewis-Langmuir version of the theory of atomic structure than with the Bohr-Sommerfeld variety. There is distinct evidence of the sharing of electrons by the electro-negative elements, and in cases of the combination of an electro-positive element with an electro-negative one, such as that of potassium and chlorine to form crystals of sylvine, KCl, that the one (here the potassium atom) loses an electron, while the other (here the chlorine atom) takes it up. In each of these two cases the more stable outer shell of the argon type with 18 electrons appears to be formed with each element, the number of electrons of these two elements, potassium and chlorine, being 19 and 17 respectively, corresponding to their atomic numbers in accordance with the immensely important law of Moseley. The unit excess of positive charge left on the nucleus of the potassium atom, and the negative excess unit charge of the added electron on the chlorine atom, act as the attractive connecting force binding the two atoms together.

§ (20) Crystallographic Significance of Moseley's Law.—The law of Moseley just referred to has also a profound crystallographic significance. This law, which it will be remembered emerged from Moseley's last two memoirs on "High Frequency Spectra" (he was killed at Suvla Bay, Dardanelles, 1915), is the essence of atomic structure, as now generally agreed, and is not dependent on the special features of either the Bohr or the Langmuir versions. It stipulates that the positive charge on the nucleus is N units, where N is the atomic number, the sequence number of the element in the periodic table, and that there are N electrons, each of unit negative charge, surrounding it, to counterbalance the nucleus and form the atom. According to Langmuir these electrons are arranged in successive shells containing 2, 8, 8, 18, 18, and 32 electrons as we proceed along the periodic table, while according to Bohr the shells comprise successively 2, 8, 18, 32, 18, and 8 electrons. Which of the two versions is correct is for the moment immaterial as regards the point now desired to be emphasised. This is that the progression in complexity of the atoms provided by Moseley's law explains most fully and satisfactorily the progression in the crystallographic elements, angles, space-lattice cell-dimensions, and in the optical and other physical properties, which has been observed by the writer to occur in the two large and important rhombic and monoclinic series of isomorphous salts (sulphates and selenates, and double sulphates and selenates with $6H_2O$) containing the alkali metals, potassium, rubidium, and caesium, when potassium is replaced by rubidium and the latter in turn by caesium. For it has been shown that these strongly electro-positive elements form the summits of the Bragg curve of atomic diameters, as clearly shown in *Fig.* 31, and their atoms increase in complexity by a complete shell of electrons at each step (from potassium to rubidium, and from rubidium to caesium), and their atomic numbers are 19, 37, and 55, differing by equal steps of 18. Hence, this regular addition in mass and complexity of the atom at each step is bound to produce a corresponding crystallographic progression, such as has been so fully revealed by the writer's work of many years, and which has now been so strikingly confirmed by the direct absolute measurement of the space-lattice cells by means of X-rays.

§ (21) Optical Properties of Crystals.—The physical properties of crystals—their Optics, their Thermal, Elastic, Electrical, and Magnetic Properties—are of equal importance and interest to the Morphological characters which have been considered in the preceding pages. For all of them are profoundly affected by the symmetry, inasmuch as this symmetry is not only that of the exterior form but of the internal structure. Indeed, it has already been made clear that the former is but the natural expression of the latter.

The optical properties[1] are of prime importance as being easily observed and often characteristic of the particular substance, and also because they frequently afford the means of readily deciding as to the type of symmetry, when the goniometrical examination leaves a doubt between certain alternatives or when crystals of adequately perfect exterior form are unprocurable. Three main operations are in general involved in the optical investigation, and they are all connected with the central fact that the optical properties of a crystal may be represented by an ellipsoid of general form, that is, one of which the three rectangular principal axes are unequal in length. Two varieties of the ellipsoid have been used, the vibration-velocity ellipsoid of Fresnel, and its

[1] See "Light, Double Refraction of"; also "Polarised Light," §§ (5)-(16), etc.

polar reciprocal, the indicatrix of Fletcher. The latter is the simplest and most useful for all practical purposes, as its axes are directly represented by (proportional to) the principal optical constant, the refractive index, corresponding to light vibrating along each of those three important directions. Hence, the main task in practical crystal-optics is to determine the refractive index of the crystal in the three rectangular directions corresponding to the axes of the optical indicatrix. The determination of refractive index is an operation familiar in the physical laboratory, and it is only necessary here to mention that it involves the measurement of the angle of the prism (on the goniometer, like a crystal angle), and that of minimum deviation for light of a number of wave-lengths distributed through the spectrum, the same goniometer-spectrometer being used for both operations.

We have first, however, to know these three axial directions of the indicatrix, and if they are not already fixed by the development of high symmetry on the crystal, to determine them, the determination of two sufficing to fix all three. This is achieved by examination of the phenomena afforded by plates of the crystal in parallel and convergent polarised light.

Now the greater the symmetry present the simpler this task becomes. If the crystal possess the perfect cubic symmetry the optical properties are the same in all directions within the crystal, and the ellipsoid becomes a sphere; a 60° prism cut out of the crystal in any direction will, therefore, give us the refractive index, just as if it were glass. There is consequently for a cubic crystal but one refractive index for light of any one wave-length. If the symmetry be that of the tetragonal, hexagonal, or trigonal system the ellipsoid becomes one of rotation about the tetragonal, hexagonal, or trigonal axis of symmetry. The refractive index for light vibrating along that axis will thus be different from that vibrating in any other direction, the maximum difference being for all rays vibrating in the circular section of the ellipsoid perpendicular to the axis. These two extreme refractive indices are respectively labelled ϵ (vibrations parallel axis) and ω (vibrations perpendicular axis and in circular section). If ω be the greater, as for calcite $CaCO_3$, the crystal is conventionally negative, but if ϵ have the higher value, as for quartz, SiO_2, the crystal is said to be positive. Light travelling along the axis remains a single beam, as its vibrations are all in the circular section. But light travelling in any other direction is doubly refracted, a bifurcation into two rays occurring, one of which always affords the index ω and is an ordinary ray, while the other is an extraordinary ray which only affords ϵ when its vibrations occur parallel to the axis. Hence, tetragonal, hexagonal, or trigonal crystals are optically "uniaxial."

In actual practice a 60° prism is cut so that the refracting edge is parallel to the tetragonal, hexagonal, or trigonal axis; this prism affords immediately ϵ and ω; for the ray traversing it at minimum deviation passes along a diameter of the circular section, and divides into two rays vibrating perpendicularly to its path and polarised at right angles to each other, one of which vibrates parallel to the refracting edge and axis and affords ϵ, while the other vibrates in the circular section and affords ω. The two images of the signal-slit corresponding to these two rays can readily be distinguished by means of a Nicol prism placed in front of the telescope eye-piece of the goniometer-spectrometer.

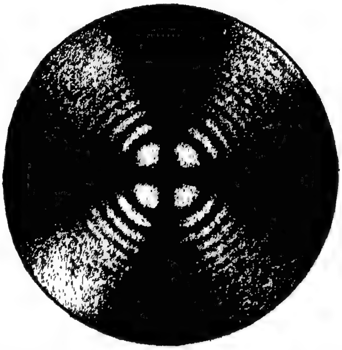

Fig. 32.—Uniaxial Interference Figure in Convergent Polarised Light.

There is usually no difficulty in recognising a uniaxial crystal, and finding the position of its axis. For a plate cut perpendicularly to the latter exhibits in convergent polarised light the well-known interference figure consisting of circular iris-coloured rings and a co-central black cross, the former being curves of equal retardation of one of the two rays behind the other, and the cross marking the directions of vibration of the crossed Nicols. The goniometry will have indicated the direction which is probably that of the tetragonal, hexagonal, or trigonal axis, and a plate cut or ground from the crystal perpendicularly to this direction can readily be tested for the production of this unmistakable uniaxial interference figure, a photographic reproduction of which is given in *Fig.* 32.

The more general case of an optical ellipsoid with three unequal rectangular principal axes corresponds to rhombic, monoclinic, or triclinic symmetry. The directions of the three axes are identical with those of the rhombic axes, but only one crystallographic axis, the symmetry axis *b*, is coincident with an axis of the ellipsoid of a monoclinic crystal, and in the case of a triclinic crystal there are no coincidences of morphological and optical axial directions. In order to determine the

three refractive indices α, β, γ, corresponding to vibrations parallel to the three respective axes of the ellipsoid, we can proceed at once in the case of a rhombic crystal to cut or grind and polish three 60° prisms, so that the refracting edge of each is parallel to one of the crystallographic axial directions (a different one in each case), and so that the bisecting plane of the prism is parallel to a principal plane of the ellipsoid; this plane will then also contain a second axis of the ellipsoid. Hence, such a prism affords two images of the signal-slit of the spectrometer, corresponding to two of the refractive indices, say α and β, or β and γ, or α and γ. Two of the prisms suffice to afford us all three indices, and one in duplicate; but the three prisms give each index twice over, affording an excellent test of accuracy. Each index is, of course, determined for light of a convenient series of wave-lengths distributed over the spectrum.

a general triaxial ellipsoid must have two radii lying in its principal section-plane (that containing the α and γ axes) which are equal to the intermediate axis β perpendicular to that plane, and so has two circular sections perpendicular to which there will apparently be equal (no double) refraction and the property of an optic axis exhibited. Hence rhombic, monoclinic, and triclinic crystals are "biaxial," and if a plate be cut perpendicular to that axis of the ellipsoid which is the bisectrix of this acute optic axial angle, we shall see (in the dark field in convergent polarised light) the well-known biaxial figure of iris-coloured lemniscates (rings, loops, and ellipse-like curves) and dark extinction brushes, as shown in *Fig.* 33. The two optic axes are at the central points of the two systems of rings, and are further indicated by the fine vertices of the hyperbolic brushes, which pivot

Fig. 33.—Biaxial Interference Figure in Convergent Polarised Light.

Fig. 34.—Biaxial Interference Figure with Nicols rotated simultaneously 45°.

In the case of a monoclinic crystal we have first to determine the situation of the two rectangular axes of the ellipsoid which lie in the symmetry plane. We do this by cutting or grinding a plate parallel to the symmetry plane, leaving the faces along its edge undamaged so as to serve as reference faces. This is then placed in the polariscope arranged for parallel light, and the directions determined (with respect to one of the reference faces) for which the dark field of the crossed Nicols is reproduced. These two perpendicular directions are those of the required axes of the ellipsoid. We then know all three axes of the indicatrix and can proceed to prepare the three prisms as in the case of a rhombic crystal.

The case of a triclinic crystal is more difficult, but the sequence of operations is the same; the section-plates required to fix the directions of the axes of the ellipsoid by extinction determinations need, however, to be more numerous.

We then proceed to study the interference phenomena in convergent polarised light. For

about the optic axes when the plate is rotated in its own plane, or when the two Nicols are simultaneously rotated instead, as shown in *Fig.* 34 for 45° of rotation. The angle between the optic axes as thus seen in air is not the true angle within the crystal, but this latter can be determined by preparing a second section-plate perpendicular to the obtuse bisectrix, and measuring the apparent optic axial angle of both plates in one and the same highly refractive liquid, when the following simple formula enables us to calculate the true angle $2V_a$, within the crystal, from the apparent acute and obtuse angles $2H_a$ and $2H_o$ in the liquid: $\tan V_a = \sin H_a / \sin H_o$.

These measurements must also be made for monochromatic light of the same series of wave-lengths as the refractive indices; for in general the angle is dispersed like a spectrum, and is different for each wave-length, giving rise to the chromatic effects seen in white light. Indeed, this dispersion is sometimes so great that for red light the optic axes are separated in another (perpendicular) plane to that

which contains them for blue light, and very beautiful interference figures are afforded in such cases of "crossed-axial-plane dispersion." The writer's spectroscopic monochromatic illuminator, described to the Royal Society in the year 1894, which supplies monochromatic light of a purity equal to the three-hundredth part of the spectrum, enables the phenomena to be very accurately followed, and the exact wave-length for the crossing, when the uniaxial figure is temporarily produced, to be determined.

and the truly orientated plates and prisms can be prepared with the aid of the cutting and grinding goniometer which the writer also described to the Royal Society at the same time as the illuminator, and which has proved so invaluable that no excuse is needed for illustrating it in *Fig.* 35. It possesses all the attributes of a goniometer, having in addition its adjusting arcs divided, combined with a cutting apparatus (revolving soft iron disc with diamond-fed edge) and a grinding and polishing lap (one of ten interchangeable ones of various suitable materials). Either cutter or grinder are removable, to leave the field clear for the other, and a pressure-controlling apparatus is also provided which effectually prevents fracture of the crystal. There are also labour-saving devices for preparing a second surface parallel to a first, or at 60° (or any other definite angle) to the first. With this instrument the many hundreds of section-plates and 60° prisms used in the writer's researches have been prepared, and the accuracy of the results is largely due to it.

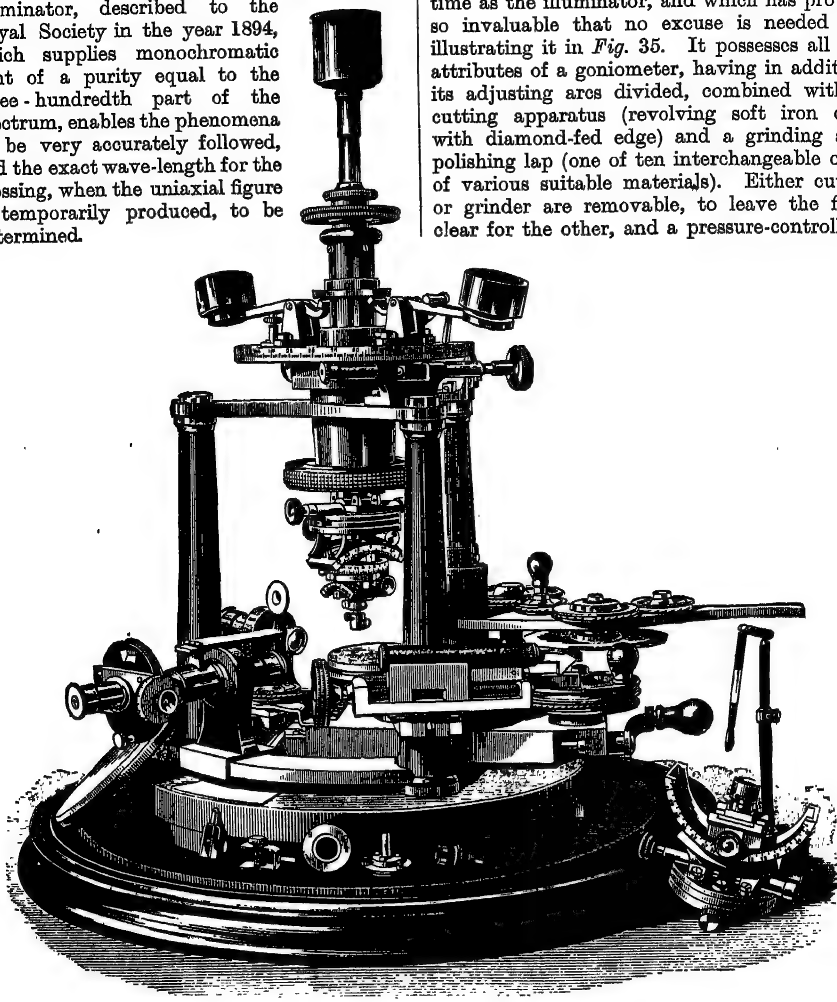

FIG. 35.—The Cutting and Grinding Goniometer.

It will now be clear that the optic axial phenomena afforded by a crystallised substance are always specific and very often characteristic of the crystals of the substance. It will be obvious, however, that a ready mode of producing pure monochromatic light of any wave-length is essential, and also a means of preparing parallel faced and truly plane section-plates and 60° prisms of any required orientation as regards the crystal faces and structure. The former is very conveniently afforded by the apparatus just referred to,

§ (22) Other Physical Properties of Crystals.—Just as the symmetry of a crystal imposes its determinative and controlling effect

on the optical properties of the crystal, so does it also in like manner determine the orientative character of the thermal, electric, magnetic, and elastic properties. The limits of this article have been reached and these properties will be found more or less dealt with under other articles of this Dictionary. But from the practical point of view it should be stated here that as crystals are usually such small objects the most refined methods of measurement are required, the ordinary large-scale methods of the physical laboratory being quite inapplicable. The wave-length interferometer is therefore the indispensable instrument of measurement. Indeed, it was in order to measure the thermal expansion of crystals that Fizeau devised this interferometric method, using curved interference fringes in sodium light as the unit of the scale. The difference of expansion of the screw-legs of a platinum tripod carrying a plano-convex lens, and of the crystal resting below the lens on the table (through which the three screws forming the tripod pass) of the tripod, was the actual object of the measurement. The method has been brought to greater perfection in the writer's interference dilatometer, in which half-wave-length rectilinear interference bands in the more purely monochromatic red hydrogen, red cadmium, or yellow neon light (the two latter being absolutely monochromatic, affording none of the secondary interference in periods, so disconcerting with sodium light) are used as the coarse units; and as these are suitable for use with a micrometer, the hundredth part of such a unit is readily measurable. Thus the one-eight-millionth of an inch, or the one-three-thousandth of a millimetre, is the fine unit. A platinum-iridium tripod carries a glass plate (not a lens) to furnish one of the surfaces (that resting on the tops of the three tripod-forming screws) reflecting the interfering light, the crystal upper surface itself, or the surface of an aluminium or black glass disc carried by it furnishing the other. (Aluminium is especially suitable, as by its large expansion a stout disc nearly compensates for the expansion of the but slightly expanding platinum-iridium screws.)

An adaptation of the same principle, and part of the same optical apparatus, to the determination of the elastic bending of a plate or bar of the crystal is also used in the writer's elasmometer, which confers the same accuracy on the determination of the modulus of elasticity of crystals. As in order to complete the elastic constants of a crystal torsion determinations are also required, a torsion-meter has also now been constructed and installed in the author's laboratory, for the application of this same refined interferometric method to the much more difficult task of determining the modulus of torsion of crystals. Moreover, this new instrument is an interferometer of general application; for it possesses all the essential features of the interference comparator for standards of length, constructed under the writer's supervision for the Standards Department of the Board of Trade, and will enable the determination to be carried out of any very minute movement or short distance in general, such, for instance, as the very small piezo-electrical movements of crystals which are so much in need of further study. A very large field of wonderfully steady black interference bands on the coloured ground of the monochromatic light employed is afforded, and one of the reflecting surfaces producing the interference is actually carried by the observing travelling microscope, the lateral movement of which over a V-and plane bed is effected by an extremely fine screw, and so steadily that the interference bands traverse the field parallel to the pair of vertical spider-lines without the slightest flicker, and can be held at any position for any length of time at the will of the observer.

Full details of all these instruments for crystallographic research (and for much more general physical purposes at the same time) will be found in the writer's *Crystallography and Practical Crystal Measurement* (Macmillan & Co.), vol. i. of the 2nd (1922) edition of which deals with crystal morphology, and vol. ii. with the physical properties of crystals.

In conclusion it may be emphasised that in all these refined measurements it has been fully confirmed that the internal structural symmetry of crystals, which is so beautifully exhibited in their exterior form, rules also absolutely over even the minutest details of their physical properties. For this reason the study of crystals should appeal more and more in the future to physicists, and a knowledge of Crystallography has now become one of the most valuable aids to original investigation in Physics.

DIFFRACTION GRATINGS, THE MANUFACTURE AND TESTING OF

Introduction.—The ideal grating consists of a large number of grooves or "lines" on an optical surface. The grooves should all be exactly alike; and if the surface is plane, they must also be exactly straight, parallel, and equidistant. If the surface is spherical the grooves, as projected on the tangent plane to the sphere at the centre of the grating, should be straight, parallel, and equidistant.

It is needless to say that the ideal grating has never been realised, and never will be. The best existing gratings do, however, approach it very nearly—the degree of approximation being about the same as that of a good telescope or microscope objective to the ideal objective.

It is the purpose of the present article to give an account of the manufacture of gratings, which will include—

I. A brief description of the ruling machine (Rowland's) with a description of the process of making those parts of the machine which are of essential importance, and numerical estimates of the accuracy required in each.

II. An account of the method of testing the performance of the machine after it has been assembled, and a brief account of the method of testing a grating.

I. The Ruling Machine

§ (1) General Description of Rowland's Ruling Machine.[1]—The main frame (36) (*Fig.* 1) supports two sets of ways, at right angles to each other. The plate carriage (11) moves on one of these, the *ruling* or diamond carriage (5) on the other. The *feed screw* (12) rests in bearings supported by the main frame and is prevented from moving longitudinally by the *thrust screw* (14). As the feed screw is rotated by turning the *spacing wheel* (23) the *nut* (15) moves toward the latter, and by means of the *thrust collar* (20) its motion is communicated to the plate carriage. The ruling carriage ways consist of two pairs symmetrically placed, one pair on each side of the plate carriage, as may be seen from *Fig.* 1. The ruling carriage is moved backwards and forwards by means of a crank on the *main drive shaft* (48A), the *connecting rod* (49), and the *cross head* (52). The main drive shaft is rotated uniformly by means of a belt passing over the wheel (48), the source of power being

[1] The numbers in parenthesis refer to the parts as shown in *Figs.* 1 and 2. (These figures are reproduced by permission of the Johns Hopkins Press, Baltimore, U.S.A.)

a water motor running under constant head. One revolution of the drive shaft may be spoken of as a cycle, for during this period one groove or "line" is ruled on the plate. We will take as the beginning of a cycle the moment when the ruling carriage is at the end of its stroke nearest the main drive shaft. At this moment the cam (55) is lifting the lever (54) which, acting through the rods (35 and 34) and the lever (56) and rod (57), lifts the *ruling diamond* (2) off the plate; the cam (47) has also lifted the *pawl lever* (26) to its highest position. During the first half cycle, while the ruling carriage moves forward the full length of its stroke, the diamond is held above the plate, being lowered just when the carriage stops at the end of its stroke. At the beginning of the forward stroke the lever (40) is lowered a little, causing the pawl to engage with the ratchet on the spacing wheel, and immediately the two levers (26 and 40) are lowered together a fixed amount, which rotates the spacing wheel and the feed screw a small fraction of a revolution, thus causing the plate carriage to move forward a distance equal to the grating space. As soon as the spacing has been accomplished the lever (40) is raised a trifle, disengaging the pawl from the spacing wheel. During the return stroke, or second half cycle, the ruling diamond is in contact with the plate, and the groove or "line"[1] is ruled.

In ruling a 5-inch grating with 15,000 grooves per inch this cycle is repeated 75,000 times, usually at the rate of about 20 per minute, so the time required is some 63 hours. If the grating is to be of good quality, it is obviously necessary that during this time the temperature must remain very nearly constant; the amount the plate carriage is advanced during each cycle must be so nearly constant that the actual position of the last groove will agree with its ideal position within a very small fraction of the distance between two adjacent grooves; the ruling carriage and the *diamond holder* (2) must perform their function so well that all the grooves shall be straight and not displaced in any way by accidental movements of any of these parts; and last, but not least, the ruling point must not change its shape during the whole process.

When we bear in mind that the whole machine is made of parts which are not rigid, but elastic, and that in actual operation many of the essential parts are deformed, by forces due to friction, to an extent *which may amount to several grating spaces*, we have reason to be surprised, not that occasionally a grating is faulty, but that any grating is ever good. After doing the very best we can in the matter of construction and adjustments there is no assurance that this will be sufficient; there is no "factor of safety." Let us try to make this important point a little clearer. As we shall endeavour to show presently, it is quite possible to make and adjust all the essential parts of the machine so accurately that if they were absolutely rigid the grating ruled would be so nearly perfect that the most sensitive optical tests would fail to reveal any error. Since, however, these parts are

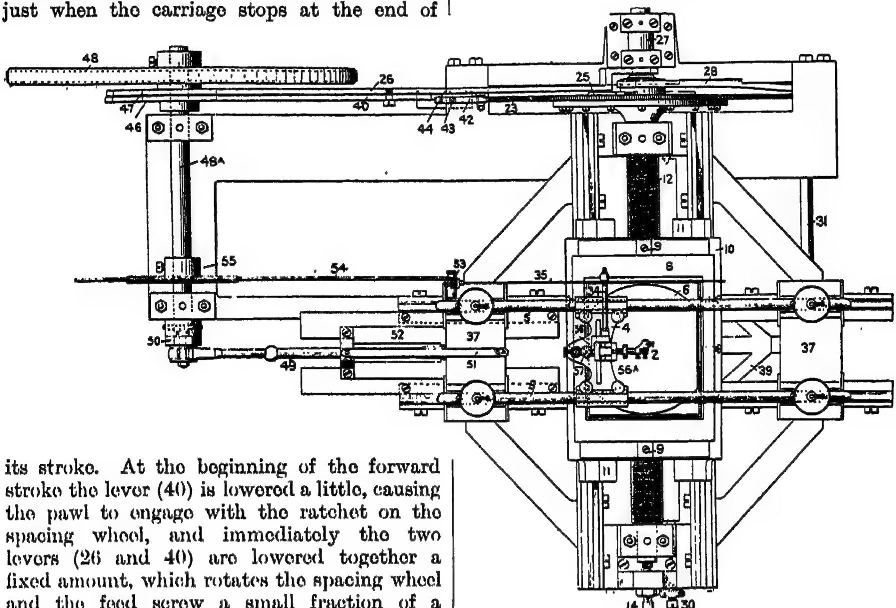

FIG. 1.

[1] In what follows we shall use the word groove, which is more nearly correct than the usual appellation, "line."

elastic, and consequently deformed by frictional forces, accuracy in the results demands that these forces and deformations *remain constant within rather narrow limits* throughout the entire process of ruling. This is the real difficulty in the manufacture of optical gratings, in comparison with which all others may be regarded as trivial.

Let us now enumerate the parts which we have spoken of as essential, beginning with those which, in general, present the greatest practical difficulties :

i. The ruling carriage with its driving connections.

ii. The connecting mechanism between the nut and plate carriage.

iii. The bearings and pivots of the feed screw.

iv. The thrust bearing for the feed screw.

v. The feed screw and its nut.

vi. The spacing wheel.

vii. The straight-edge guide for the wings of the nut.

Perhaps the reader will be surprised to find the feed screw placed fifth in this enumeration. There appears to be a general impression that the manufacture of a perfect screw is difficult, and that if it could be accomplished, the construction of very accurate measuring or ruling machines would be a simple matter. Nothing could be further from the truth. In fact, Professor Rowland himself clearly states that screws made by the process outlined by him,[1] on being tested failed to show any error as large as 1/100,000 inch, but that errors due to the mounting would certainly be encountered. The writer has made several screws by a process essentially the same as that described by Rowland, and has tested them by modern methods fully 10 times as sensitive as those employed by him, without ever discovering the slightest indication of any error. Errors due to the mounting are, however, less easy to avoid, and hence these have been placed 2nd, 3rd, and 4th in the enumeration.

The spacing wheel and straight-edge guide are placed last, because the error in the grating space produced by errors in these parts is only from 1/500 to 1/1000 of the error in the parts themselves, and hence nothing beyond ordinary mechanical accuracy is required.

The ruling carriage is properly placed first, and would, indeed, have been in a class entirely by itself except for a device found on Professor Rowland's machines which will be described more fully below. It is remarkable that Rowland never mentioned the ruling carriage in any of his writings; for its construction is such that even he must have had to give it considerable thought.

Professor Rowland did not deem it necessary to avoid entirely the periodic errors introduced by faulty mounting, but took care of these by an elaborate correcting mechanism working through the straight-edge guide. The writer had so much trouble with this correcting mechanism that he decided to do away with it altogether, preferring to eliminate the errors due to the mounting by careful attention to the items 2, 3, and 4 in the enumeration above. The advantage of this method is that when the machine is once in good adjustment it is likely to remain so at least for some years.

We will now discuss briefly the construction of the essential parts, remembering that periodic errors of spacing which in a half cycle add up to a quantity as large as 1/1,500,000 inch must be avoided, and that errors not periodic in nature must be kept correspondingly small.

§ (2) Construction of the Feed Screw.—A grade of well-annealed tool steel employed by manufacturers of taps and dies is used for the screw, and, if possible, also for the nut. The cutting is best done on a lathe having two tool rests [2] so that two tools, one on each side and 180° apart, may be used in cutting the threads. This automatically removes the greater part of the error in the head of the lathe. Let us suppose that the finished thread which is to be of the V-type is to have an angle of 52°. Three pairs of tools ("gooseneck" or spring type) should be prepared, the angles being 45°, 52°, and 60°. Cut to full depth of the finished thread with the 45° tools; then, use the 60° tools, cutting until the tops of the threads are sharp; finish with the 52° tools.[3] This being done, the pivots are turned to size, the taper to receive the spacing wheel is cut, and the screw is ready for grinding. It is a waste of time to take any elaborate precautions against introducing errors due to the lead-screw or gears of the lathe. A lathe is not, and never can be, a high precision machine.

Three nuts should be prepared, using for the purpose steel tubing whose finished internal diameter is about ⅜-inch larger than the outside diameter of the screw. One of the nuts should have a length equal to ¾ the length of the screw; another should be very short, say an inch, or two at most. The third nut should be just twice as long as the nut which is finally to be used on the screw; in fact, the latter is to be one of the halves into which the third nut is finally cut. The longer nut will be spoken of as the *grinding nut*, the very short one simply as the *short nut*, while the third one is usually designated the *testing nut*. Each is split in two by a longitudinal cut

[1] *Encyclopædia Britannica*, article "Screw."

[2] This device is due to Mr. L. E. Jewell, formerly of the Johns Hopkins University.

[3] This is the method employed by Mr. C. Jacomini of the Mount Wilson Observatory.

through its axis.[1] A brass cylinder previously machined to fit snugly inside the nut casings, having walls $\frac{1}{4}$ inch or a little more in thickness, is now cut into rings each about $\frac{1}{2}$ inch in length. Each of these is, in turn, cut into two parts by longitudinal cuts, and the halves are fastened securely in the casings of the grinding nut and the short nut, by screws; care being taken to leave about $\frac{1}{16}$-inch clearance between them. The testing nut is treated similarly, except that Babbitt's metal[2] is used instead of brass. This is best done by casting in place, no screws being required, since the molten metal will flow readily into the countersunk holes provided for the purpose.

The grinding nut is now bored to size and threaded, the two halves being clamped together with a spacer about $\frac{3}{16}$ inch thick between them. The short nut is treated in a similar manner, but it is better to postpone the threading of the testing nut until the process of grinding is nearly completed.

For grinding, the screw is supported between the centres of a lathe, and rotated at a speed of from 60 to 120 turns per minute. The grinding nut is balanced by a counterweight, and prevented from rotating by a simple lever held in the hand of the operator, who is thus enabled to regulate the friction by feeling, and who will also be warned immediately if any accident should occur. The nut is clamped on the screw by two or four rings held in place by pointed screws in contact with the two halves of the nut. To prevent slight rotations of the halves relative to one another, strips of corrugated spring steel or brass may be inserted in the slots between the nut casings. Emery or carborundum (washed 5 minutes) and oil is used as the grinding material. The process is carried out in air, and no extreme precautions against temperature changes in the room are necessary. One must, however, be careful not to heat the screw by too much friction or too great a speed. The nut is rotated 180° about the axis of the screw frequently; and once, or at most twice, a day it should be turned end for end; occasionally, only one of its halves should be turned end for end.

It is a good plan to wash both screw and nut at the end of a day's work for purposes of inspection. After two or three days' grinding a glance at the screw from a distance of a few feet will reveal all the errors introduced by the lathe. The appearance is so striking that it need not be described. Grinding should be continued for a short time after all these irregularities have disappeared, which will usually require from four to twelve weeks. The diameter of the screw should be frequently measured at several points, by a micrometer caliper, to be sure that it is everywhere the same, and also to see how fast it decreases under the grinding. It is usually found that the process reduces the external diameter by from 0·010 to 0·020 inch. The operator will soon be able to detect variations in the diameter of the order of 1/20,000 inch with certainty. When the first stage of the grinding has been completed, the short nut is fitted by grinding, which may require a day or so, care being taken to run it evenly throughout the full length of the screw. The parts are then thoroughly cleaned, and the short nut replaced, using only oil with no grinding material. A lever attached to the short nut is held by means of a spring balance, and the reading of the balance is noted as the nut is run from one end of the screw to the other. In this way a very accurate test for constancy of the diameter is obtained. If this is not constant it must, of course, be corrected by further use of the grinding nut.

This is followed by a few days' grinding with 30-minute-washed emery or carborundum, after which the short nut is again used to test the diameter.

The testing nut is now threaded and fitted to the screw, using the 30-minute-washed emery. If this requires more than two days the diameter should again be tested.

The screw is then polished, using oil and rouge, first with the grinding nut, and then with the testing nut. It is now finished, except that it is necessary to remove completely all traces of grinding material and rouge, which are likely to be imbedded in both screw and nut. This is accomplished by using the testing nut with oil only, washing thoroughly at the end of each day's work. *It is important that this process be continued a few days longer than the operator thinks it is necessary.*

§ (3) Testing the Feed Screw.—The testing nut is cut into two nuts of the same length, to each of which is added a steel wing about 7 inches long. The screw is mounted in its bearings on a suitable frame which carries a straight-edge against which the wings of the nuts may rest, to prevent them from turning when the screw is rotated. One plate of a Fabry and Perot type of interferometer is mounted on each nut, so that the line of sight through the interferometer shall be parallel to the axis of the screw and 4 or 5 inches vertically above it. A mercury lamp is a good source of light for use with the interferometer.

If in one rotation of the screw the interference rings remain stationary, the axis of

[1] The writer had to discard the four-part grinding nut recommended by Rowland. It is impossible to adjust it properly during the process of grinding.

[2] The use of Babbitt's metal instead of wood in various parts of the machine is due to Mr. L. E. Jewell.

the screw is straight. An easy calculation shows that this method will readily detect a curvature of the axis having a radius of 300 miles. If, however, the steel used in making the screw is of good quality and well annealed, and if the work of machining has been done in such a way that no strains have been introduced, no curvature of this amount will be found. It is interesting to bear in mind that the screw mounted in this way sags down in the middle under its own weight, so that the actual radius of curvature is anywhere from 2 to 10 or 20 miles; but as the screw is rotated, this radius always points upwards, so that it does not affect the interference rings. A clear mental picture of this cannot help but be of immense value to any one who has to deal with apparatus where great accuracy is a consideration.

By repeating the interferometer test with one of the nuts rotated 90° or 180° relative to the other, the operator may satisfy himself in regard to the absence of any periodic error; by separating the two nuts a considerable distance, and repeating the test, errors of run may be investigated. For this it is, of course, necessary to watch the interference rings while the nuts are moved a distance of several inches, if the test is to be sufficiently sensitive. No errors of any kind will be found except very close to the ends of the screw. The operator will, however, discover that it is no easy matter to put two well-fitting nuts on a screw without introducing anything between the threads except oil. If the fit is perfect (nothing but oil between them) pressure applied to *any* part of either nut will displace the interference rings, but on removing the pressure they will return exactly to their original position. If a particle of foreign matter has been introduced this will not be the case.

It should be noted that a screw made as described above will not necessarily have "perfect threads" as defined by the specifications of our national physical laboratories during the late war. Those specifications were intended to apply to parts which are to be interchangeable. The screw and nut described above form a unit; another nut, for example, cannot be used with the screw, without first being ground to a fit with all due care.

§ (4) Adjusting the Pivots of the Feed Screw.—One of the nuts is removed, and the other is moved near one end of the screw, but not so close as to engage the imperfect part of the thread. One interferometer plate is mounted on this nut so that the normal to its surface is vertical and fairly accurately at right angles to the axis of the screw. The other interferometer plate is supported from the frame and mounted above the first plate. On rotating the screw it will be found that the lower plate describes a small circle with its axis parallel to that of the screw. This shows that the lathe did not turn the pivot in such a way that its axis coincides exactly with that of the screw. The pivot must then be corrected locally, and be kept truly cylindrical by grinding in its own bearing, until the circle is quite small, say, until its diameter is of the order of 1/100,000 inch. It is not advisable to carry the correction further at this stage, for the other pivot is probably contributing something to the apparent error. The nut is moved near the other end, and that pivot is treated the same way, only that the correction is carried somewhat further, perhaps to 1/250,000 inch. Then, return to the first pivot, and so on until no error can be detected. The pivots are finally polished with rouge, and again tested as described above.

Three part bearings should be used with the screw pivots, making certain of contact at three points of each pivot, these points being 120° *apart.* The proper design and construction of such bearings present no serious difficulty.

§ (5) The Thrust Bearing.—One end of the screw, outside the pivot, is provided with a taper bearing for the spacing wheel. In the other end four holes are drilled and tapped for receiving the screws used to fasten the mounting of the thrust plate. It is advisable to finish this end of the screw optically flat, the surface being at right angles to the axis within about one or two seconds of arc. Various materials for the thrust plate have been tried, but none have been found as satisfactory as the reconstructed ruby, especially those of French make. A cylinder of this material $\frac{3}{16}$ inch to $\frac{1}{4}$ inch long, and from $\frac{1}{4}$ to $\frac{3}{8}$ inch in diameter. is finished optically flat and highly polished, at least on one face. No error as large as $\frac{1}{20}$ of a light wave should be allowed. The ruby is rigidly secured in a steel mounting, which is fastened to the end of the feed screw by four well-made screws as indicated above. The surface of the mounting in contact with the flat end of the feed screw must be worked until, when the two are in contact, the face of the ruby is also normal to the axis of the screw within one or two seconds of arc.

All of this requires some patience but is not especially difficult to accomplish. Suitable optical tests are, of course, needed to ensure the required accuracy in alignment, and this is one reason why the face of the ruby must be so flat. If it is not flat to $\frac{1}{20}$ of a wave-length, the diffraction disc observed at the focus of the lens or mirror used in the test will not be truly circular, thus making it difficult to observe a motion of $\frac{1}{10}$ of its diameter when the screw is rotated.

The end of the thrust screw (14) is a hardened steel spherical surface, highly polished.

having a radius of curvature of from 2 to 6 inches. It should make contact with the ruby at a point on the axis of the screw, but, thanks to the accuracy of alignment of the surface of the ruby, an error of 1/100 inch in the position of the contact can at most produce a periodic to-and-fro motion of the screw of something like 1/5,000,000 inch, which is too small to produce any harmful effect.

A thrust bearing of this kind, after continuous use for several years, will not show the faintest indication of a mark due to wear on either surface; the force acting across the contact may safely be as high as 40 lbs. No doubt a diamond would be as good or even better than a reconstructed ruby, but it would cost considerably more and would be more difficult to work. Agates, topazes, natural sapphires, etc., have been tried and found unsatisfactory.

§ (6) The Connecting Mechanism between the Nut and Plate Carriage.—The original design by Professor Rowland, described in his article on the screw,[1] and shown in *Fig.* 2 (20), is still followed. This consists of a ring or collar loosely supported by the plate carriage, and making definite contact with it at two points near the ends of a vertical diameter. The nut makes contact with the ring at two points near the ends of a horizontal diameter. In each case the contact is made by a hard flat surface against a softer rounded metallic lug. In one machine the two pairs of flat surfaces are mounted respectively on the plate carriage and the nut; on another machine, the flat surfaces are on the ring. It is important that the four contact points shall lie in one plane at right angles to the axis of the screw.

We will now try to give the reasons for placing this part second in the enumeration in § (1). The ring or collar is not difficult to make, and it is practically self-adjusting; but, located as it is at the most vital point in the whole machine, it is very likely to act as a trigger, bringing into action potential sources of error which otherwise would be held in abeyance.

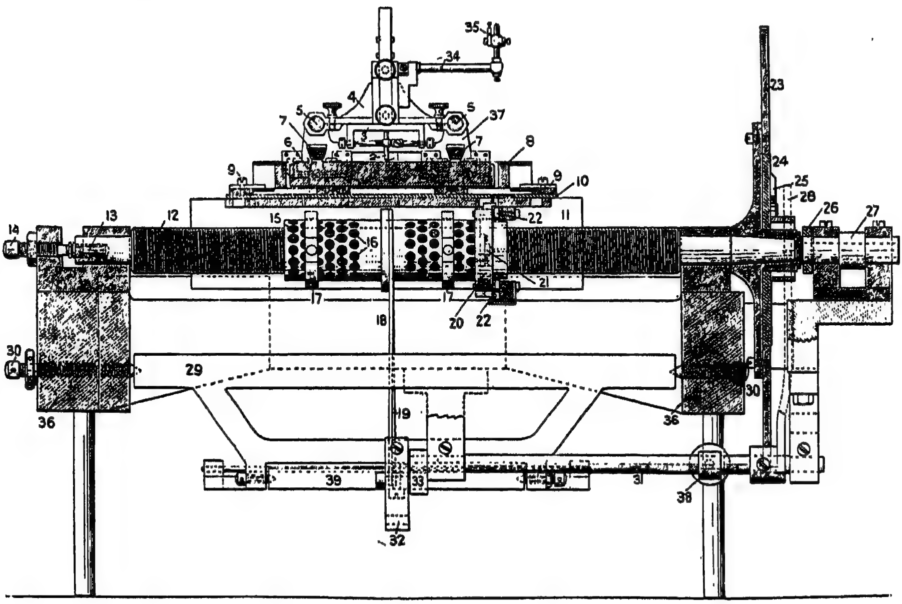

Fig. 2.

Let us examine a little more minutely the action of the ring. It is attached to the plate carriage in such a way that, when not in contact with the nut, it may move slightly in a direction parallel to the axis of the screw; it cannot move at right angles to this direction. It may rotate through a small angle about a vertical axis, but it cannot rotate about a horizontal axis, parallel to the screw. When the nut acts through it to move the plate carriage, its plates are brought into contact with the lugs of the latter, after which it has only one degree of freedom, namely a slight rotation about its vertical axis. Now since the axis of the screw can never agree *exactly* with that of its pivots, nor be exactly parallel to the plate carriage ways, it is evident that

[1] *Encyclopædia Britannica*, 9th edition.

as the screw rotates the nut describes a vertical circle of small radius, and in addition it moves very slowly in a direction at right angles to the ways of the plate carriage. The little circle is described once in each revolution of the screw, during which time the carriage moves forward, say 1000 times, 1/20,000 inch at a time. Suppose the diameter of the circle to be 1/200,000 inch, or its circumference, roughly, to be 1/60,000 inch. Assuming all the parts to be perfectly rigid, the lugs on the end of the nut, during each forward motion of the carriage, would slide along the plane surfaces on the ring a distance of 1/1000th of 1/60,000 inch or 1/60,000,000 of an inch. In the actual case, where the parts are not rigid but elastic, nothing like this can happen on account of the friction between the lugs and the plates. What really happens is probably this: no actual slip takes place until, owing to the relative displacements of the parts, the stress becomes sufficient to overcome the friction, when a comparatively large slip occurs, perhaps even "overshooting the mark." Remembering now that, during the normal operation of the machine, the screw is compressed a certain amount, and the nut, ring, and the parts of the plate carriage are all deformed as a result of the "forces of friction," and that *the successful performance of the machine depends upon these deformations remaining constant to a high degree of accuracy*, one can readily see what a catastrophe may easily result from the action just described.

The question naturally arises: "How accurately would the adjustments have to be made to ensure that no slippage whatever would occur during a revolution of the screw?" This the writer is unable to answer. A maladjustment to such an extent that a slippage would necessarily occur in each cycle would no doubt make matters much worse.

§ (7) THE RULING CARRIAGE.—Let us consider the task the ruling carriage has to perform in ruling say a 5-inch grating, having grooves 4 inches long. If the spacing is 20,000 per inch, it must move back and forth 100,000 times, or a distance of some 13 miles of actual travel, involving 200,000 stops and starts. It must move in one and the same straight line, deviating from this not more than 1/1,000,000 of an inch if the result is to be satisfactory. Moreover, the power that moves the carriage is derived from a main shaft which is called on to deliver power intermittently to several other parts at the same time.

Obviously, the friction coefficient must be made as small as possible, and the force required to start the carriage from rest should not differ greatly from that required to keep it in motion. Probably these conditions can not be satisfied with V-type ways. A better form of way is one having a flat top, with sides making an angle of 80° or more with the top. The weight of the carriage is thus mainly supported by the flat top; one of the sides serves to define the path of the carriage, and a spring acting on the opposite side ensures contact. The constant motion of the carriage causes an appreciable wear of the way surfaces. Measured in units of 1/1000 inch this wear is exceedingly slow; but it is relatively rapid when measured in the unit which concerns us here, namely, 1/1,000,000 inch. The wear of the top surfaces is of little or no consequence, as it merely displaces the carriage in a vertical direction, but that of the sides which define the path is of great importance. During the ruling of a single grating the sides change enough to make a considerable difference in the position and curvature of the first and last grooves. As the stroke is different for gratings of different size, one readily sees that after a year's work the defining sides of the ways will no longer be straight, but in reality quite irregular curves. In spite of these changes in the ways, and the wear of the bearing blocks of the carriage, Rowland's machines still rule grooves which are quite as perfect as those ruled at first when the ways were really straight. This result is due to following the device mentioned in § (1).

It will be recalled that the ruling carriage moves on two pairs of ways symmetrically placed, one pair on each side of the plate carriage, or we might describe it by saying that there is but one pair of ways with a section some 10 inches or more in length removed from the middle, in order to allow space for the plate carriage, its ways, and the screw (see *Fig.* 1 (37)). Let us call the pair farthest from the main shaft the front pair, the other the rear pair. *The defining sides of the front pair are on the left, those of the rear pair being on the right side, and the ruling point is at the centroid of the four contact points.* Hence if the two pairs of ways are straight initially, and the amount of wear is the same for both, the ruling point will always describe the *same* straight line. The wear will be the same provided the ways are made from the same material, and the pressure produced by the two sets of springs is the same.

The crank on the main shaft moves the cross-head (52), and a connection between this and the ruling carriage communicates the motion to the latter. The cross-head ways can, of course, never be made parallel to those of the ruling carriage, and hence this connection presents difficulties of the same nature as those discussed in § (6). A well-made universal coupling is employed and does fairly well, but it must be confessed that no entirely satisfactory solution has yet been found.

§ (8) The Spacing Wheel and the Straight Edge Guide.—As stated in § (1) the effect on the grating of errors in these parts is at most of the order of 1/500 of the error. Hence if these parts are correct to about 1/10,000 inch they will be satisfactory, and since this is little more than ordinary mechanical accuracy, we need not consider them further.

II. Testing the Machine and Gratings

§ (9) Method of Crossed Rulings.—Every one is familiar with the appearance of "watered silk," the pattern seen when looking through two moderately fine-meshed wire screens nearly parallel to each other, and separated by a small interval; or the pattern observed when viewing a screen and its reflection in a mirror immediately behind it. The principle illustrated by these familiar phenomena is used as follows to obtain a delicate test of the performance of a ruling machine.

A grating which may be $\frac{1}{8}$ inch wide is ruled on a well-polished plate. The plate carriage is moved back to the starting-point, and the plate holder is moved back an additional distance of from $\frac{1}{4}$ to $\frac{1}{2}$ the pitch of the feed screw, and given a rotation about a vertical axis of about one minute of arc, after which the plate is again ruled the same width as before. The second ruling crosses the first at the small angle mentioned, and on viewing the ruled surface in the light of one of its spectra a series of bright and dark bands will be observed, generally at right angles to the direction of the individual grooves. We speak of the dark bands as the locus of the intersections of the two sets of grooves, but in reality they merely run parallel to the loci. (A complete account of the phenomena observed with such a cross-ruling has never been given, and would apparently be quite difficult.) If the ruling diamond has been properly chosen and adjusted [1] the dark bands will be very narrow as compared to the distance between them, and hence will be well suited for testing the accuracy of spacing. If the spacing is perfect, the dark bands will be straight lines. normal to the grooves; errors of spacing will be indicated by departures from these conditions.

Choose rectangular axes, and take as the origin the intersection of the first groove of the first ruling with the first groove of the second ruling. (This point will not actually be on the plate, since the plate was displaced slightly before being rotated.) Let the X axis bisect the obtuse angle, the Y axis the acute between the two grooves.

[1] Ordinarily a diamond which will rule first-rate gratings will give only a poor cross-ruling pattern, the bands being so faint and diffuse that they are difficult to see.

(i.) *Ideal Spacing.*—Let the intersections with the X axis be given by

$$x_n = na(n=0, 1, 2, 3, \ldots), \qquad (1)$$

a, being the grating space, very nearly.

The equations of the two sets are

$$y_{1,n} = mx_n - mna, \qquad (2)$$

$$y_{2,n} = -mx_n + mna. \qquad (3)$$

We seek the intersection of any groove n of the first set with the groove $n+2p$ ($2p$, any integer) of the second set. The locus of these intersections is evidently

$$y = pma = \text{constant}; \qquad (4)$$

m is the tangent of the angle between any groove of the first set and the x axis, *i.e.* $m = \tan 89° 59' 30'' = 7000$ nearly. We will speak of $2p$ as the "order" of the intersection. Thus, for $p=0$, or the zero order, the locus is the x axis. For $p=\frac{1}{2}$ or the first order, $y=ma/2$, a straight line parallel to the x axis and at a distance $ma/2$ from it. Taking $a=1/15,000$ inch, which is the spacing usually employed in recent years, $ma/2$ is a little less than $\frac{1}{4}$ of an inch, which is the distance between the "orders."

(ii.) *Simple Periodic Error.*—Let

$$x_n = na + b \sin \frac{2\pi n}{N}. \qquad (5)$$

The locus of intersections of order $2p$ now becomes

$$y = mpa + mb \sin \frac{2\pi p}{N} \cos \frac{2\pi(n+p)}{N}. \qquad (6)$$

N is the number of grooves ruled in a period, and as the fundamental period will always correspond to one revolution of the screw, N is simply the number of teeth on the rim of the spacing wheel.

Again the zero order ($p=0$) reduces to the x axis; also, $2p=N$, $2N$, etc., give straight lines parallel to the x axis. Other values of p give cosine curves, the amplitude of which is a maximum for $2p=N/2$, $3N/2$, etc.

The amplitude of the curve whose order is $2p$ is $mb \sin 2\pi p/N$. If this equals $ma/4$ we speak of it as "unit amplitude." Such a choice of unit is necessary, as the actual amplitude depends upon m, which changes very rapidly with the angle, and, even when great care is taken to keep the angle constant, will vary considerably in different cross-rulings. The value of b which gives unit amplitude in the $2p$ order is evidently

$$b_0 = \frac{a}{4 \sin(2\pi p/N)}.$$

Let the actual amplitude as measured in

terms of the unit defined above be A (where in general $A<1$). Then our error is

$$b=\frac{aA}{4\sin(2\pi p/N)}=\frac{aA}{4\sin(\pi S/N)}, \quad . \quad (7)$$

S being the "order."

As a numerical example, let us take $A=\frac{1}{25}$, which under ordinary conditions is fairly easy to observe. If $a=1/15{,}000$ inch, $S=N/2$, we have $b=1/60{,}000\times 1/25=1/1{,}500{,}000$ inch as the maximum periodic displacement of the plate away from the position it should have during ruling.

We may also compute the value of the maximum and minimum grating space in such a ruling. Referring to formula (5) and taking $N=750$, we have

Max. spacing $=1/15{,}000+1/190{,}000{,}000$ in.

Min. spacing $=1/15{,}000-1/190{,}000{,}000$ in.

A variation of the spacing as large as this, if it were not periodic, would, of course, destroy the value of the grating as an optical instrument. (This should be borne in mind in connection with the discussion in § (6).)

It is well known that the effect of a simple periodic error is to produce ghosts of bright lines [1] in a spectrum. If the error is not too large and is simply periodic in character, there will be two ghosts of each line, symmetrically placed with respect to it, at a distance which varies inversely with N. It is a simple matter to calculate the intensity of such ghosts when b is known, provided it is small compared to a. The derivation of the formula is, however, rather lengthy,[2] and therefore only the formula itself will be given here. Taking the intensity of the spectrum line as unity, the intensity of the ghost is given by

$$I_g=\frac{M^2}{4}\left(\frac{2\pi b}{a}\right)^2, \quad . \quad . \quad (8)$$

M being the order of the spectrum observed. If $b/a=1/100$, as in the example given above, we have

$M=$	1	2	3	4	5
$I_g=$	0·001	0·004	0·009	0·016	0·025,

or in the 5th spectrum the ghosts have an intensity equal to $\frac{1}{40}$ of that of the line itself. In a number of the gratings ruled since 1911 the ghosts are rather weaker than this.

(iii.) *Linear "Error of Run."*—If the spacing varies linearly across the grating, it is commonly spoken of as showing an "error of run." The law of spacing is

$$x_n=na+n^2c, \quad . \quad . \quad . \quad (9)$$

where $2c$ is the constant difference between any grating space and the preceding one. The equation of the cross-ruling band of order $2p$ is

$$y=mpa+2mcp(n+p)\,; \quad . \quad . \quad (10)$$

a straight line whose slope is $2mcp$.

In order that the test for this type of error shall be sensitive, it is necessary to take p quite large, and also to rule quite a wide space, so that the length of the band may be great enough to allow an accurate determination of its slope.

As a numerical example, let us consider a ruled space 4 inches wide, 15,000 grooves per inch, and let the plate be displaced 4 inches between the first and second rulings. Let y_1 and y_2 be the distances from the x axis to the beginning and ending of the band of order $2p$. We have

$$y_2-y_1=2mcp(n_2-n_1). \quad . \quad . \quad (11)$$

In this case $p=3\times 10^4$; $n_2-n_1=6\times 10^4$; m may be taken as 7×10^3. Suppose $y_2-y_1=\frac{1}{25}$ inch, which should be measurable. We have

$$c=1{\cdot}6\times 10^{-15} \text{ inch.}$$

The departure of the last groove from its ideal position on a 4-inch grating having this error is $n^2c=5{\cdot}8\times 10^{-6}$ inches, or about $\frac{1}{4}$ of a light wave.

The two illustrations just given will suffice to show that in cross-ruling we have a powerful method for studying the performance of the machine. Other cases might be discussed, such as variation in spacing along the length of the grooves and curvature of the grooves, but the reader will have no difficulty in seeing how these cases are investigated.

(iv.) *Accidental Errors and Diffused Light.*—Accidental errors are due to two principal causes:

(*a*) That discussed in § (6).

(*b*) Slight errors in the motion of the ruling carriage, and those due to faulty adjustment of the diamond-holder (2, 3).

If (*a*) alone is present, the cross-ruling pattern will appear somewhat like *a* in *Fig.* 3. The band is clean and narrow but shows a large number of breaks, indicating that, superposed upon the regular, even displacements of the carriage, there are sudden shifts, which occasionally may amount to as much as $\frac{1}{10}$ of a grating space, but usually are very much smaller than this. If (*b*) alone is present, the pattern is very much as shown in *b*, *Fig.* 3. The pattern is not clean, but may be best described by saying it is "hairy." In general, both causes are present, so that an

[1] If the error is very large, ghosts may also appear in absorption spectra such as the solar spectrum, but such cases probably do not occur with any grating actually used in spectroscopic work. In ruling gratings one often finds them.

[2] It is easiest accomplished by using the so-called "vector method" of treating diffraction phenomena.

is in the *same* direction on both sides of the normal, which is not so when the error is in the ruling. (In the preceding discussion it has been tacitly assumed that the angle of incidence is zero, merely for simplicity. When the angle of incidence is different from zero, the different cases are affected somewhat differently, making it still easier to separate the causes of error.)

If the Foucault test is satisfactory, and periodic errors have been determined and found sufficiently small, the grating is satisfactory, provided it is also reasonably free from diffused light. The determination of the amount of diffused light, and also of the brightness of the different orders of spectra, do not require any comment.

§ (11) The Selection and Adjustment of the Ruling Diamond.—Natural crystal edges, free from little breaks or other imperfections, are used in ruling gratings. Small white diamonds, each weighing about $\frac{1}{30}$ carat, are securely mounted, each in the end of a short steel rod $\frac{1}{8}$ inch in diameter. The diamond-holder permits rotations about three mutually perpendicular axes in order that a given edge of the crystal may be brought into contact with the plate, and may also be adjusted parallel to the ruling carriage ways.

The diamond-holder can be removed from the machine and mounted under a microscope, where the preliminary adjustments are actually made, after which it is replaced in the proper position on the machine. The correct pressure of the diamond on the plate must be found by trial for each ruling edge, and is regulated by a counterweight.

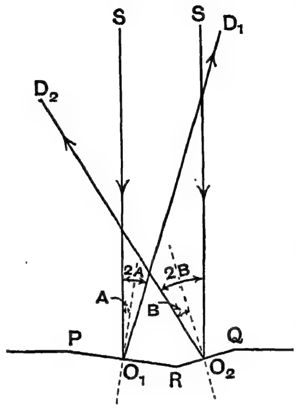

Fig. 4.

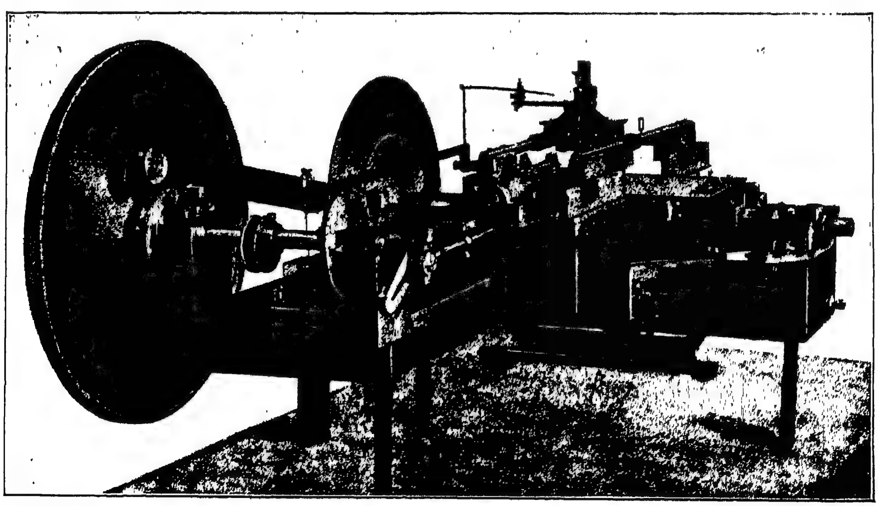
The ideal groove is V-shaped, and the actual groove approaches this form very closely if the adjustments are good. It remains to determine the angle of the groove, to give it the right width, and to orientate it properly for the kind of ruling desired.

Let a single groove be ruled on a well-polished plate. Suppose the normals to the sides of the groove make the angles A and B with the normal to the surface. If light be incident normally on the surface, the light diffracted by the groove will show two maxima, viz. in the directions making angles 2A and 2B with the incident beam. The diagram, *Fig.* 4, which represents a section normal both to the surface and to the groove, will make this clear. PR and QR are the sides of the groove; O_1D_1 and O_2D_2 are the directions in which the maxima of the diffracted light will be found. Since PR and QR are very narrow, having in general a width of from $1\frac{1}{2}$ to $2\frac{1}{2}$ wave-lengths of light, the angular width of the diffracted beams will



Rowland's Ruling Machine.

be considerable, and, in the figure, O_2D_2 will be wider than O_1D_1. It is, however, quite possible to measure approximately this width, that is, the angular separation of the first diffraction minima belonging to O_1D_1 and to O_2D_2, and this being done, the distance PQ becomes known. It should be as nearly as possible the same as the grating space, and may be adjusted to this value by varying the weight on the diamond. If more than two maxima are found, the groove is not of the simple V-type, and should in general not be used.

As it is desirable to have some particular spectrum as bright as possible, the diamond should be tilted until the direction of O_1D_1, for example, falls in that spectrum. The direction of O_2D_2 will in general be that of some higher order spectrum on the other side, but it cannot be controlled independently except by changing the grating space. The lower order spectrum which is bright at zero angle of incidence will also be bright for other values of this angle,[1] at least within reasonable limits.

This discussion is far from complete, but it is hoped that enough has been said to show that the finding of a suitable ruling point is not altogether a matter of chance. J. A. A.

DIFFRACTION GRATINGS, THEORY

I. Theory of Gratings

§ (1) Introductory.—A Diffraction Grating consists, in effect, of a number of parallel and equidistant slits in an opaque screen. The slits are usually very narrow and very numerous, but this is not invariably the case. If a parallel beam of light is incident on such an arrangement, some of it passes through the slits while some is stopped by the opaque intervals. If the transmitted light is brought to a focus by a telescope or camera lens, it is found that spectra are produced in certain directions. Such spectra are usually described somewhat vaguely under the comprehensive title "Diffraction Spectra." Physically there are three quite distinct processes contributory to the production of the phenomena observed: these are:

(*a*) *Diffraction* by the individual slits of the grating, converting them, in effect, into a series of similar light sources emitting light over a considerable range of angle on either side of the direction of incidence. The wavelets emanating from these sources start, however, with definite phase relationships; this renders possible the next stage, viz.—

(*b*) *Interference* between the wavelets from different slits, which results in their completely annulling one another except in certain directions.

[1] See *Astrophysical Journal*, 1911, xxxiii. 350.

(*c*) *Diffraction* by the aperture of the observing system. This gives finite breadth to the spectrum lines, and introduces a series of secondary maxima between them.

Needless to say these phenomena cannot be discriminated in the final result. Thus we do not observe any diffracted light resulting from process (*a*) except in those directions determined by process (*b*). Moreover it is impossible to observe the resultant of these two processes except under the limitations of total aperture set by the dimensions of the observing system, which introduces the further modifications due to process (*c*).[2] We cannot therefore dissociate the contributory processes in practice. This tempts us, in developing the theory of the grating, to put all the ingredients into our mathematical mill at once, and after mixing them thoroughly, obtain final equations from which we may extract all the essential information. This is the method followed in the classical treatments of the subject which are found with slight modifications in the majority of text-books. While of great mathematical elegance, such a treatment almost invariably fails to convey to the student any clear conception of why the various results which the equations indicate, and which he can see in practice, do actually happen. In order to understand these it is desirable to keep quite separate in one's mind the processes (*a*), (*b*), and (*c*). This desideratum is partly fulfilled in the vector method originally used by Kimball and subsequently employed by Wood, Sparrow, and others. In this treatment process (*a*), which merely supplies the light in the necessary directions, is dissociated from the subsequent spectrum formation. The analysis, however, automatically obtains the joint effects of (*b*) and (*c*) and is, in consequence, misleading as to the origin of secondary spectra and of the finiteness of resolving power. The method is of great use and beauty, nevertheless, and further reference will be made to it later; but the various properties of grating spectra will be deduced in the following paragraphs by a method which it is hoped will render their origin as clear as possible by treating each of the contributory processes separately.

§ (2) Diffraction by a Rectangular Aperture.—Although the starting point for any investigation of gratings, the theory of

[2] In any spectroscope the observing telescope is usually of sufficient aperture to take all the light from the prism or grating. In practice therefore the length of the grating and its obliquity determine the aperture of the system, but if in any case the telescope is of smaller aperture, in the plane of dispersion, than that required to take in light from the whole grating, it is the actual aperture which determines the results of process (*c*). For simplicity we shall assume in what follows that the aperture, whether due to the limited size of the grating or of the telescope objective, is bounded by straight sides parallel to the slits.

diffraction is outside the scope of this article. We must simply quote the result in the case of a rectangular aperture, as developed in any of the standard text-books.[1] Let A, *Fig.* 1 (*a*), be a point source of light situated at an infinite distance from a screen, B, in which there is a rectangular aperture *s*, with sides parallel and perpendicular to the plane of the paper. The light which passes through *s* does not pass straight on in the direction *s* A′, but spreads out in the space to the right of B, and would produce illumination over an area, more or less extensive, of a screen C. In what follows we need only concern ourselves with diffraction in the plane of the paper. It is also convenient in this case to substitute a line source, perpendicular to the paper, instead of a point source. Let the width of the aperture in the plane of the paper be a, then the light is spread out in this plane to an extent depending on a, the intensity in a direction making an angle θ with *s* A′ being proportional to the quantity

$$a^2 \frac{\sin^2 \{(\pi a/\lambda) \sin \theta\}}{\{(\pi a/\lambda) \sin \theta\}^2}, \quad . \quad . \quad (1)$$

where λ is the wave-length of the light.

In the direction *s* A′ $\theta = 0$, and the limiting value of the expression is a^2. When $(\pi a/\lambda) \sin \theta = p\pi$, p having the values 1, 2, 3, . . . etc., the intensity is zero, while it has maximum values at intermediate angles. If the light is received in a telescope focussed on infinity, so that all rays having the same value of θ are brought to the same focus, a series of bands will be seen corresponding to these alternate maxima and minima.

It is obvious from the form of expression (1) that the intensity curve of the lateral maxima is simply a sine squared curve of which the ordinates are divided by a quantity proportional to the square of the distance from the central band (measured in terms of $\sin \theta$). The proportional variation of this quantity is steep at first, with the result that the maximum ordinates of the maxima near the central band are displaced from the point half-way between the minima, being slightly nearer the central band. Their actual position corresponds to $\tan \{(\pi a/\lambda) \sin \theta\} = (\pi a/\lambda) \sin \theta$ instead of to $\tan \{(\pi a/\lambda) \sin \theta\} = \infty$. This follows at once from differentiation of expression (1). These values do not, however, differ greatly, and to a close approximation it is convenient to take the central maxima as occurring half-way between the minima, *i.e.* at the points when $(\pi a/\lambda) \sin \theta = (2p+1)\pi/2$,[2] beginning with $p = 1$. The ordinates at these points are given by

$$I \propto \frac{a^2}{\{(2p+1)(\pi/2)\}^2} = \frac{4I_0}{\pi^2} \frac{1}{(2p+1)^2},$$

where I_0 is the intensity at the centre of the central band. From this we find that the approximate maximum intensity in the first lateral band is 1/22·3 that of the central band; of the second 1/62; of the third 1/121, etc. The true values will be slightly greater than this, and can be calculated if required from the more accurate positions. The intensity curve is shown in *Fig.* 1 (*b*).

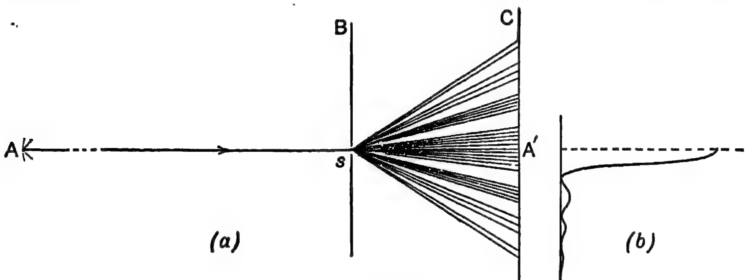


FIG. 1.

The positions of the lateral maxima depend on the wave-length, so if the light employed is not monochromatic, the bands corresponding to different colours will be in different positions. These bands were termed by Fraunhofer "*Spectra of the First Class.*"

If the width a of the aperture is very small the width of the central band, which extends to $\theta = \pm \sin^{-1}(\lambda/a)$, will be quite large. In fact if a is comparable with λ the central band will extend very nearly over the whole angular space on either side of the incident beam. Such a fine slit therefore acts practically as a line source of light as far as direc-

[1] *E.g.* Preston, *The Theory of Light*, chapter ix.; see also "Light, Diffraction of."

[2] The actual departures from this may be calculated easily by giving $\pi a/\lambda \sin \theta$ its approximate value corresponding to the middle of the band, and using this to obtain a closer value from a table of tangents. Thus for the first band $\pi a/\lambda \sin \theta$ is in the immediate neighbourhood of $3\pi/2 = 4{\cdot}7$; the true value will be very nearly $\tan^{-1} 4{\cdot}7 = 3\pi/2 - 12°$. Similarly the second maxima occurs at $5\pi/2 - 7°$, and the third at $7\pi/2 - 5°$. Since the width of a band corresponds to 360°, the first maximum is displaced by 1/30 of the width of a band, the second by 1/51, and the third by 1/72. As the order of the bands increases the distortion quickly becomes negligible.

tions in a plane perpendicular to its length are concerned.

§ (3) GRATINGS.—If we have a number of similar slits situated side by side the diffraction bands from each of them coincide in direction, and therefore in position if observed in a telescope. If the slits were illuminated by independent sources of light, the observer would see a system of diffraction bands exactly similar to those from a single slit, but more intense on account of the superposition of the systems from the several slits. In a grating, however, all the slits are illuminated by the same source. The diffracted waves emanating from them have therefore a constant phase relationship and so are capable of mutual interference. Since we are now regarding the grating elements as separate sources it is convenient for the time being to assume uniform radiation in all directions. The effects of the actual variation which takes place in accordance with the results of the previous paragraph can be investigated later.

Let the dots, *Fig.* 2, represent the equidistant slits of a grating on which a plane

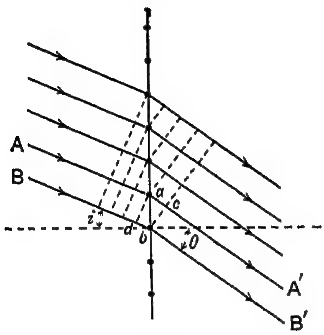

FIG. 2.

wave of perfectly monochromatic light is incident at an inclination i to the normal. In order that we may at this stage avoid the complications introduced by diffraction by a restricted aperture we must regard the grating as extending to infinity in both directions. Clearly any ordinary grating may be regarded as an infinitely long grating viewed through a restricted aperture.

Let Aa and Bb be rays incident on corresponding points of two adjacent slits, while aA′ and bB′ are rays diffracted in the direction θ. The disturbance from a lags behind that from b by a path difference $ac - bd = \Delta(\sin\theta - \sin i)$. In this expression $\Delta = ab =$ the distance between corresponding points of adjacent slits. The path difference between any slit and the rth from it is clearly $r\Delta(\sin\theta - \sin i)$, so that if $\Delta(\sin\theta - \sin i)$ is a whole number of wave-lengths, say $m\lambda$, the path difference between the disturbances from any two slits whatever is also a whole number of wave-lengths and all the disturbances are in the same phase. Hence if these are combined by a telescope, they will reinforce each other and the field will be bright at the position corresponding to this direction.

For directions differing slightly from the values of θ given by the above relation there is a phase difference, $\delta\lambda$, between the disturbances from adjacent slits. It is clear that however small $\delta\lambda$ may be, the resulting illumination due to the whole of the infinitely long grating is zero, because, since the phase step accumulates from one slit to the next, whatever the phase of one slit there can be found another slit for which the phase differs by $\lambda/2$. These two slits nullify each other. Similarly for all other slits. The grating therefore concentrates the light in a series of bright lines of infinitesimal width at infinity, in such directions that

$$\Delta(\sin\theta - \sin i) = m\lambda, \quad . \quad . \quad (2)$$

with complete darkness in the intervening intervals. Those lines for which $m = 1, 2, 3,$ . . . etc., are said to be of the 1st, 2nd, and 3rd, . . . etc., order. Equation (2) is referred to as the grating law. Those lines, of which the position depends on the wave-length, were termed by Fraunhofer "*Spectra of the Second Class.*" They are the true spectra of the grating *qua grating*, and we observe that they are not a diffraction phenomenon at all but are due purely to interference between the radiations from a series of equally spaced similar sources of light. Their position depends simply on the separation, Δ, of the sources, and is unaffected by their dimensions, precisely as in the case of interference fringes produced by, say, Fresnel's Mirrors or Biprism,[1] and it is no more legitimate to attribute them to diffraction than to attribute bi-prism fringes to refraction. The part played by diffraction in the action of the diffraction grating is, as we saw in § (2), the subsidiary one of converting the individual slits into sources of light radiating over a wide angle within which the interference phenomena may take place.

§ (4) EFFECTS OF FINITE APERTURE.—Such a simple instrument as the ideal grating of infinite length is naturally unrealisable. The finite size of any practical grating introduces very profound modifications in the observable phenomena. Nevertheless such modifications cannot properly be classed as grating action because they are precisely those modifications, and nothing more, which any optical system introduces in the image of a point or line source at infinity. The proper way to regard this part

[1] See article on "Interference."

of our subject is to consider the grating alone as supplying a spectrum consisting of infinitely thin lines at infinity, and then to consider the effect of examining these in an optical system of aperture determined by the size of the actual grating, or of the telescope, whichever is least.

If A is the effective aperture measured perpendicular to the axis of the telescope, the image of a true line of light consists (§ (2)) of a series of diffraction bands, the intensity and location of which are given by the formula

$$I \propto A^2 \frac{\sin^2\{(\pi A/\lambda)\sin\phi\}}{\{(\pi A/\lambda)\sin\phi\}^2},$$

where ϕ is measured from the position of the geometrical image. The points of zero illumination occur when $(\pi A/\lambda)\sin\phi = p\pi$, where $p = 1, 2, 3, \ldots$ etc.

The angular semi-width of the central band and the width of the lateral bands in its vicinity is λ/A.

Each spectrum line is therefore represented by a diffraction band of width $2\lambda/A$ flanked by a series of fainter bands of half this width. The maximum intensity in the pth band is $I_0(4/\pi^2) \cdot 1/(2p+1)^2$ where I_0 is the maximum intensity in the central band. These are the so-called secondary maxima. We see that they are in no way uniquely connected with gratings. The same type of central image with the same maxima in attendance is obtained with a prism spectroscope, or, for that matter, with the direct image of the slit, provided the same aperture be used. The only properties of secondary maxima peculiar to gratings become manifest when the number of grating elements is small, and are due to the overlapping of the secondary maxima associated with the primaries of different orders.

A primary occurs, as we saw in the last paragraph, whenever the phase difference between disturbances from corresponding points of adjacent grating elements has the value zero. A secondary minimum occurs whenever the phase difference between opposite edges of the aperture has the value zero, that is to say, when the phase difference between the *first* and *last* of the effective grating elements is zero. Clearly, therefore, if there are n elements, a primary of any order will coincide with the nth secondary minimum associated with the primary of the next order, and *vice versa*.

There are therefore $(n-1)$ minima between the two primaries, and consequently $(n-2)$ secondary maxima. With ordinary gratings the separation of the orders is so large compared with the distance between the secondaries that those associated with one primary are quite outside the influence of those associated with the next. The intensity of the secondaries diminishes so rapidly with p that the great bulk of the space between the spectra is quite dark. In fact the aperture has to be made quite small or a very high magnification has to be used to see any secondary maxima at all. If the total number of grating elements is small, however, the primaries of successive orders may only be separated by a few secondary maxima, and those associated with the different primaries will reinforce each other.

If we remember that there are $(n-2)$ maxima between each primary, and that the latter occupy the width of two of the former, it is easy to see that the pth secondary maximum associated with the primary of the mth order coincides with the $(n-1-p)$th, $(2n-1-p)$th, $(3n-1-p)$th . . . etc. secondaries of the $(m+1)$th, $(m+2)$th, $(m+3)$th . . . etc. orders, and with the $(n+p)$th, $(2n+p)$th, $(3n+p)$th . . . etc. secondaries of the $(m-1)$th, $(m-2)$th, $(m-3)$th . . . etc. orders.

The total intensity of this secondary is therefore

$$\frac{4I_0}{\pi^2}\left\{\frac{1}{(2p+1)^2}+\frac{1}{(2p-2n+1)^2}+\frac{1}{(2p-4n+1)^2}+\frac{1}{(2p-6n+1)^2}+\ldots+\frac{1}{(2p+2n+1)^2}+\frac{1}{(2p+4n+1)^2}+\frac{1}{(2p+6n+1)^2}+\ldots\right\}. \quad (3)$$

From this we can evaluate the intensities of the secondary maxima. As would be expected, except when n is very small, all but the first term in the bracket is negligible for secondaries in the neighbourhood of the mth primary, and all but the second term for those near the $(m+1)$th, and so on. Even for $n=4$ it is only necessary to consider the effect of the two adjacent orders on either side of the order in question.

The most intense secondary is the one nearest the primary. Its maximum intensity relative to that of the primary is about 1/16 for 4 elements, 1/21 for 8, 1/22 for an infinite number of elements. Thus there is little difference between the relative intensities of the strongest secondary whether a grating has an infinite number of elements or only a few. This is sometimes regarded as a surprising result, but when we realise that the secondary maxima are merely the ordinary diffraction bands due to the aperture of the system, we see why they are unaffected by the nature of the grating, except when the successive orders of spectra are so close that the relatively strong secondaries associated with the different images overlap. Moreover, this is a pure superposition effect; if we place a number of equidistant slits at the end of a collimator and adjust the aperture of an observing telescope to such a value that the angular width, λ/A, of the diffraction bands bordering each image is exactly $1/q$th of the angular separation of the images, we obtain precisely the appearance of several orders of spectra produced by a grating of q elements, with the appropriate secondary maxima between, without the presence of any grating whatever.

Expression (3) is symmetrical for values of p on either side of $p=(n-1)/2$, which represents the point half-way between the primaries; the reason of this symmetry is obvious from what has gone before.

§ (5) Vector Method.—Expression (3), obtained by adding the effects of the superposed diffraction bands which border the primaries of different orders, represents by its structure the actual method of formation of the secondary maxima. It is not so convenient for calculation purposes as that which is directly obtained by the vector method, in which the net result of interference and diffraction by the aperture is deduced in one process. We shall briefly outline this method, which is of great utility in many of its applications. Let there be n elements in the grating, and let the amplitude of the disturbance from each element be k. Let the phase difference between the disturbances from corresponding points of adjacent elements be $\delta\lambda$. It is convenient to express this in angular measure ϕ, where $\phi=(2\pi/\lambda)\delta\lambda$. The amplitude of the resultant disturbance is represented by the gap between the extremities of the first and last sides of a vector polygon composed of n sides of length k (on some suitable scale), each inclined to the one preceding it by the angle ϕ. Since the sides and angles are equal, the polygon lies on a circle, of radius such that k is the chord of ϕ. The size of the circle varies with ϕ, but at any stage the gap between the free ends of the first and last sides is

$$k\times\frac{\text{chord } n\phi}{\text{chord } \phi},$$

which is the amplitude of the resultant disturbance. The intensity is proportional to the square of the amplitude and is therefore

$$Bk^2\frac{\text{chord}^2\, n\phi}{\text{chord}^2\, \phi}=Bk^2\frac{\sin^2(n\phi/2)}{\sin^2(\phi/2)},$$

where B is a constant.

In those directions for which ϕ is zero, *i.e.* when the phase step between adjacent elements of the grating is an integral number of wave-lengths, the value of this is n^2Bk^2, which is the intensity at the centre of the principal maxima. Denoting this by I_0 we see that the intensity in intermediate directions is

$$I=I_0\frac{\sin^2(n\phi/2)}{n^2\sin^2(\phi/2)}. \quad . \quad . \quad (4)$$

This is zero when $n\phi=p\pi$, where $p=1, 2, 3, \ldots n-1$.

The $(n-2)$ secondary maxima occur between these minima, where $n\phi=(2p+1)\pi/2$, their intensities being given by

$$I_p=I_0\frac{1}{n^2\sin^2(2p+1)\pi/2n}. \quad . \quad (5)$$

The secondary maxima were termed by Fraunhofer "*Spectra of the Third Class.*"

§ (6) Dispersion and Resolution.—The rate at which θ, in equation (2), varies with wave-length is a measure of the spreading out of the spectrum, and is termed the *dispersion.* By differentiation of equation (2),

$$\frac{d\theta}{d\lambda}=\frac{m}{\Delta\cos\theta}=\frac{\sin\theta-\sin i}{\lambda\cos\theta}, \quad . \quad . \quad . \quad (6)$$

from which we see that for a given angle of incidence the dispersion in the neighbourhood of wave-length λ depends simply on the direction, θ, in which the spectrum is formed. It is independent of the properties of the grating, a large or small grating space Δ being compensated by the higher or lower order of the spectrum formed in the direction required.

It is not the dispersion which is of greatest importance in determining the utility of a spectroscope, but the *resolving power,* that is the power of producing two distinguishable images for two monochromatic radiations of slightly different wave-lengths. This power is usually measured by the ratio $R=\lambda/\delta\lambda$, where $\delta\lambda$ is the smallest difference which can be resolved at wave-length λ.

We saw in § (3) that the grating alone, in the absence of diffraction at the bounding aperture, would give infinitely fine lines. Its resolving power would therefore be infinite, since, however close two lines might be, they would still be perfectly distinct. However, the lines can never be observed except as diffraction bands, and if two of these are too close together they will merge into a single maximum of illumination and will not be seen as separate bands. Following Lord Rayleigh (7), it is always conventionally assumed in calculating the resolving power of optical instruments that two diffraction images will be resolved when the centre of one falls on the first minimum of the other, as shown in *Fig.* 3. The angular

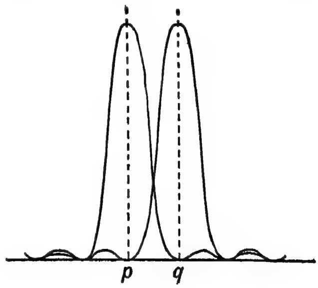

Fig. 3.

value of pq is $\delta\theta$, $=\lambda/A$, A being the effective aperture. The difference in wave-length comprised in this angle is

$$\delta\lambda=\delta\theta\cdot\frac{d\lambda}{d\theta}$$

$$=\frac{\lambda}{A}\cdot\frac{\Delta\cos\theta}{m}. \quad \text{(From 6.)}$$

L, the total length of the grating which is utilised, is equal to $A/\cos\theta$,

$$\therefore \delta\lambda = \frac{\lambda}{L}\cdot\frac{\Delta}{m}.$$

Whence $$R = \frac{\lambda}{\delta\lambda} = m\frac{L}{\Delta},$$

$$= mn. \qquad (7)$$

Thus the resolving power is equal to the product of the total number of grating elements and the order of the spectrum; but while this is a convenient form in which to remember the result, the apparent dependence on n is illusory. In any given direction Δ/m is constant, and R depends simply on the total length, or, more strictly, on A. It is only when varying the number of elements *while keeping the grating space constant* that altering n alters the resolving power, since in this case an increase in n involves an increase in L and *vice versa*, but for a given available aperture the resolving power does not depend on how many or how few grating elements we introduce.

It facilitates the understanding of spectroscopic resolution if we always separate, as in the above treatment, the two factors on which it depends. There is first the resolving power *in angle*, which is purely a function of the aperture of the observing system, the minimum angle for resolution being λ/A (assuming a rectangular aperture). The difference in wave-length corresponding to this angle depends on the dispersion of the spectrum whether produced by interference or prismatic refraction. The usual methods of deducing resolving power tend to conceal that its finiteness is purely a question of aperture, and lead the student to suppose that each type of spectroscope is a law unto itself in the matter of resolving power, which appears to depend on numbers of rulings, or length of prism base, etc., whereas these are merely quantities which happen to be conveniently related to the aperture of the system for formula purposes.

Reverting to the special case of gratings, suppose λ' is the wave-length in the mth order which coincides with λ in the $(m+1)$th order; $\lambda'-\lambda$ is the range of wave-length in the mth order which lies between the mth and $(m+1)$th orders of λ.

$$m\lambda' = (m+1)\lambda,$$

$$\therefore \lambda' - \lambda = \frac{\lambda}{m}.$$

The minimum resolvable difference, $\delta\lambda$, is λ/mn, from which we see that a grating will resolve a difference of wave-length $1/n$th of the range of wave-length comprised within the width of an order.

In practice it is impossible to obtain a line source of light of infinitesimal width. A narrow slit at the focus of a collimating lens is usually employed. The spectral "lines" are in reality images of this slit and have therefore a finite width apart from the broadening due to diffraction. Such lines have to be further apart in order to be resolved. The ratio of the resolving power actually obtained with a given slit width to the theoretical resolving power mn is termed the *Purity* of the spectrum.

§ (7) Overlapping Spectra.—Since the number of elements is without effect on the dispersion in a given direction, the resolving power in a given direction, the width of the spectral lines, or, provided there are more than about a dozen elements, the relative intensities of the secondary maxima, it may not be obvious what advantage accrues from using a large number. There are several advantages. We saw earlier that in order to have light in oblique directions the width of each elementary slit must be small. If we only had a few of such slits the grating would be practically an opaque screen. For the sake of brightness, therefore, it is desirable to put as many slits into the available space as possible.

There is another important consideration, however, due to the overlapping of spectra of different orders. From the grating law the mth order spectrum of wave-length λ is formed in a direction such that

$$\Delta(\sin\theta - \sin i) = m\lambda.$$

In general, therefore, if $m_1\lambda_1 = m_2\lambda_2$, the wave-length λ_2 in the spectrum of m_2th order will coincide with λ_1 in the m_1th order. Thus the blue end of the second order spectrum ($\lambda = 0{\cdot}4\mu$) will overlap the red end ($\lambda = 0{\cdot}8\mu$) of the first order. Overlapping becomes progressively more serious in higher orders. If λ_1 and λ_2 are the extreme wave-lengths at either end of the spectrum to which the receiving apparatus (eye, photographic plate, or whatever it may be) is sensitive, a wave-length λ in the mth order will be overlapped by λ_1 in the m_1th order and λ_2 in the m_2th order, where $m_1\lambda_1 = m_2\lambda_2 = m\lambda$. All orders between m_1 and m_2 will clearly be represented at the same place by wave-lengths between λ_1 and λ_2, so that all orders from m_1 to m_2 inclusive, *i.e.* $m_2 - m_1 + 1$ orders, overlap at this point. Since

$$m_2 - m_1 + 1 = \frac{m\lambda}{\lambda_1\lambda_2}(\lambda_2 - \lambda_1) + 1, \qquad (8)$$

we see the importance of keeping m as small as possible if we wish to avoid confusion with polychromatic spectra. To reduce the order of the spectrum found in a given direction we must reduce the grating space Δ, that is, we must increase the number of elements in a given length of grating. Thus, although the resolving power does not depend on n, we obtain it in spectra of lower order, and thereby minimise the difficulties of overlapping, if we make n large.

§ (8) Distribution of Light in Spectra: Effects of Groove Form.—In what has gone before, we have assumed for convenience

that each element of the grating radiates uniformly in all directions. On this basis we found that the maximum intensities of the spectrum lines of all orders were equal, and that the secondary maxima had certain intensities relative to these. Since both primary and secondary maxima are extremely narrow, the eye does not appreciate their intrinsic brightness (light per unit area) but integrates this over the whole width of the lines and appreciates their total candle power;[1] consequently the relative apparent brightness of primary and secondary maxima is the ratio of the area of the intensity curves and not of their maximum ordinates. If we introduce the factor 2, the relative width of a primary and secondary band, and assume the primaries to be twice as bright, relative to the secondaries, as the ratio of the maximum ordinates obtained in preceding paragraphs, we shall obtain a fair approximation to the truth.

This phenomenon accounts for the apparent increase in the relative brightness of the secondary maxima when the aperture is reduced. In such circumstances the width of the maxima may increase until they occupy quite appreciable areas. The eye then measures their intrinsic brightness, and the secondaries seem twice as bright relatively to the primaries as when they are narrow lines. The effect of contrast also helps to subdue the secondaries when they are close to the primaries. What we have just said may explain the common conception that increasing the number of grating elements reduces the intensity of the secondary maxima. Such conclusions are usually drawn from experiments in which the aperture of a grating is varied. As we saw earlier, the relative maximum intensities are independent of the number of elements except when this is reduced to less than 20, and even then the difference is trifling. All the phenomena can be observed, as was pointed out in § (4), without any grating at all.

As regards the relative intensities of lines in different directions, these are clearly proportional to the ordinates of the intensity curve for the diffraction by the individual slits of the grating (see § (2)). In the case of the simple grating which we have so far considered, consisting of very narrow slits in an opaque screen, the central image would be of maximum brightness, while the spectra on either side would diminish symmetrically in brightness as the order increased. In practice, however, such a simple grating is not obtainable. Gratings are usually produced by ruling fine grooves on glass or metal with a diamond point. The technique of their manufacture is dealt with in another article,[2] from which the reader will find that the grooves are usually of V shape, and, for the best results, are cut sufficiently deep to leave none of the original surface remaining. The ruled surface is in fact a ploughed field in miniature. When the ruling is successful the sides of the groove are reasonably smooth, and act, in the case of metal gratings, as reflecting surfaces. Considering one side of these grooves the incident light would be reflected, in the absence of diffraction, in a certain direction in accordance with the ordinary law of reflection. As in the case of a simple slit, the diffraction spectra of the First Class are symmetrical about the direction which the rays would take in the absence of diffraction. If the ruling is narrow the central band occupies a wide angle, but its centre of symmetry and of brightness is in the direction of geometrical reflection. Similar considerations apply to the other sides of the grooves, the direction of maximum intensity being, of course, quite different for these. Each ruling therefore provides diffracted light strongly concentrated in two directions, and spectra lying near either of these directions will be relatively strong. This property is utilised to rule gratings which will concentrate the light in the spectrum of a particular order. The angle which a side of the groove must make with the plane of the grating in order that the central diffraction band from that side will lie in the same direction as the required spectrum is calculated, and the ruling diamond is set to give a groove of this form. An important experimental investigation on the effect of groove form on the intensity of different orders has been made by Trowbridge and Wood, while various writers have discussed the subject theoretically (References 10, 11, 12, 13, and others).

§ (9) Absent Spectra.—If the ruling is of appreciable width, the central diffraction band does not extend over the whole angular field, and first class minima will occur in certain directions. The light from each of the rulings is zero in those directions; consequently their joint action is zero, and any spectra which would otherwise be formed in such directions are absent. It is easy to deduce which spectra will be absent when assumptions are made as to the type of ruling and the method of using the grating, but such calculations lose in practical value from the difficulty of predicting or determining the precise form of a ruling. In general the orders of absent spectra are multiples of the first absent order. Thus, if the 2nd order is absent, the 4th, 6th, etc., are also absent; if the 3rd is absent, so also are the 6th, 9th, etc.; if the 4th is the first that is absent, then the 8th, 12th, etc., will be absent. It does not follow that the same orders are absent on both sides of the central image, since the centre of symmetry of the first class system does

[1] See article on "The Eye."
[2] "Diffraction Gratings, The Manufacture and Testing of."

not usually coincide with this in the case of a ruled grating. Not only so, but the spectra on opposite sides of the central image may be mainly due to light of the first class systems diffracted by the different sides of the groove, and are really due to different grating elements altogether, although the grating space is the same for both sets. With this brief notice the subject of absent spectra must be left. The reader desirous of further information must consult the references (2 and 3) in which the simple case of a grating consisting of transparent slits in an opaque screen, used at normal incidence, is treated at length.

II. Types of Grating

§ (10) Plane Grating.—This, the simplest type of optical grating, is usually produced by ruling parallel lines on optically flat surfaces by means of an accurate dividing engine.[1]

Two forms require mention, namely *transmission gratings*, in which the rulings are on glass or other transparent material, and *reflection gratings*, in which the rulings are on brightly polished metal. Transmission gratings are much more difficult to rule than reflecting gratings because of the hardness of the glass and the liability to change of form, if not complete breakdown, of the ruling point. For this reason reflecting gratings are almost invariably used for accurate work. On the other hand, small transmission gratings, suitable for the use of students, can be made very cheaply by taking a cast in celluloid of a good grating and mounting this on a glass plate. Such film replicas are sometimes of excellent quality. Photographic processes have also been used with some success. For accurate work, however, it is necessary to use a machine-ruled grating, as slight unevenness in shrinkage of the films on drying renders replicas of little use for research purposes.

A description of the various methods in which such gratings may be used is given in another article,[2] and need not be described here.

§ (11) Concave Grating.—Rowland discovered that if the grating were ruled on a concave spherical surface instead of a plane it produced focussed images without the use of a lens. This is not due to any new property acquired by the rulings but simply to the image-forming properties of a concave mirror superposed on the ordinary grating action.

The mirror causes a beam of light, diverging from the slit, to converge towards a real image in accordance with the ordinary laws of reflection. The effect of the grating is to deviate the rays of the convergent beam into a series of lateral spectra on either side of the geometrical image in accordance with the principles we have already discussed. It simplifies the conception of the concave grating if this is kept quite clearly in mind; the grating action is responsible for the presence of light in the directions given by the grating law, but the curvature of the wave front which produces the focussed images in these directions is due to the focal properties of the mirror.

Except for objects on the axis, a concave mirror produces astigmatic images. A point source so situated that the light is incident obliquely on the mirror gives rise to two focal lines respectively perpendicular and parallel to the plane of incidence. If instead of a point source we have a slit perpendicular to the plane of incidence, an image of the slit, drawn out in the direction of its length, *but not broadened*, will be formed at the first of these focal lines. It is this astigmatic image with which we are concerned, since it is the nearest approach to an "image" of a slit which the mirror will give. If S, *Fig.* 4, is the slit

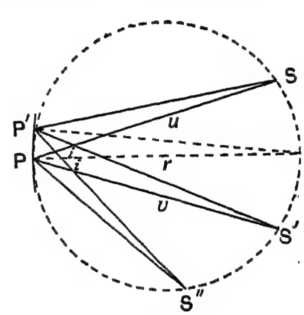

Fig. 4.

situated at a distance u from a concave mirror of radius r, the image is formed in a direction equally inclined to the normal and at a distance v in accordance with the ordinary law for oblique reflection by such mirrors, viz.

$$v=\frac{ur\cos i}{2u-r\cos i}.$$

Wherever the object may be situated, an image will be formed in the position given by this law. The quality of the image is not, however, equally good for all positions of S. Like all optical instruments a mirror suffers from spherical aberration. In the case of a spherical surface this aberration is least, being practically absent, if the object and image are equally distant from the mirror. In this case $u=v=r\cos i$, that is, the object (and also the image) is situated on the circumference of a circle with PC, the radius of the mirror, as diameter. We may term this the *focal circle*;

[1] See article on "Diffraction Gratings, The Manufacture and Testing of."
[2] "Wave-lengths, Measurement of."

the slit must be situated on this circle if the image is to be free from spherical aberration.

Let us now consider the effect of the grating action on the rays converging to S′. Part of the light will be thrown into a series of lateral spectra at inclinations, θ, to the normal CP such that $\Delta(\sin\theta - \sin i) = m\lambda$ in accordance with the usual grating law. Since S, C, P, and any point P′ on the grating are concyclic,[1] $S\hat{P}'C = S\hat{P}C$, that is to say, the angle of incidence is constant over the grating. All rays in the beam are therefore deviated to the same extent, so that the convergence in the lateral spectra is the same as in the central beam. Thus if S″ is one of the spectra,

$$P\hat{S}''P' = P\hat{S}'P',$$

i.e.
$$\frac{PP'\cos\theta}{PS''} = \frac{PP'\cos i}{PS'},$$

or
$$PS'' = v\frac{\cos\theta}{\cos i} = r\cos\theta.$$

Hence if the slit is situated on the focal circle not only the central image but also the spectral images are situated on this circle.

In the general case in which S is not situated on the focal circle, the position of the spectral images is still obtained to a close approximation by regarding the central beam as deviated without change of convergence, so that if v is the distance of the central image,

$$PS'' = v\frac{\cos\theta}{\cos i},$$

$$PS' = \frac{ur\cos\theta}{2u - r\cos i} \quad . \quad . \quad . \quad (9)$$

This, however, is not quite accurate, because in the general case the angle of incidence on the grating, and consequently the deviation of the rays by the grating action, varies across the surface. The convergence of the spectral beams is therefore not exactly equal to that of the central beam, although each ray is simply deviated in accordance with the relation $(\sin\theta - \sin i) =$ constant, and the points of convergence such as S″ are nearer or further from the grating than indicated by (9). The correct formula[2] is more readily obtained on somewhat different lines than those followed above, which have been adopted in order to show that the focal effect is purely the ordinary property of the concave mirror, and that the effect of the grating, whether plane or concave, is merely to deviate the light into lateral spectra in accordance with the grating law.

The error of formula (9) is very slight in any case of practical importance. Since the grating merely deviates the rays, the aberration which characterises the central image if the slit is far from the focal circle also characterises the spectral images, so it is necessary for good definition to keep to the concyclic arrangement.

True focal effects of gratings, which do not depend on mirror action, may be encountered if the grating space is not constant but varies according to certain laws. These effects are discussed in the article on the "Manufacture and Testing of Diffraction Gratings" and need not be referred to further here. In any case they are freak effects and cannot be produced at will on any type of ruling engine at present in use.

Discussions of the aberrations of concave gratings will be found in references 26, 27, 28 and others.

In Rowland's method of mounting the grating the slit is placed at such a point on the circumference of the circle that the spectrum is formed at C, *i.e.* $\theta = 0$. This arrangement gives a normal spectrum, *i.e.* a spectrum in which equal distances on the photographic plate (which is bent to be tangential to the focal circle) represent equal increments of wavelength. We saw earlier (§ 7) that the dispersion of a grating, $d\theta/d\lambda = m/\Delta\cos\theta$. The rate of variation of dispersion from one part of the spectrum to another is

$$\frac{d}{d\theta}\left(\frac{d\theta}{d\lambda}\right) = \frac{-m\sin\theta}{\Delta\cos^2\theta},$$

and is zero if $\theta = 0$.

In the apparatus used by Rowland the grating and photographic plate are mounted opposite each other at the extremities of a rigid beam GP, *Fig.* 5, P being at the centre of curvature of the grating. The two ends of the beam can be moved along rails, *S* A and *S* B at right angles to each other. The slit is mounted at *S*. It is obvious that whatever position GP occupies *S* is on the semicircle with GP as diameter. The instrument when once adjusted is therefore always in focus. All that is required is to move the bar GP until the required spectrum occupies the plate. Full details of the use of Rowland's mounting are given in Kayser's *Handbuch der Spectro-*

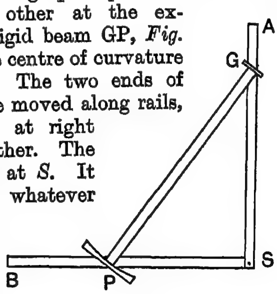

FIG. 5

[1] The diameter of the grating is never such a large fraction of its radius of curvature that the distance of any point on it from the focal circle is appreciable.

[2] This formula is

$$PS'' = \frac{ur\cos^2\theta}{ur(\cos i + \cos\theta) - r\cos^2 i}.$$

The condition for the formation of an optical image is that terms involving the square of the aperture should vanish in the expression for the retardation of rays from different parts of the aperture. The above formula follows at once in the case of a mirror if θ is different from i. When $\theta = i$, that is for the ordinary catoptric image, it reduces to the usual formula connecting u and v.

scopie, vol. i. A defect of Rowland's mounting is that it takes up very considerable space. An arrangement in which the plane of the apparatus is vertical, so that all except the slit and camera are contained in a pit beneath the floor, has been described by A. S. King (20). Eagle (21) has described a most useful mounting for a concave grating in which the centre of the plate coincides (virtually) with the slit. Full details and a critical comparison of its advantages and disadvantages as compared with Rowland's mounting are contained in the paper. Its two main advantages are that higher orders can be used and that the astigmatism of the spectrum is very much less. The outstanding defect of concave gratings is the astigmatism of the images, particularly in the higher orders, for although this does not affect the sharpness of the definition the brightness is greatly impaired, which is a serious matter in photographing faint spectra. With Eagle's mounting much shorter exposures are required than with Rowland's arrangement.

§ (12) THE ECHELETTE.—For work in the infra-red region R. W. Wood (10) constructed gratings of wide spacing, $\Delta = \cdot 0123$ mm. These were ruled on a gilt copper plate, using the 120° angle of a carborundum crystal. In the majority of cases this was mounted to cut grooves one face of which made an angle of about 20° with the original surface. With normal incidence these facets give a concentration of light with the centre at 40° from the normal. With visible light such gratings throw the energy into a small group of spectra near the 15th order on one side of the normal. They show no central image nor any spectra to the other side. According to Wood,[1] "The gratings behave, with infra-red radiation of wave-length above, say, 3μ, as almost ideally perfect gratings; that is, they give spectra similar to what we should have with an ordinary grating which threw practically all of the light into one or two orders on one side of the central image." For this wave-length, 3μ, the brightest spectrum will be of the 2nd or 3rd order. The useful spectra for wave-lengths in this neighbourhood are not therefore of high order; so that the resolving power is much less than for visible light. This is no actual loss, however, because the relatively large width of the radiometric receiver makes it impossible to utilise such high resolving powers as in the visible and photographable regions of the spectrum.

Wood has termed these gratings "*Echelettes*" because, in their relatively large phase-step, about 15λ for visible light, they lie between the ordinary grating and the Echelon, which we are now about to describe.

§ (13) THE ECHELON.—This instrument, which was devised by Professor Michelson (29), is as unlike the traditional grating as possible. It consists of a number of glass plates, of precisely the same thickness and plane parallel to a high degree, arranged like a flight of steps, or *in echelon*, whence the name. The width of the steps is made as accurately equal as possible. If the light is incident normally on the broadest plate, *Fig.* 6, some of it emerges from each of the steps which act as rectangular apertures and diffract the light over a very small angle. The light emerging from any step has traversed one plate more or less than from the next, so there is a constant phase-step depending on the thickness and refractive index of the plates. Let $a\,e$ and $c\,e'$ be rays diffracted in a direction θ from the outer edges of two adjacent steps. Let $c\,f$ and $b\,g$ be perpendicular to $a\,e$. The difference in optical path is obviously the difference between $b\,c$ in glass and $a\,f$ in air. Let t be the thickness and β the width of a step, then

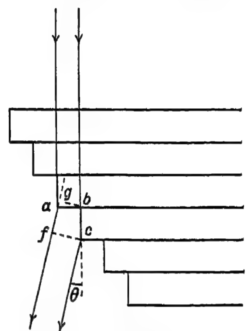

FIG. 6.

$$af = gf - ga = t\cos\theta - \beta\sin\theta = t - \beta\theta,$$

since θ is necessarily very small.

Thus the phase-step is

$$\mu t - (t - \beta\theta) = (\mu - 1)t + \beta\theta.$$

A spectrum line of the mth order will therefore be formed when

$$(\mu - 1)t + \beta\theta = m\lambda. \qquad (10)$$

Since θ is very small m is approximately $(\mu-1)t/\lambda$. For a plate of thickness 2 cm. $(\mu - 1)\,t$ is about 20,000 wave-lengths for green light, and the order of the spectrum is 20,000 or so.

The dispersion,

$$\frac{d\theta}{d\lambda} = \left(m - t\frac{d\mu}{d\lambda}\right)\Big/\beta,$$

$$= \left\{\frac{(\mu-1)t}{\lambda} - t\frac{d\mu}{d\lambda}\right\}\Big/\beta,$$

$$= \frac{bt}{\lambda\beta},$$

where $$b = \left\{(\mu - 1) - \lambda\frac{d\mu}{d\lambda}\right\}$$

and is purely a property of the glass. The total aperture is $n\beta$ where n is the number of plates. The minimum angle resolvable is therefore $\lambda/n\beta$.

[1] *Physical Optics*, 1911, p. 229.

The minimum wave-length difference resolvable is

$$\delta\lambda = \frac{\lambda}{n\beta} \cdot \frac{d\lambda}{d\theta} = \frac{\lambda^2}{nbt}.$$

Hence the resolving power, R,

$$= \frac{\lambda}{\delta\lambda} = \frac{nbt}{\lambda}. \quad . \quad . \quad . \quad . \quad (11)$$

But $\qquad m = (\mu - 1)\frac{t}{\lambda},$

$$\therefore R = mn\frac{\{\mu - 1 - \lambda(d\mu/d\lambda)\}}{(\mu - 1)}.$$

Thus the effect of the dispersion of the glass is to increase the resolving power (since $d\mu/d\lambda$ is $-ve$) from that given by the ordinary grating formula $R = mn$. In the case of a particular echelon described by Baly,[1] $\mu - 1$, in the neighbourhood of the sodium line, was 0·5746, while $\mu - 1 - \lambda(d\mu/d\lambda)$ was 0·6165.

For an echelon of 20 plates 2 cm. thick, the resolving power is a little over 400,000 for visible light. Such a grating would therefore resolve lines differing in wave-length by only one four-hundredth of the difference of the sodium lines.

This large resolving power, obtained with a relatively small aperture,[2] may appear to contradict the conclusion of §§ (6) and (7), that the resolving power for a given aperture was independent of the grating space. We were there concerned with ordinary gratings in which the phase retardation between adjacent elements depends simply on the obliquity of the light.

We must not confuse the width of the echelon step with the grating space of an ordinary grating. The width of the step corresponds to the width of one of the elementary apertures of the grating and determines the distribution of light in the field in accordance with § (2), but the analogue in the case of the echelon to the grating space of the ordinary grating is the separation of the apertures *parallel to the length of the echelon*, which introduces the enormous phase-step $(\mu - 1)t$ (approx.) between rays from corresponding points of the different apertures. This results in a dispersion very much greater than anything obtainable with an ordinary grating, so that for a given total aperture, and therefore given resolving power *in angle*, the spectral resolution is greatly increased. An ordinary grating of 20,000 lines per inch would require to be ten inches long to give the same spectral resolution in the second order as we obtain with an echelon of under an inch.

The difficulties of ruling such a grating are very considerable, and very few of this length have been produced at the present time, whereas the echelon we have mentioned is by no means an extreme case.

The angular field within which all the phenomena are compressed is the angular width of the central diffraction band from a single aperture. This is $2\sin^{-1}(\lambda/\beta) = 2\lambda/\beta$.

[1] "Spectroscopy," chapter vi.

[2] β is usually about 1 mm., so $n\beta$ is 2 cm. in the case we are discussing.

The angular separation of successive orders will be given by $d\theta/dm$ since m is large.

From (10) $\qquad \dfrac{d\theta}{dm} = \dfrac{\lambda}{\beta}.$

Thus the distance between two orders is half the width of the total region in which light is available. There will thus in general be two orders visible, of different intensities unless they happen to be symmetrical with respect to the centre of the diffraction maximum. By slightly altering the angle of incidence one of the orders may be brought to the centre, when it will be of maximum brightness; the spectra of adjacent order on either side then coincide with the diffraction minima, and are invisible or faint. These two positions are termed positions of single or double order.

Though not more than two orders of *one wave-length* are in the field at once, if another wave-length is present this will appear in some other order. The mth order of wave-length λ will coincide with the $(m \pm p)$th order of wave-length $\lambda m/(m \pm p)$, where p is any integer 1, 2, 3, . . ., etc. Since m is large, a very slight range of wave-length indeed will give rise to so many overlapping spectra of different orders that complete confusion will occur. With the sodium lines, for instance, if D_1 is in the 20,000th order D_2 may be in the 20,020th. The lines may overlap or lie between one another, or, in fact, have any relative position whatever, depending on the exact thickness of the plate and the exact angle of incidence.

Thus very homogeneous radiation must be employed or the appearances presented are unintelligible. In practice, therefore, the light is always analysed by means of an auxiliary spectroscope, usually a prismatic instrument, though sometimes a grating is employed, and only that radiation is allowed to enter the echelon which it is desired to examine.

Another drawback to the instrument is this. The closest doublet which a grating will resolve is, as we saw in § (6), separated by $1/n$th of the separation of adjacent orders. Since the useful field is the space between two orders we can only examine a range of wave-length of about n times the resolvable minimum. Since, in the case of the echelon, n is so small, this limitation is serious. It is clearly advantageous for a given resolving power to use a large number of thin plates rather than a smaller number of thick ones. However, owing to practical difficulties of construction and to loss of light by reflection at interfaces, it is not feasible to use a very large number of plates. There is little gain in going beyond 30, while most echelons have under 20.[3]

[3] Messrs. Adam Hilger, as the result of improved methods of construction, have recently put echelons of fifty-six plates on the market.

Since a broadened line, or the components of a multiple line may extend over the whole width of the first class maximum, the apparent brightness will be misleading. Correction must be made for the distribution of intensity within the field. The formula of § (2) reduces in this case to

$$I = I_0 \frac{\sin^2 (\pi\beta/\lambda)\theta}{\{\pi(\beta/\lambda)\theta\}^2},$$

where I_0 is the intensity at the centre of the diffraction band. An experimental investigation of the agreement of practical results with this formula has been made by Burger and van Cittert (Ref. 33), who also pointed out that owing to that side of a spectral maximum which is further from the centre of the field being more weakened than the other, the position of the maximum is appreciably displaced towards the centre of the field. They found errors amounting in some cases to 0·5 per cent of the width of an order. This displacement appears to have been generally overlooked by users of the instrument. It is analogous to the displacement of the secondary maxima on account of their rapidly diminishing intensity, to which attention was called in § (2).

When all its difficulties have been taken into account, however, the Echelon remains a beautiful and powerful weapon of physical research. It is easy to use, requiring little adjustment, and as the pioneer among spectroscopes of extreme resolving power, has been responsible for the opening up of important fields of investigation previously inaccessible. The actual use of the instrument is dealt with in another article.[1]

§ (14) Defective Gratings.—We have hitherto assumed ideal gratings and investigated their properties. In practice gratings may suffer from various defects. Principal among these are departures from exact equality of the grating space over the whole grating. The effects of such errors are dealt with in another article,[2] and we need only mention here that any periodic variation in the ruling virtually constitutes a second grating of which the grating space is equal to the periodicity. Thus a spectrum line is flanked with a series of faint companions which are simply lateral spectra produced by the second grating. Such companion lines are termed *ghosts*. Variations in optical thickness of the plates of an echelon may also give rise to ghosts. Aberrations of another character may also be found in echelons due to the clamping of the plates (30). Stansfield and Walmsley (32) described a case in which an asymmetrical distribution of light in the secondary maxima resulted from this cause.

A useful treatment of imperfect gratings has been given by Sparrow (35).

§ (15) Conclusion.—In an article of this length it has been quite impossible to deal exhaustively with the subject of diffraction gratings, either in the theoretical or practical aspects. It has not been possible to deal with the practical methods of mounting employed, and for such information the reader is referred to Kayser's *Handbuch der Spectroscopie*, vol. i., to Baly's *Spectroscopy*, and to several of the papers mentioned in the bibliography. On the theoretical side, space has forbidden reference to the state of polarisation of the diffracted light from the grating elements (37 to 43). To repair these omissions and supplement the information contained in the article, a bibliography is appended which, though far from complete, will be found useful by those desirous of pursuing the subject further.

DIVIDED CIRCLES

I. Historical

§ (1) General.—The graduated or divided circle is the basis of all instruments for measuring angles. The earlier circles were divided by hand, and in order to get any degree of accuracy they had to be of large diameter. During the last 150 years there has been a great development in the art, and it is now possible to obtain circles of a foot or 18 in. diameter in which no division has a greater error than 2 seconds of arc, while the probable error of any division is less than half a second. The first notable example of a divided circle was a mural circle of 8 ft. radius divided by George Graham for Greenwich Observatory in 1725. Two circles of 96·85 and 95·8 in. were marked off by beam compasses, the inner, or working circle being graduated to degrees and twelfths of a

degree. The chord having the same length as the radius gave the 60° point, with the points 0° and 60° as centres, and a distance on the beam compass very nearly equal to the chord of 30°; two light dots were made on the arc, and the distance between these was bisected by hand, using a magnifying glass, thus giving the 30° mark. The chord of 30° set off from the 60° point gave the 90° point. Each 30° arc was then bisected in a similar manner, and the resulting divisions trisected, thus dividing the quadrant into 5° spaces. These were then divided into 5 parts, giving single degrees, and the twelfths of a degree were found by further bisection and trisection. The outer circle was divided into 3 parts as before, and each of these into 512 parts by continued bisection. This method was considered more accurate than the first, and the resulting divisions were used as a check on the inner circle.

John Bird[1] in 1767 divided a similar circle. He first prepared a lineal scale of equal parts, and having obtained the 60° point by laying off the chord equal to the radius, 30° and 90° were obtained by laying off the chord of 30° from the 60° point, the length of this chord being obtained by calculation and measurement from his scale. From 60° the chord of 15° was laid off giving 75°, and from this the chord of 10° 20′ gave 85° 20′, which was checked by the chord of 4° 40′ from 90°; $85° 20' = 5' \times 2^{10}$, hence the further subdivision of this can be found by continued bisection. The remainder of the quadrant beyond 85° 20′ contains 56 divisions of 5′ each; the chord corresponding to 64 such divisions was laid off, and subdivided by continued bisection as before.

§ (2) Troughton.—Edward Troughton adopted another method for dividing (described in *Phil. Trans.*, 1809, as applied to a 4 ft. circle). The circle to be divided was first accurately turned on its inner and outer edges as well as on its face. A cylindrical roller was then made of such diameter that it revolved 16 times on its axis when rolled once round the outer edge of the circle. The roller was then divided as accurately as possible into 16 equal parts by lines parallel to its axis, and was mounted on a framework which could slide round the circle, the roller revolving by means of frictional resistance on the outer edge of the circle. Two microscopes attached to the frame served to observe the circle and the divisions on the roller respectively. By means of these microscopes the points of contact of the marks on the roller with the circle were observed and marked on the circle by dots; the circle was thus divided into 256 nearly equal parts. Two microscopes A and B were used to obtain the errors of these dots; they were placed so as to bisect dots 0 and 128 respectively; the circle was then turned so that A bisected 128. B should then bisect dot 0; if it did not, then half the movement of the cross-hairs necessary to bisect the dot gave the error of the dot, and this was measured on the micrometer screw. Microscope A was then again set over dot 0 and B over dot 64; the circle was then turned till A bisected dot 64. B should then bisect dot 128 ± the error already found for dot 128; half the residual error gave the error of dot 64. Similarly the error of dot 192 was found. By continued bisection in the same manner the errors of all the other dots were found. The final graduations were required at 5′ intervals, and to obtain these a sector with about four times the radius of the roller was mounted concentrically on the roller, so that it normally turned with the roller, but could be adjusted independently. The sector was divided as accurately as possible into divisions such that it would revolve one division on its axis for each 5′ which the frame was moved round the circle, $16\frac{7}{8}$ of such divisions corresponding to $\frac{1}{16}$ of the circumference of the sector, *i.e.* to the amount the sector would revolve as the roller moved between two consecutive dots on the circle. Sixteen such divisions were marked on the sector, together with an extra division at each end which was divided into $\frac{1}{8}$ths. Two microscopes H and K were carried by the frame, H reading on the circle and K on the sector; the frame was then adjusted so that H read dot 0, and the sector adjusted with its zero under K. The zero mark of the circle was then cut under H by a dividing knife, and the frame moved till the sector had revolved one division under K; the next line was then cut under H, and so on, until 16 divisions had been cut. Before cutting the 17th H was adjusted over dot 1, due allowance being made for its error as already determined, and the sector was set to division $-\frac{1}{8}$ under K; the graduations between dots 1 and 2 were then cut on the circle. In this way the errors of the dividing were controlled by the dots and prevented from accumulating.

§ (3) Copying.—When a circle has once been accurately divided it can be copied by placing the master circle and the blank concentrically on a table, and laying a straight-edge to each division of the master circle in turn, and cutting the division on the blank with a dividing knife.

§ (4) Dividing Engines.—Modern circles are invariably machine divided. The first notable dividing engine was made by Jesse Ramsden,[2] and an account of this machine was published by the Commissioners for Longitude

[1] John Bird, *The Method of Dividing Astronomical Instruments*. London, 1768.

[2] J. Ramsden, *Description of an Engine for Dividing Mathematical Instruments*. London, 1777.

in 1777. This and all later engines are made on the same general lines; the work to be divided is mounted concentrically on a circular plate which revolves on a vertical axis. This plate has teeth cut on its edge and is rotated by a worm; the worm is moved by a ratchet driven by a band wound round a cylinder, stops being provided to ensure the worm being turned the correct amount. In the earlier machines the band was pulled down by a treadle, the other end of the band being attached to a weight. On pressing down the treadle the plate was rotated by a definite amount and the divisions marked on the circle by hand. On releasing the treadle the ratchet allowed the weight to descend without rotating the worm. In later machines the cuts are made automatically, thus enabling the engine to be power driven.

In 1793 Edward Troughton completed a somewhat similar machine. Others have been made by Andrew Ross,[1] William Simms,[2] and others in this country and abroad.

II. Modern Dividing Engines

§ (5) Description.—One of the best and most modern of these was completed by George Watts in 1905. This machine and the methods used in constructing it will be described below.

It will be seen from what has been said that the principal aim is to construct an accurate worm and worm-wheel so that one revolution of the worm shall revolve the worm-wheel through a predetermined angle, no more, no less, with the smallest possible amount of deviation, and this must be true in any relative position of the worm and wheel. The only certain method of producing such a worm-wheel is to cut the teeth one by one from an accurately divided circle, and unless such a circle is available the first step is to divide one. In order to carry this out the following precautions were taken. The work of dividing and testing was carried out in a specially constructed room where the temperature could be maintained constant within one degree Fahr. The circle A (*Fig.* 1) to be graduated revolved smoothly upon an accurately machined axis B without the suspicion of any journal shake. The bearings of this axis were carried by a very rigid frame C, which was so designed as to furnish also a rigid circular table D, somewhat lower in height and a little larger in diameter than the circle to be graduated. This circular table was for the purpose of mounting micrometer microscopes at different positions round the circle. These microscopes should be of sufficient power to detect clearly an amount equal, in angular value, to the tenth part of a second on the circle. Some idea of the power necessary can be obtained from the fact that in

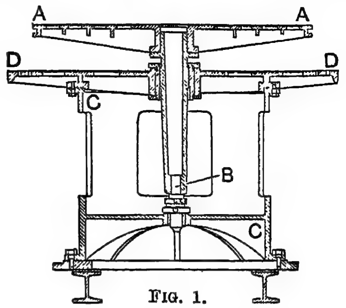

Fig. 1.

linear measure this amounts at 4 ft. diameter to about $\frac{1}{80000}$ inch. The design for the mounts of these microscopes must be very carefully considered from the point of view of temperature changes, as a cold draught striking one side of such a mount may produce errors which are by no means negligible.

Another essential piece of apparatus is a mechanically mounted steel or diamond cutter for cutting the actual divisions to be read by the micrometers. This cutter must be so mounted and swung that it can be lowered into contact with the circle, moved across it, and again raised mechanically without any direct impetus or control of the hand. Obviously also the moving parts of this mechanism must be free from the least shake, while at the same time perfectly free to move or swing with the least possible friction.

§ (6) Dividing the Master Circle.—The cutter mechanism was securely bolted down to the table D, and the first line ruled (0°). Then by actual measurements the position of the 180° line was determined, and this position brought as nearly as possible under the cutter. A micrometer microscope A was then mounted and adjusted exactly over the 0° line, *i.e.* directly opposite the cutter, and 180° line ruled; the circle was then revolved as nearly as possible through 90°, and microscopes B and C mounted over the marks already cut; they will thus be about 90° from A. Microscope B was then adjusted exactly over the zero mark and C over the 180° mark, and the circle turned till the zero mark was exactly under C; if the 180° mark had now appeared exactly under B, both marks and microscopes would have been exactly 180° apart, but if not, the error was shared equally by the positions of microscope B and line 180°. The total amount of this error was read on the micrometer, and the zero line again placed under the A microscope, but with its error allowed for on the A micrometer, and a fresh 180° line was ruled. This was again tested,

[1] *Trans. Soc. Arts*, 1830-31.
[2] *Memoirs of the Astronomical Society*, 1843.

and the process repeated until the two lines 0° and 180° had no appreciable error; the micrometer reading at A corresponding to the point exactly opposite the cutter was then also known. The zero line was then adjusted under B and the 90° line cut; 0° was then placed under C, when 90° should appear under A. As before, the error was read off, half this error being in the position of the 90° line, and half in the positions of B and C. A correct 90° line could therefore be marked, and the 270° line followed. By similar methods, and using more microscopes, accurate lines were cut first every 45° and then every 22½°. This gave 16 fundamental lines. By the same methods of trial and error microscopes D and E were placed 120° from A and the 120° and 240° lines cut. By placing each of the original 16 lines under each of the three microscopes A, D, and E in turn, three times 16, or 48, lines were obtained. On the same principle five microscopes were placed at equal distances round the circle, and more lines cut, thus giving 240 lines in all, or one every 1½°. So far the work was straightforward, if tedious; but these divisions had now to be divided into 18ths in order to obtain 5′ spaces.

For this purpose micrometers were mounted at 0°, 70° 30′, and 141°, and the two spaces included were trisected, *i.e.* intermediate micrometers were mounted at 23° 30′, 47°, 94°, and 117° 30′. By this means 720 divisions were obtained, or one every ½°. Three micrometers were then mounted at 0°, 60° 30′, and 121°, and the two spaces subdivided into three by micrometers mounted at 20° 10′, 40° 20′, 80° 40′, and 100° 50′. By this means 2160 divisions were obtained, or one every 10 minutes. Finally four micrometers were mounted at 0°, 40° 10′, 80° 20′, and 120° 30′, and the three spaces bisected by micrometers at 20° 5′, 60° 15′, and 100° 25′. This gave the required 4320 divisions, or one every 5 minutes.

§ (7) Testing. — The circle being thus divided the same geometric process was employed to ascertain the individual errors of the graduations, which were tabulated. An entirely fresh set of graduations was then cut, using a slightly different diameter of circle, the errors being eliminated, as far as possible, by making the appropriate allowances on the micrometers. The errors of this new circle were again determined and tabulated, and yet another circle divided. It was found that the individual errors were considerably diminished with each cycle of operations, and after a considerable number of such cycles, involving about six months of very tedious work, a ring of divisions was obtained the errors of which were known, and with one or two exceptions were well within ½ second of arc.

§ (8) Teeth Cutting.—The next step was to cut the teeth of the worm-wheel. In the place where the driving worm was finally to be mounted was placed a spindle carrying a multi-toothed V cutter of about 35° angle. The axis of this cutter was mounted in an inclined position, not parallel to the plane of the revolving table. The amount of this inclination was the mean angle of that portion of the thread of the worm that was to engage and drive the revolving table. Mechanical means were provided for revolving this V cutter and also for feeding it into the edge of the revolving table as required. There were also two or three warning devices for the purpose of indicating when the cutter was well out of contact with the revolving table so that the latter could be moved with impunity.

Seven micrometers were then mounted round the revolving table, and also, in a convenient position among them, a firm clamp and slow-motion screw for holding the table, and bringing it to the required position before each individual tooth was cut. This position was determined by the positions of the several divisions under their respective microscopes, due allowance having been made on each micrometer for the tabulated errors of each graduation. The V cutter was then entered a certain depth into the metal at the periphery, and again swung clear. When the "safe" position was indicated by the warning devices the table was revolved to the next division, and the cutter entered again, and so on all round the table without removing the cutter to resharpen it (it had been so prepared as to stand up well under this test of its durability).

In the dividing engine described there are two rows of teeth, one above the other, the upper row spaced 10 minutes apart, and the lower 5 minutes. The purpose of this arrangement was to simplify the driving mechanism and also to provide more equal wear on the bearings of the main spindle of the engine. The tooth-cutting operation was repeated three times round the entire circle in the case of the upper and deeper row of teeth, and twice in the case of the lower row, the final cut in each row being a very light one and effected with a 40° V cutter. The teeth of the cutter were well washed with turpentine during the whole operation, to facilitate the cutting of the metal, which was a very tough alloy of bronze.

The first care after cutting the teeth was to protect them, and for this purpose the rigid circular table provided a permanent support for a substantial cast-bronze shell bolted to it in segments, which completely surrounds the teeth, except where the worm-screws engage them.

§ (9) Driving Mechanism. — It now remained to provide suitable mechanism for

driving the revolving table, and cutting the divisions, each to have a suitable adjustment. Intermittent motion had to be provided for the former, and co-ordinated with this in a very positive manner, a "tracelet," or mechanism operating the actual cutting knife, with its automatic movements. Both are very simple in principle. The intermittent movement of the worm-wheel is arranged as follows: There is, mounted on the worm-spindle A (*Fig.* 2), and rigid with it, a ratchet wheel B, engaged and driven by a pawl C, which revolves on a spindle D. This spindle is separate from, but with its axis in exact prolongation of, the worm-axis. A coarse V-shaped worm E, round which a cord is passed several times, is rigidly mounted on axis D; one end of this cord is attached to a pin on a revolving arm F, the length of which can be varied; the other end of the cord carries a weight. On revolving the arm F the cord round E will be alternately pulled and released. The pawl, therefore, will be revolved round its axis alternately in opposite directions. In one direction it will carry the worm round with it by the pawl engaging in the ratchet wheel, and in the other direction the pawl will slide back over the ratchet wheel teeth. Thus the worm-wheel is alternately revolved and left stationary. The amount of revolution imparted depends on the amount of pull and release given to the cord, or, in other words, to the length of the arm F; this controls the spacing of the graduations. Various adjustments and limiting devices are introduced to make the apparatus as positive in its action as possible.

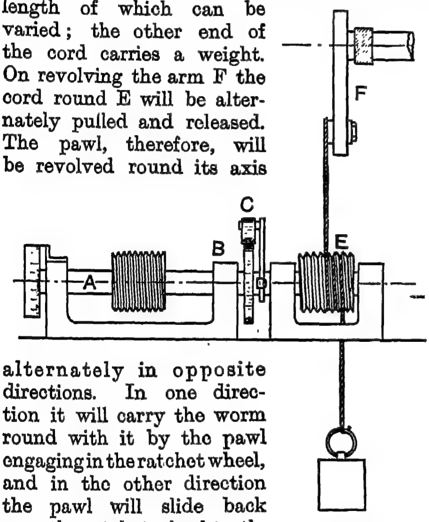

Fig. 2.

As regards the tracelet; two movements of the cutting knife are necessary—one a lowering and lifting movement, and the other a traversing movement; the former to bring the knife into contact with the surface to be graduated and to raise it again, and the latter to cut the division. There are several methods of automatically accomplishing the movements; one of the simplest is shown diagrammatically in *Fig.* 3, where A is the cutting-frame, having at one end a knife or cutter, while the other end is prolonged in order that the cam C, when revolving, may come in contact with it and alternately lift and lower the cutter at the other end. It is important for this cam to

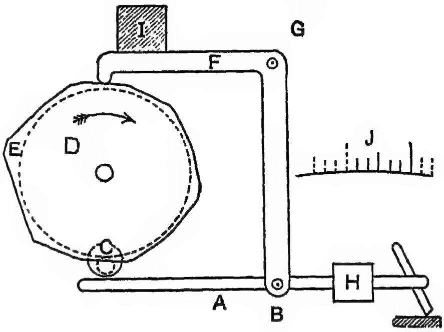

Fig. 3.

revolve at exactly the same rate as the revolving arm F (*Fig.* 2), and to be so adjusted that the cutter is out of contact with the work being graduated while the latter is being rotated by the worm. The shaft carrying the lifting cam C (*Fig.* 3) also carries a pinion geared with a definite ratio (in the case illustrated 1 : 6) into a larger gear wheel D, the spindle of which carries a large cam wheel E, having 6 equally spaced projections round its edge. In close contact with this undulated edge is a "feeler," or a projection of the member F, which is a right-angled frame pivoted at G, into the lower end of which the cutting-frame A is pivoted at B. H is a weight for determining the pressure of the cutting knife on the work, and I is a weight to keep the "feeler" in close contact with the edge of the cam E. The amount of the traversing movement communicated to the cutting frame, and therefore to the cutter, is controlled by the radii of the projections of the cam E.

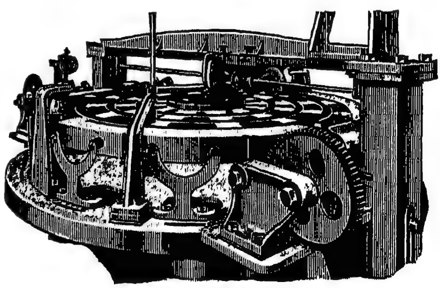

Fig. 4.

In the case illustrated the apparatus would produce graduations somewhat as illustrated at J (*Fig.* 3), the firm lines being cut during one revolution of the cam E. The machine is illustrated in *Fig.* 4.

III. Methods of Reading

§ (10) Method of Reading.—Circles are read by a single pointer, by a vernier, by a reading microscope, or by a micrometer microscope, these being mentioned in their order of increasing accuracy.

§ (11) *The Vernier.*—Suppose a scale divided into equal divisions, with a second scale sliding alongside it, the divisions of the second scale each $1/n$th smaller than those of the main scale. The second scale, or "Vernier," generally contains only n divisions. If the zero of the vernier coincide with a division of the main scale no other division will coincide except the nth, which will coincide with the $(n-1)$th division of the main scale. If the vernier be now moved along a distance of $1/n$th of a division of the main scale, the first division of the vernier, and only the first, will coincide with a division of the main scale; similarly, if it be moved m/n of a main division, the mth division of the vernier will coincide with a division of the main scale. As the eye is very sensitive to lack of continuity in a line, this forms a very sensitive device for splitting the main divisions of a scale. With the aid of a magnifying glass a 6-in. circle can easily be read by a vernier to 30″ of arc, and with a little care to 10″. It will be seen that the divisions of the vernier might equally well be $1/n$th larger than those of the main scale, but in this case the divisions of the vernier must be numbered in the reverse direction from those of the main scale. The device was first described in a treatise by Pierre Vernier, entitled *Construction, usage et propriété du quadrant nouveau de mathématiques*, published at Brussels in 1631.

§ (12) Reading Microscopes.—This device consists of a simple microscope having a fixed cross-hair. This enables a more finely divided circle to be used; but the interval between the cross-hairs must be estimated. If the cross-hair in the microscope be replaced by a scale, the divisions of the main scale can be subdivided by this means, but the final subdivision must still be estimated. The apparent size of the eyepiece scale must obviously agree with the apparent size of the main scale, and this can be adjusted in the same way as the adjustment for run in the case of the micrometer microscope.

§ (13) Micrometer Microscopes.—Here the fixed cross-hair of the reading microscope is replaced by a moving wire, which can be traversed across the field by an accurate micrometer screw, against the pull of a spring. The number of complete revolutions of the screw is counted (if necessary) by a comb cut in a diaphragm in the focal plane. The portions of a revolution are read on a drum attached to the screw. In any case there is a pointer (or zero notch in the comb) which indicates the point being read. When the drum reads zero the cross-hairs should be directly over the pointer or one of the notches in the comb. The run should be adjusted so that the cross-hairs move from one division on the main scale to the next in one or more complete revolutions of the drum. The run can be adjusted by moving the object glass of the microscope toward the circle if the apparent size of the circle division is too small, and away if too great. Any movement of the object glass involves refocussing the microscope. The drum is friction tight on its spindle, and so can be adjusted as necessary; a screw passing through the axis of the milled head used to turn the drum regulates its tightness. The comb or pointer can be moved by turning a screw at the far end of the micrometer box, in prolongation of the micrometer screw (see *Fig.* 5).

In taking a reading the cross-hairs are set over the division on the circle nearest the

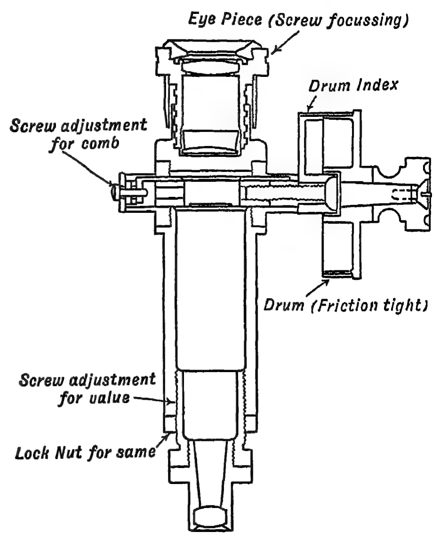

Fig. 5.

pointer. The pointer (or zero of the comb) indicates the division of the circle to be read, and the odd fraction is read off on the drum and comb (if necessary). It is best to have a cross-hair composed of two parallel wires spaced slightly wider than the apparent thickness of a graduation. Two fixed wires at right angles to the movable ones ensure that the readings are always taken on the same part of the graduations. With a 6-in. theodolite it is convenient for the circle to be divided into 10-minute spaces, and for one revolution of the drum to correspond to one division. If the

circumference of the drum be divided into 60 parts, each of these will correspond to 10 seconds, and no comb will be required. With a 12-inch theodolite the main divisions would be 5′, and the microscopes more powerful, so that one revolution of the drum would correspond to 1′. In this case a comb is necessary to count the odd minutes, and one division of the drum corresponds to 1″. In such a case it is convenient to have a lower-powered reading microscope to read the scale direct to the next lowest 5′, only the odd minutes and seconds being read on the micrometer microscopes. The drum reading should be the same whichever graduation be intersected, and it is often convenient to read the graduations on either side of the pointer, as this gives a check on the run of the micrometer, and enables a correction to be made if necessary.

The accuracy of reading depends to a considerable extent on the illumination of the circle. The graduations are engraved lines, and if the light falls from one side the illumination of the two edges differs; the light should fall from above, and in the direction of the length of the lines.

EYE, THE

I. Structure

§ (1) The eye, or organ of sight, is probably the most important of the physical sense-organs by which we accomplish the perception of the objective world. A complete treatment of its anatomy and functional processes from the physiological point of view would be outside the purview of this work; but an elementary knowledge of its structure is essential to the comprehension of its properties as an optical instrument, with which the Applied Physicist is primarily concerned, and which is the subject-matter of this article.

In *Fig.* 1[1] a diagrammatic horizontal section of the right eye is shown. The principal features to which we require to call attention here are the following:

The *Eyeball*, which is an elastic body of about one inch diameter, is of the shape shown, being distended at the front to form a spherical cap of smaller radius than the remainder. The wall of the eye consists of three principal layers or coats which, passing from the outside inwards, are met in the following order:

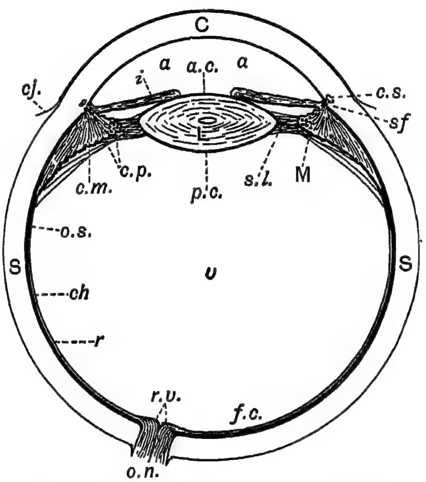

Fig. 1.—Horizontal Section of the Right Eye (Diagrammatic).

aa, aqueous; *v*, vitreous; L, crystalline; C, cornea; S, sclerotic; *ch.*, choroid; *r*, retina; *c.m.*, ciliary muscle; *c.p.*, ciliary processes; M. Müller's ring; *f.c.*, fovea centralis; *i*, iris; *s.l.*, suspensory ligament; *sf*, spaces of Fontana and pectinate ligament; *c.s.*, canal of Schlemm; *a.c.*, anterior capsule of lens; *p.c.*, posterior capsule of lens; *cj.*, conjunctiva; *o.n.*, optic nerve; *o.s.*, ora serrata; *r.v.*, entrance of retinal vessels.

The Sclerotic and Cornea: The *sclerotic* is a white opaque membrane of tough fibrous tissue which extends over about five-sixths of the ball. The *cornea*, which covers the other sixth, is continuous with the *sclerotic*, but is colourless and transparent to admit light to the eye.

The Choroid: This is a layer of highly vascular membrane in close contact with the sclerotic externally and lined internally with dark brown pigment cells.

The Retina: This is the seat of vision. It is a reticulated structure of fibres and cells and is directly connected to the optic nerve. It consists of ten distinct layers, of which the first and second (passing from the choroid inwards) are the receptive layers. The first of these, which adjoins the choroid, is the *hexagonal pigment layer*, a glandular structure in which is secreted a substance known as *visual purple*. That the *visual purple*, which becomes bleached on exposure to light, is associated with vision is regarded as certain, but the part which it plays is unknown, many conflicting theories of its function having been advanced. Next comes the *bacillary layer* or the layer of *rods* and *cones*. These consist of minute bodies, of which the shape is conveyed in their names, and of which vast multitudes are packed side by side perpendicularly to the plane of the retina. The light waves strike these bodies and, by means at present unknown, the radiant energy is converted into some form suitable for transmission along the ramifications of the optic nerve to the brain.

The remaining layers, which need not here be particularised, contain the blood-vessels and the nerve fibres which radiate from the optic nerve to all parts of the layer of rods and cones. It will be observed that the light, before reaching this layer, has to pass through the eight inner layers.

[1] Taken from *Visual Optics and Sight Testing*, by Lionel Laurance, which the reader should consult for fuller information than is here given.

Other books which deal with the physiology of the eye are *Handbuch der physiolog. Optik*, H. von Helmholtz; *Handbuch der Physiologie des Menschen*, W. Nagel; *Optique physiologique*, Tscherning; *Elementary Textbook of Physiology*, T. Huxley.

At the back of the eye, with its centre at the point where the line of sight[1] meets the retina, is the *yellow spot* or *macula lutea*. The spot is slightly elliptical and is about 2·5 mm. in diameter. At its centre is a depression where all the retinal layers, with the exception of the receptive layers, are very much attenuated. This is known as the *fovea centralis*. Its diameter is about 0·25 mm. The acuity of vision is greatest at the fovea, falling off rapidly towards the outer parts of the retina.

The distribution of the rods and cones also varies from the fovea, where there are practically no rods, to the periphery, where there are relatively few cones.

At the point where the optic nerve passes through the wall of the eye the retina is absent and there is no sensitivity to light. This region, which is about 2 to 2·5 mm. in diameter, is known as the *blind spot*.

§ (2) Optical Elements.—The image-producing elements of the eye are the *cornea*, which has already been described, and the *crystalline lens*. The space between the cornea and the lens contains a fluid known as the *Aqueous Humour*, which is practically water with some salts in solution. Its refractive index is nearly that of water and differs little from that of the cornea, which is therefore optically equivalent to a single refracting surface.

Between the lens and the retina is the *Vitreous Humour*, a transparent substance of a consistency similar to the white of an egg (raw). Its refractive index is similar to that of the aqueous humour.

The *Crystalline Lens* is composed of fibres arranged with considerable complexity. It is highly elastic, and its form and position are maintained by a membranous frame known as the *suspensory ligament* which extends from the edges of the lens to the *Ciliary Processes*. These are a direct prolongation of the *Choroid*. Their function is nutritive; they secret a fluid which nourishes the lens and vitreous humour and replenishes the aqueous humour.

Associated with the ciliary processes and the suspensory ligament is the *Ciliary Muscle*. This consists of two parts, the *radiator* and the *sphincter* or *Müller's ring*. Its function is to vary the tension of the suspensory ligament, which results in an alteration of curvature of the posterior surface of the lens, thereby producing the change of power, known as *accommodation*, by which objects at various distances are brought into focus.

The Iris.—This is a diaphragm which limits the aperture of the eye. It consists of a pigmented membrane, in the centre of which is a hole—termed the *pupil*—by which light enters the eye. The iris contains straight radiating fibres, the contraction of which tends to dilate the pupil. This contraction is opposed by a ring of contractile muscle, termed the *sphincter pupillae*, round the edges of the pupil. The operation of the *sphincter pupillae* is involuntary, being due to reflex action. When the retina is subjected to strong illumination, or when a high degree of accommodation is called into play, the *sphincter pupillae* contracts and causes a diminution of the aperture of the pupil.

[1] *Vide infra.*

§ (3) The Eye as an Instrument.—The eye, either alone or in conjunction with external optical instruments, plays an important part in physical experiments. In a great number of determinations one of the factors limiting the accuracy attainable is the precision with which the eye indicates the fulfilment of some particular criterion; for instance, the coincidence of the cross-wires of a telescope with the image of some external object, the equality of brightness or of colour of two illuminated areas, etc. The eye is therefore a physical instrument, of which the capabilities and limitations must be understood equally with those of any other instrument and given due consideration in devising methods and designing apparatus if the experimenter would secure the maximum accuracy in his results.

Unlike most instruments of human design and construction, any one of which is rarely expected to perform more than one special function, the eye has to do a variety of things. These may be grouped under three heads, viz. the perception and measurement of light; the discrimination of colour, and the determination of the position of objects in the field of view. In the following paragraphs we shall study the properties of the eye regarded as an instrument capable of doing these things.

II. The Perception of Light

§ (4) Threshold Phenomena.—The perception of light being fundamental to all the other functions of the eye, we shall first consider the laws governing this perception. There is a minimum quantity of light, known as the *threshold quantity* or *extinction quantity*, which must reach the eye in order that light may be perceived at all. After the eye has become adapted to the dark, a small source of ·02 candle-power, one metre distant, would just be seen when looked at directly. If received indirectly, so that the image falls outside the fovea, a much fainter light could be seen. For most practical purposes it is foveal vision that is important.

In order that a light may be visible it is *necessary* and *sufficient* that the eye should

receive the threshold quantity, *whatever the area of the source*, provided the latter does not subtend a greater angle at the eye than about 50 minutes of arc—or nearly the whole foveal area. This means that for very low intensities the light is completely cumulative, and that, whether concentrated at a point on the retina or spread over an area of 50′ diameter, it produces the same total physio-psychological effect. This is usually expressed by saying that for very feeble light the *visibility*, or apparent brightness, depends only on the total candle-power, and not on the intrinsic brightness of the source so long as its angular size is less than 50′. For larger areas the light required to produce a given brightness near the threshold varies as the linear dimensions of the source. Beyond 4° there is no further cumulative effect, and the apparent brightness is proportional to the intrinsic brightness.

As the brightness increases the area over which complete accumulation takes place diminishes. Thus Paterson and Dudding [1] found the transition from complete to partial accumulation to take place at 10′ for faint sources somewhat above the threshold brightness.

By summing up the results of various observers,[2] S. D. Chalmers [3] arrived at the generalisation that for the true intrinsic brightness of an object to be recognised, *at least the threshold quantity of light must fall on the area of the retina occupied by a single cone; i.e.* an area of 25 to 30 secs. angular diameter.

For very low brightnesses colour is not recognised. From a study of Abney's results for the extinction of colour, Chalmers deduced that the recognition of colour begins at the same stage as the recognition of true brightness, viz. when the threshold quantity of light falls on each cone.

§ (5) Fechner's Law.—At intensities well above the threshold values, but not bright enough to dazzle, the relation between the sensation of light and the stimulus producing it is such that the difference in brightness of two objects which is necessary for one to be recognised as brighter than the other is a constant fraction of the actual brightness: If I is the intensity, and δI_m is the minimum difference which can be detected, $\delta I_m/I$ is constant, $=A$, say. This is known as *Fechner's law*. A, which is about 1 per cent or thereabouts for the average eye, is known as the *Fechner fraction*. The law is only approximate; considerable departures occur at high and low intensities, as already indicated. The value of A, while it may be regarded as constant for practical purposes over the range of medium intensities, in reality follows a shallow curve, having a minimum value when the retinal illumination is about 6·5 metre candles. According to Chalmers [4] the approximate values of A at low intensities are 1·1 per cent at 0·25 metre candles; 1·6 per cent at 0·12 metre candles; 3·2 per cent at 0·03 metre candles. At high intensities A also increases considerably.

III. Colour Phenomena

§ (6) Visibility.—We need not deal here with the theory of the mechanism by which the wave-length or vibration frequency of the light imparts to the sensation that character which we know as colour; but some of the properties of colour vision are of great practical importance.

If we look at two areas illuminated by light of different wave-lengths and vary their relative intensities, we perceive that there is a certain condition in which we appraise them as equally bright, although their colours may be quite different. The criterion of equal brightness in such a case is probably purely psychological, since there is nothing in the external stimuli, nor, as far as is known, in their physiological effects, which can be said to be equal in any ordinary sense of the word. The mind appreciates the illuminations as equally bright when they make equal claims on the attention. What determines this claim is obscure, and in any case does not concern us here: the important point is the experimental fact that for radiations of different wave-lengths there is a unique relation between the quantities received by unit area of the retina for which the radiations will be regarded as equally bright.

The degree of brightness produced by a given quantity of energy falling on unit area of the retina in unit time depends on the wave-length of the radiation. For blue and yellow-green lights, for instance, to appear equally bright, the energy flux from the blue must be many times as great as from the yellow-green. The blue radiation is said to be of lower *visibility* than the yellow-green. The inverse ratio of the energy fluxes required to give equality of brightness may be regarded as the *relative visibility* of the two colours; or, if we take the visibility of the yellow-green as unity, the inverse ratio of the fluxes measures the *visibility* of the blue.

The visibility of monochromatic illumination throughout the visible spectrum has been

[4] *Loc. cit.*

determined by various observers.[1] For a normal eye the curve connecting visibility and wave-length is of the form shown in *Fig.* 2, maximum visibility occurring for a wave-length about $0{\cdot}55\mu$.

The curve can be represented to a close approximation by the following expression:[2]

$$V_\lambda = A\left(\frac{R_1}{\lambda}e^{1-\frac{R_1}{\lambda}}\right)^\alpha + B\left(\frac{R_2}{\lambda}e^{1-\frac{R_2}{\lambda}}\right)^\beta + C\left(\frac{R_3}{\lambda}e^{1-\frac{R_3}{\lambda}}\right)^\gamma,$$

where

$A=0{\cdot}999$	$R_1=0{\cdot}556$	$\alpha=200$
$B=0{\cdot}04$	$R_2=0{\cdot}465$	$\beta=400$
$C=0{\cdot}095$	$R_3=0{\cdot}610$	$\gamma=1000$

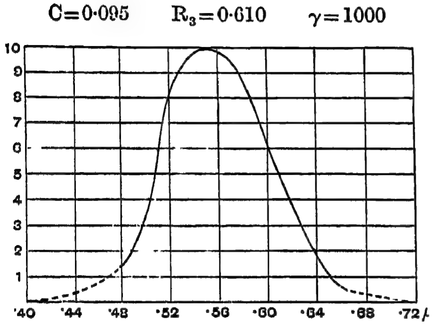

Fig. 2.

§ (7) White Light.—A stimulus in which components of all wave-lengths were present in brightnesses proportional to the ordinates of the visibility curve would not produce white light; for in none of the sources of radiation which the eye regards as white is the energy distributed uniformly in the spectrum. For any actual source, the relative quantity of light sensation produced by each wave-length is proportional to the product of the ordinates of the visibility curve and the energy distribution curve of the source for the wave-length in question. This product is termed the *luminosity* of the source for this wave-length. If the luminosity for each wave-length be plotted, a new curve will be obtained differing from the visibility curve to the extent that the energy distribution curve of the source departs from a horizontal straight line. The energy distribution curve of a "black body" at 5000° C., which can be calculated from Wien's law, may be taken as the standard "white" light. In practice the radiation from the crater of an electric arc is about the whitest artificial light, and is the source to which the majority of the colour vision determinations of Abney and others refer.

§ (8) Hue and Saturation.—In the case of light which is not white, the eye appreciates three factors—*Hue, Degree of Saturation,* and *Brightness.* As we shall see later, any colour, with the exception of purples and magentas, can be produced by mixing a proper proportion of white light with monochromatic radiation of suitable wave-length. The *hue* of the colour is specified by the wave-length of the monochromatic radiation; the degree of *saturation,* or rather lack of saturation, by the percentage of white in the total. The perception of hue is, of course, entirely subjective, and the rate at which it changes with wave-length is very irregular. If two adjacent areas be illuminated with monochromatic light of different wave-lengths, the extent by which these must differ for a hue difference to be perceptible can be determined at all parts of the spectrum. This difference has been measured by various experimenters.[3] The curve obtained by Jones is shown in *Fig.* 3. The inverse of this curve

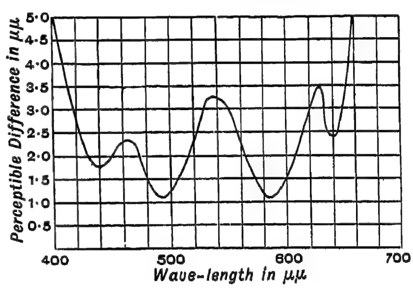

Fig. 3.

indicates the sensitivity of the eye to variation of wave-length at different parts of the spectrum.

A slight change in hue of the light reflected or transmitted by a substance is frequently the fiducial criterion in physical and chemical processes, and its detection with the utmost sensitivity is therefore of importance. For instance, the "dose" of X-rays administered for the treatment of ringworm, etc., is measured by the change of hue of Saburaud pastilles, which change from lemon to orange with the

proper exposure. The accuracy with which the latter tint can be matched with a standard determines the accuracy with which the dose can be administered.

The sensitivity of any colour criterion will be greatest if the final colour is near one of the minima of *Fig.* 3. In arranging such reactions an attempt should always be made to bring the tint to a sensitive region by the addition of colouring-matter which is inert to the reaction, or, possibly, by the use of suitable colour-filters. In using such expedients, however, care must be taken to avoid suppressing those wave-lengths which are affected by the reaction.

§ (9) The Trichromatic Basis of Colour.—As an expression of what the eye perceives, the specification of colour by its hue and degree of saturation is the most natural; but it does not give the readiest means of co-ordinating colour-mixture phenomena with the properties of the receiving mechanism. It is found that if monochromatic light of three suitable wave-lengths—a red, a green, and a blue—be mixed in suitable proportions, white light will be produced. Further, it is possible to match the *hue* of any colour whatever by mixing some pair of these primaries in suitable proportions. In general the saturation of this mixture will differ from that of the colour. If it is too highly saturated an exact match can be obtained by adding white, or, alternatively, by adding suitable amounts of all three primaries in the proportions which make white. That is to say we can match such a colour both in hue and saturation by a suitable mixture of our three primary colours.

It is necessary to attach a meaning to the term "quantity" when we refer to mixtures of certain relative quantities of light of different colours. It is found to be most convenient in practice to choose the units for the three primaries such that an equal number of units of each will, when mixed, give white light. It should be noted that this is quite an arbitrary choice; there is no physical, physiological or psychological property of the radiations which are equal for equal quantities as defined on this basis. For instance, they would not appear equally bright if separated. It is, however, a convenient system for expressing the numerical data of colour mixing.

We may therefore express any colour, of which the saturation is not too high, in terms of three primaries R, G, and B, by three quantity coefficients a, a', and a'', which give the numbers of units of each primary, as above defined, which are required to match the colour, thus

$$\mathrm{C}=a\mathrm{R}+a'\mathrm{G}+a''\mathrm{B}.$$

We may find that the colour to be matched is of greater saturation than the two-primary mixture which gives its hue. In this case an exact match is impossible, since addition of the third primary can only produce mixtures of still lower saturation. We may, however, add white to the colour, thereby reducing its saturation to such an extent that it can be matched by combination of the two appropriate primaries. Expressing this white by its equivalent in terms of the three primaries we have the relation

$$\mathrm{C}+\alpha\mathrm{R}+\alpha\mathrm{G}+\alpha\mathrm{B}=a\mathrm{R}+a'\mathrm{G},\text{ say,}$$

or

$$\begin{aligned}\mathrm{C}&=(a-\alpha)\mathrm{R}+(a'-\alpha)\mathrm{G}-\alpha\mathrm{B}\\&=b\mathrm{R}+b'\mathrm{G}+b''\mathrm{B},\text{ where }b''=-\alpha.\end{aligned}$$

Thus, although we cannot match such a colour by any actual mixture of our three primaries, we can arrange a slightly different colour match from which we are able to *specify* our original colour in terms of the three primaries by introducing a negative coefficient for some one of them.

It is evident that instead of adding white to the colour we could have adopted the alternative procedure of adding the third primary alone, and have obtained the colour match

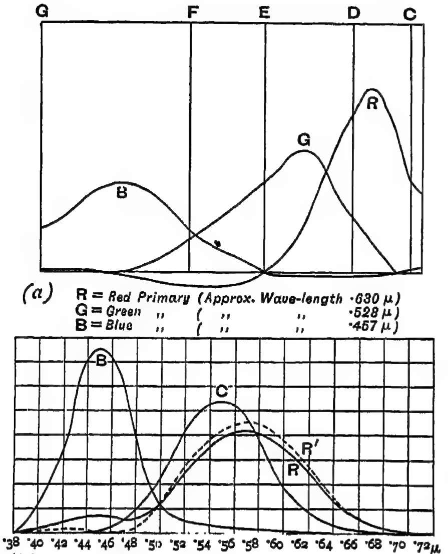
$$\mathrm{C}+\alpha\mathrm{B}=b\mathrm{R}+b'\mathrm{G},$$

the final specification for C being the same in each case. It depends on the construction of the colour-matching apparatus employed whether it is more convenient to add white or one of the primaries.

There is a comparatively wide range of wave-length within which each of the three primary colours may be chosen to fulfil the fundamental condition of being miscible with the other two to make white. For colour-matching purposes, however, it is undesirable to choose any primary near an extremity of the possible range, as in such a case some of the mixture colours are of very low saturation.

§ (10) Mixture Curves.—If we plot at each wave-length the quantities of the three primaries required to match the spectrum both in colour and brightness we obtain a set of three curves, which are termed the *Mixture Curves*. The curves for the primaries used in Clerk Maxwell's colour-mixing apparatus are shown in *Fig.* 4 (*a*). The heights at which the ordinate at any wave-length cuts the three curves R, G and B give the relative quantities of the primaries required to match the spectrum colour. For any one primary the aggregate quantity required to match every part of the spectrum is clearly $\int_0^\infty s_\lambda d\lambda$, where s_λ is the quantity of that primary required at the wave-length λ. The value of the integral is measured by the area enclosed between the curve and the base-line, parts below the base being regarded as negative.

Since the total effect of the spectrum is to give white light, and since our units are chosen so that equal quantities of the primaries



(b) FIG. 4.—The Fundamental Sensation Curves of the Spectrum.

Full lines mean values of Koenig's five observers; dashed line, new red curve, obtained by different choice of blue primary dictated by luminosity considerations.

make white, the areas of the three mixture curves are equal.

§ (11) YOUNG'S THEORY OF COLOUR VISION.[1] —The fact that all colours can be reproduced for practical purposes by mixing suitable quantities of three primary colours suggested to Thomas Young that there are three receiving mechanisms in the eye which when stimulated give rise to primary colour sensations of red, green, and blue respectively. Each sensation is stimulated by radiation from a considerable range of the spectrum, though for each there is a maximum response at a certain wave-length. The receiving mechanisms have, in fact, the properties of damped resonators with natural periods corresponding to the wave-length which produces maximum response. The resultant colour effect produced by radiation of any wave-length is the mixed sensation due to the partial stimulation of the three primary sensations.

If we had three colours, each of which stimulated one *and one only* of the primary sensations, these would form the natural system of primaries to which all colour mixture phenomena should be referred; since, by mixtures of such primaries, it would be possible to reproduce any possible colour, both in hue and purity, without introducing negative coefficients.

Unfortunately we cannot find three such colours. If we choose a red of wave-length about $0·7\mu$ or longer, the resulting colour is almost entirely due to pure red sensation; and if we take a blue from a very short region about $·446\mu$ we will, according to the most recent work,[2] obtain nearly pure blue sensation; but there is no colour which stimulates the green sensation alone, every green, to the normal eye, stimulating not only green sensation but varying amounts of the other two. There is, however, a point in the spectrum, about $0·50\mu$, where the red and blue sensations are equally stimulated. The colour here may be regarded as made up of equal stimulations of red, blue, and green, plus the remainder of the green; that is to say, it is green diluted with a certain amount of white. Thus at $0·50\mu$ the spectrum is the same *hue* as the pure green sensation would be, were the others absent or atrophied, *but it is less saturated.*

By making colour matches with these primaries we can construct their mixture curves as described above. By combining these with data for colour-blind observers of different types[3] it is possible to construct the *sensation* mixture curves, *i.e.* curves showing the amount of stimulation of the three primary sensations at different wave-lengths. In *Fig.* 4 (*b*) are shown the sensation curves as obtained by Koenig and modified by H. E. Ives.[4]

Every colour can be specified in terms of these three sensations by coefficients indicating the degree to which they are stimulated; thus

$$C = aR + a'G + a''B.$$

The sum of the coefficients $a + a' + a''$ is termed the *quantity* of the colour, being the sum of the quantities of the three sensations.

§ (12) COLOUR GEOMETRY.—Since colours can be specified by three coefficients in this way it is evident that colour mixture data can be represented by points in a three-dimensional figure, and that geometrical methods can be used to solve colour mixture problems. A full treatment of mixture diagrams would be beyond the scope of this article,[5] but reference may be made to the colour triangle. This is a section of the three-dimensional diagram (the colour pyramid) by a plane which makes equal intercepts with the axes.

In the colour triangle the three primaries are represented by the corners of an equilateral

[1] In its later form, as modified by v. Helmholtz, this is known as the Young-Helmholtz Theory of Trichromatic Vision.

[2] H. E. Ives, *Journ. Franklin Inst.*, 1915, clxxx. 409.

[3] See, for instance, Abney, *Colour Vision*, chap. vii.

[4] *Journ. Franklin Inst.*, 1915, clxxx. 409.

[5] *Loc. cit.*

triangle. Any point in the figure represents a colour $aR + a'G + a''B$, where a, a', and a'' are proportional to the perpendicular distances from the point in question to the sides of the triangle opposite R, G, and B respectively. A triangle can be constructed for any set of primaries used for colour-mixing; but a particular colour will occupy different positions in different triangles, since different proportions of the primaries are required to match it. White, however, will always be represented by the centroid of any triangle; for, *by choice of units*, equal quantities of the primaries make white.

Any possible hue obtainable by mixing two colours is represented by a point on the line joining their positions in the colour triangle, dividing the line in the inverse ratio of the quantities of the two in the mixture.

Since the sum of the perpendiculars from any point to the three sides of the colour triangle are equal, all points on the diagram represent colours in equal quantities, *i.e.* equal values for $a + a' + a''$. We may take this as unity. Any point, therefore, represents unit quantity of colour. It then follows from simple geometry that the colour obtained by mixing two colours represented by points A and B, in proportions x of A to y of B, will be given by the point which divides the line AB in the ratio $y : x$. If the line joining any two colours passes through white, the colours are complementary, since by mixing them in suitable proportions white is produced.

For many purposes the relative luminosities of the constituent colours in a mixture are required. This is not equal to the relative quantities of the colours as obtained from the colour triangle, since equal quantities of different colours on the arbitrary quantity convention on which the triangle is based are not of equal luminosity. We may obtain the relative luminosity of unit quantities of any colour if we know the relative luminosities of equal quantities of the three primaries. Suppose we have unit quantity of colour, C, given by $C = aR + a'G + a''B$, where $a + a' + a'' = 1$. Its luminosity, L_C, is clearly $aL_R + a'L_G + a''L_B$, where L_R, L_G, and L_B are the luminosities of unit quantities of the three primaries. L_R, L_G, and L_B are easily determined, so that it is possible to calculate the relative luminosity of unit quantity of any colour of which the trichromatic coefficients are known.

Having found from the triangle the relative quantities of any two colours C and C_1 in a mixture, it is only necessary to multiply the result by the ratio L_C/L_{C_1} to obtain the relative luminosities of the constituents. Conversely, if it is desired to determine the colour which results from mixing, in a given luminosity ratio, two constituents C and C_1 of which the colour triangle coefficients are a, a', a'' and a_1, a_1', and a_1'', respectively, we first calculate $L_C (= aL_R + a'L_G + a''L_B)$ and $L_{C_1} (= a_1 L_R + a_1' L_G + a_1'' L_B)$, the relative luminosities of unit quantities of the two colours, from which we can find the quantity ratio corresponding to the required luminosity ratio. The mixture colour is then found in the triangle by dividing the line joining the constituents inversely as the quantity ratio.

Since the ratios of L_R, L_G, and L_B to one another differ for different sets of primaries, the relative luminosities of unit quantities of different colours also vary. That is to say, the relation between quantity and luminosity differs for different colour triangles. The final result of any colour calculation is, however, the same on whatever triangle the specifications are based.

Ives[1] has calculated that the relative luminosities to be attributed to the sensation primaries are $L_R = 0{\cdot}648$; $L_G = 0{\cdot}336$; $L_B = 0{\cdot}016$. These are expressed so that their sum is equal to unity. The luminosity of unit quantity of white, for which $a = a' = a'' = \frac{1}{3}$, is therefore $\frac{1}{3}(L_R + L_G + L_B) = \frac{1}{3}$.

It is necessary for many colour measurements to have the spectrum colours plotted in the triangle. This is done by taking the values a, a', and a'' for different wave-lengths from the mixture curves of the spectrum, *obtained with the primaries for which the triangle is constructed*, and plotting the points at their proportionate distances from the three sides. If as primaries we take the three *sensations* we use the sensation curves of *Fig.* 4 (*b*). In *Fig.* 5 the spectrum is shown in the fundamental colour sensation triangle, the new red curve of *Fig.* 4 (*b*) being employed in its construction.

We can now express any colour, of which the sensation coefficients are known, in terms of its spectral hue and degree of saturation. Take the colour whose sensation values are $\cdot55R + \cdot30G + \cdot15B$. It is represented by P, *Fig.* 5. The line WP produced cuts the spectrum curve at H, where the wave-length is $\cdot611\mu$.

The hue of the colour is that of the spectrum at $\cdot611\mu$, and it is diluted with white to the extent of 100 HP/HW per cent $= 43{\cdot}3$ per cent on the quantity basis.

To obtain the percentage *luminosity* of the white we must multiply this figure by the ratio of unit quantity of white to unit quantity of the total colour. As we have already seen

$L_W = 0{\cdot}333$.

$$L_C = 0{\cdot}55 \times 0{\cdot}648 + 0{\cdot}30 \times 0{\cdot}336 + 0{\cdot}15 \times 0{\cdot}016 = 0{\cdot}459.$$

[1] *Journ. Franklin Inst.*, 1915, clxxx. 409.

The percentage luminosity of white is therefore

$$43 \cdot 3 \times \frac{0 \cdot 333}{0 \cdot 459} = 31 \cdot 4.$$

The colour triangle readily gives other information about the colour properties of the eye. If a straight line drawn through W cuts the spectrum in two points, the colours at these points will be complementary, producing white when mixed in inverse proportion to their distances from W. The colours of the spectrum from about $\cdot 493\mu$ to $\cdot 56\mu$ have no complementaries in the spectrum. They are complementary to colours lying in the region approximately bounded by RWB, the region of purples and magentas. We see now why purples and magentas are exceptions to the rule that any colour can be made up of monochromatic light plus white; in this region a line joining white to the colour does not intersect the spectrum. A colour of this kind has to be specified, on the hue and purity scale, by the *amount of its complementary spectral hue which must be mixed with it to make white.*

Precisely the same method of use applies to colour triangles constructed for actual primary colours instead of the fundamental sensations. The position of the spectrum in the diagram will be different; the three wave-lengths chosen as primaries will occupy the corners, while the location of the other wave-lengths will depend on the form of the colour mixture curves for the primaries concerned.

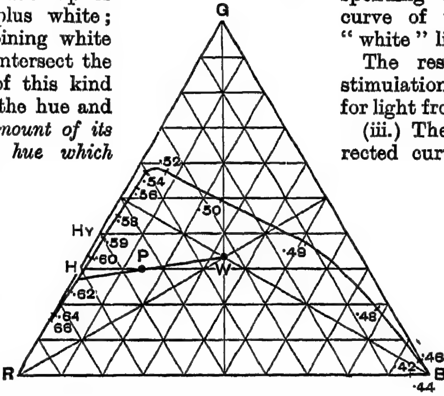


FIG. 5.—The Fundamental Colour Sensation Triangle.

In practical colorimetry actual spectrum primaries must, of course, be used. These may either be isolated spectroscopically or may simply be obtained by coloured glasses. For the co-ordination of colorimetric data it is necessary to reduce the data obtained with the mixing instrument to a standard system; and the most suitable is that based on the three fundamental sensations. The methods of reduction are outside our present scope. They are fully developed by H. E. Ives in the paper already quoted,[1] in which the parallel problem of the reduction of measurements on the hue and purity system to the trichromatic system and *vice versa* is also treated.

§ (13) DOMINANT HUE OF FILTERS.—As an illustration of the application of mixture curves and colour triangles, a case that often arises in the laboratory may be quoted. It is frequently desired for various purposes to use a "filter" of coloured glass or other material to render light approximately monochromatic. If a knowledge of the wave-length of the dominant hue is required—as, for instance, in using such filters for optical pyrometry—the following process has to be followed:

(i.) The spectrophotometric curve for the filter is obtained.

This gives the percentage of the incident light transmitted at all wave-lengths.

(ii.) If the energy distribution in the spectrum of the light with which the filter is to be used differs from that of the "white" light to which the sensation mixture curves refer, it is necessary to multiply the ordinates of these curves by the ratio of the corresponding ordinates of the energy curve of the source and of the "white" light.

The resulting curves give the stimulation of the three sensations for light from the source in question.

(iii.) The ordinates of these corrected curves must be multiplied by the transmission coefficients of the filter.

The double reduction of (ii.) and (iii.) may be done in one process since the intermediate curves are of no special interest.

The ratios of the areas of the final mixture curves to their initial values give the coefficients a, a', and a'', which express the colour of the transmitted light in terms of the three sensations. This can be plotted in the sensation triangle, *Fig.* 5, and the predominant wave-length and degree of saturation obtained as described in the preceding paragraph.

§ (14) PHENOMENA AT LOW INTENSITIES.—In the foregoing paragraphs the visibility curve and the sensation mixture curves have been regarded as invariant. For medium intensities this is practically the case; but at low intensities the colour perception is not represented by the curves as given in *Figs.* 2 and 4.

As the intensity of the spectrum is reduced, the maximum of the visibility curve shifts towards the blue, the eye becoming relatively less sensitive to the red end of the spectrum. At low intensities the red disappears entirely; the orange becomes yellow, and the green bluish, this process continuing until nothing is left but a faint bluish grey. With still further reduction, the last trace of colour

[1] *Journ. Franklin Inst.*, 1915, clxxx. 409.

isappears, leaving only a nondescript grey. 'his variation of colour sensitiveness with ıtensity is known as the *Purkinje effect.* Jnless care is taken to work at suitable ıtensities, it may introduce undesirable omplications into colorimetric measurements.

Not only do the colour sensations vary with ntensity, but they are not constant for all ›arts of the retina. Within the *macula lutea* ›r "yellow spot" there is considerable absorpion towards the blue end of the spectrum.[1] Chis region is therefore relatively more sensiive to red than regions just outside it. As ve recede from the centre the visibility curve changes in approximately the same way as when we reduce the intensity, the peripheral portions of the retina being quite colour-blind, and all colours appearing of the nondescript grey already referred to. The reason why this is never noticed in ordinary vision is because of the very great difficulty of seeing anything distinctly at any distance from the fovea.

To explain these phenomena the "Duplicitats Theory" of von Kries assumes that the colour sensitive mechanisms are associated with the cones, and that the colourless sensation, which predominates at low intensities and towards the periphery of the retina, is located in the rods. The cones are only excited at comparatively high intensities, and the Purkinje effect is explained by the gradual passage from cone to rod vision as the intensity is reduced. The relative concentration of the cones is greatest at the centre of the retina, diminishing practically to zero towards the outskirts. Hence the passage from chromatic to colourless vision from the centre outwards. In most eyes there are no rods at all at the centre of the fovea, and in this region the Purkinje effect is found to be absent, there being no light visible when the colour has disappeared.

§ (15) Dark Adaptation.—The sensitiveness to faint light depends very considerably on the length of time which has elapsed since last the retina was exposed to a bright illumination. Every one is familiar with this phenomenon. It requires about ten minutes to become completely dark-adapted, and the sensitivity to feeble illumination is then about a hundred times as great as it is immediately after exposure to daylight.[2] According to Parinaud,[3] dark adaptation is entirely due to the increased sensitivity of the colourless sensation. Thus at the red end of the spectrum, where there is no change of hue and no passage into colourless vision on diminishing the intensity, there is no gain in sensitiveness due to adaptation. The effect of adaptation commences about the C line ($\lambda = \cdot 656\mu$) and becomes of increasing importance towards the blue end. *Fig.* 6 shows Parinaud's results. The lettering indicates the Fraunhofer lines. The ordinates indicate the quantity of light necessary in order to be perceived. The upper curve refers to the dark-adapted eye and the lower to the non-adapted eye. The unit chosen is the quantity required by the adapted eye in the neighbourhood of E ($\cdot 527\mu$, green). The figure shows that the non-adapted eye requires 100 units[4] at this wave-length as against 1 for the adapted eye, and 1500 units for blue light in the neighbourhood of the G line, as against 100 for the adapted eye. The increase of sensitivity on adaptation is not due, however, to increased sensitivity of the colour perception, but only of the colourless rod vision. At the centre of the fovea, where, as we have seen, there are no rods, and in consequence no Purkinje effect, there is also, according to Parinaud, no dark adaptation.

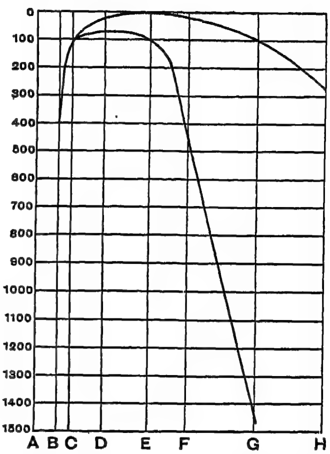

Fig. 6.—Position in Solar Spectrum.

§ (16) Visual Fatigue and Successive Contrast.—When a bright object is viewed steadily for some time it becomes appreciably fainter, due to the elements of the retina on which the image falls becoming fatigued. The effect of fatigue remains for some time after the stimulus ceases; and, if the gaze be transferred to a uniformly illuminated surface, a dark "negative image" of the bright object will be seen, due to the diminished sensitivity of the part of the retina previously occupied by it. If the object is coloured, that sensation which is most stimulated is also most fatigued, and the negative image is of a colour approximately complementary to that of the object.

[1] Abney, *Colour Vision*, p. 91.
[2] Abney, *loc. cit.* p. 120.
[3] *Ann. d'Oc.*, 1894, t. cxii. 228. *Vide* Tscherning, *Optique physiologique*, p. 226.
[4] Compare Abney's result *supra*.

This phenomenon is known as *Successive Contrast*. It is not, of course, a true contrast effect. True or simultaneous contrast is observed when two areas of different brightness adjoin each other. Near the junction the brighter area appears even brighter and the darker area even darker than at places remote from the junction. If the areas are of slightly different colours the difference is intensified by contrast in the immediate neighbourhood of the junction. Contrast effects of this character disappear almost entirely if the areas are separated by a black line. Diffuseness of the border appears to favour the effect.

If a screen is illuminated by two lights, one of which is white and the other coloured, and an object is placed in front of the screen, it will cast two shadows, one of which is illuminated solely by the white light, and the other solely by the coloured light. The former, which ought to appear white, appears coloured. The colour is approximately complementary to the colour of the coloured light, though according to Abney it is not always exactly complementary. Tscherning [1] accounts for contrast colours obtained in such circumstances as due to defective judgment of white. There is always a tendency to take a large illuminated area as white, unless it is very strongly coloured. Even then it appears whiter than it should, the "white" with which it is mentally compared being tinted with the colour in question. If, then, a small area of true white exists in such a background, it is poorer than the temporary standard white in the colour with which the latter is adulterated, and, therefore, appears of the complementary colour.

Contrast effects, both of brightness and colour, are of great importance in connection with the design of photometers and colorimetric apparatus.

§ (17) Time Effects.—When a light is suddenly turned on it is not immediately perceived, nor, when it is turned off, does perception immediately cease. The time lag in the second case exceeds that in the first case, with the result that vision of an instantaneously exposed light (for instance, an electric spark) persists for an appreciable time. Thus if a light is rapidly intermittent, the impression of one exposure may still persist until the next exposure, and the light will be seen continuously. The period which may elapse between successive exposures without the appearance of flicker may be termed the duration period. The total duration, of course, exceeds this considerably. E. L. Nichols [2] and E. S. Ferry [3] have determined the duration period as defined above. The general results are as follows:

1. The persistence decreases as the intensity increases.
2. It varies with wave-length, being greater towards the ends of the spectrum than at the middle.
3. It is greatest for very short exposures.
4. It differs for different eyes.
5. An average duration under ordinary conditions is from $\frac{1}{30}$ to $\frac{1}{10}$ second.

§ (18) Talbot's Law.—The apparent intensity of an intermittent light is diminished, even if the intermittence is so rapid that continuous vision results. Talbot [4] enunciated the law that the apparent intensity of the light in those circumstances bears the same ratio to its actual intensity as the time of exposure to the total time. Thus if the period of exposure is equal to the period of eclipse the intensity is diminished 50 per cent. Talbot's Law is utilised in the employment of rotating sector discs to cut down the intensity of light without altering its spectral composition. Contrary to the results of earlier workers,[5] E. P. Hyde [6] has shown that the law holds for all sector openings, at any rate down to 10°, and for all colours.

§ (19) Visual Diffusivity.—The time lag which precedes the perception of light has not so far been measured; but it is easy to measure its variation under different conditions. H. E. Ives [7] has shown that it diminishes as the intensity increases, and increases from the red end of the spectrum to the blue. It is greatest of all for the colourless rod vision, this, in fact, constituting the "after image" which is seen about half a second after a bright flash. Ives shows that these various phenomena are all consistent with the theory that the transmission of impressions from the retina to the brain is in accordance with the physical laws of conduction, the stimulus being transmitted through matter having a coefficient of *diffusivity* which varies with wave-length and intensity. He deduces that for coloured light the diffusivity is a rectilinear function of the logarithm of the stimulus intensity; and the time lag, t, which varies inversely as the diffusivity, $=1/(a \log \mathrm{I}+b)$, a and b being constants for the wave-length concerned. Thus the difference of lag for two different intensities is

$$t_1-t_2=\frac{1}{a \log \mathrm{I}_1+b}-\frac{1}{a \log \mathrm{I}_2+b}.$$

[7] *Phil. Mag.*, 1917, xxxiii. 18.

For two different colours, red and blue say, at the same intensity,

$$t_B - t_R = \frac{1}{c \log \overline{I+d}} - \frac{1}{a \log I+b}.$$

In a series of papers[1] Ives and Kingsbury have shown the importance of visual diffusivity in the theory of the Flicker Photometer.

Many interesting phenomena related to the subject-matter of this and preceding paragraphs have been described by Shelford Bidwell,[2] but a description would be outside our present scope.

IV. Dioptric Properties

§ (20) Accommodation.—The power of the normal eye in repose is approximately 59 diopters. By the process of *Accommodation* the power can be varied at will so as to bring objects at various distances into sharp focus. This power is greatest in children and diminishes regularly with age. Its range is about 10 diopters at 20 to 25, about 2 diopters at 50, and is negligible above 60 years of age. While these figures apply approximately to the conditions of daily use, the actual amount of accommodation called into play is not equal for all parts of the eye, the accommodation at the centre of the pupil being greater than near the periphery. This is due to the fact[3] that during accommodation the anterior surface of the crystalline lens increases in curvature near the centre but actually flattens near the periphery. Nature compensates for this by reducing the size of the pupil when the eye is accommodated for near objects, thereby cutting out the peripheral regions, which would otherwise spoil the definition. If the pupil is dilated by some drug which does not affect the range of accommodation,[4] the deterioration of the definition for near objects is usually marked.

§ (21) The Pupil.—This is the name given to the circular aperture of the eye. It is usually concentric with the optic axis, *i.e.* with the line through the centres of curvature of the various refracting surfaces. The centring of the eye is never exact, though the departures from it are rarely important. The most common defect is that the centre of curvature of the cornea is not on the axis of the crystalline lens. The error may sometimes amount to a quarter millimetre. Occasionally the pupil is displaced outward from the axis. Relatively large defects of centring do not appear to detract from the acuity of vision.

The pupil diameter alters under various influences. The mechanism by which this happens is complex and is not completely understood. As mentioned in the last paragraph it varies with the degree of accommodation and also with the intensity of the light. As regards the former effect, J. W. French[5] found it to be negligible until, for a normal eye, the distance of vision came within about 30 cm. Thereafter the contraction was rapid. In a particular experiment the pupil shrank from 6·5 mm. at 30 cm. to 3·5 mm. at 10 cm.

As regards the second effect French found that the pupil area could be represented over a large range of brightness by the relation

$$A \propto I^{-\frac{1}{5}}.$$

Thus, in order to reduce the area of the pupil by half, the intensity would have to increase thirty-two times. The above equation is for the central area covered by the *macula lutea.* French also investigated the effect on the pupil of light falling on other zones of the retina. The most sensitive zone is the one just outside the macula, the index for this zone being $-\frac{1}{4}$. On going further from the centre the effect diminishes, the peripheral zone being very insensitive. In French's words: "This portion of the retina requires all the light it can get, and the pupil opens out to nearly its maximum diameter and responds but little to variations of intensity."

It is usually stated that the two pupils always vary together, even if the intensity to which they are exposed is widely different. This view is undoubtedly based on considerable evidence under ordinary conditions of vision; but French describes experiments in which one pupil remained of constant size under constant illumination, while the other varied over a wide range under varying illumination.

This independence may not be common to all eyes, but it is evidently unsafe to assume that in all circumstances the two pupils will be of equal diameter.

§ (22) The Line of Sight: Fixation.—When the observer "looks at" a particular object he is said to *fix* it. The line joining the front nodal point of the eye to the *point of fixation* is termed the *line of sight.* The image of the point of fixation is formed on the fovea centralis, but only a very minute area is fixed at a time. In fact, however close two points may be, provided they can be seen as separate points, it is also possible to say that one of them is being looked at rather than the other.

Contrary to what might be expected, the line of sight is not coincident with the optic axis. It is inclined inwards and downwards with respect to it by 5 to 7 degrees. Since it passes

[1] Ives and Kingsbury, *Phil. Mag.*, 1914, p. 708; *Phil. Mag.*, 1916, p. 290; Ives, *Phil. Mag.*, 1917, xxxiii. 360.

[4] *E.g.* cocaine or homatropine.

[5] *Trans. Opt. Soc.*, 1919, xx. 209.

through the front nodal point it does not pass through the centre of the pupil, but through a point about half a millimetre from the centre towards the nose. This is the normal case; in bad cases of excentricity, however, the pupil may be so far off the axis that the ray which represents the line of sight does not enter the pupil at all.

It is difficult to account for the uniqueness of the line of sight and the curious selectiveness by which we can look at *either* of two just separable points and not at *both* simultaneously. It probably arises not from any property of the eye but from the inability of the mind to direct *attention* to more than one point of the image at a time.

The definition falls off very rapidly from the centre of the retina outwards. Few people realise the very bad picture which the eye forms. The fact that we only look at one point at any moment prevents us from realising that the great bulk of the picture is only a suggestive blur; for immediately any part of it attracts our attention we automatically direct the line of sight to it and *fix* it. It is only after some training that an observer is able to give some attention to objects other than the one fixed. This renders very difficult measurements of the properties of non-foveal regions. Only a subordinate degree of attention can be given to the observation, for the primary portion is inexorably demanded by the object at the point of fixation. The moment one gives less attention to this than to the marginal object the line of sight is immediately switched over to the latter, which then ceases to be marginal. This divided attention, combined with the bad definition, renders such observations among the most difficult in physiological optics.

§ (23) The Nature of the Image: Effect of Diffraction.—If optically perfect, and subject only to the limitations imposed by its aperture, the eye could resolve objects 25 seconds apart when the pupil diameter is 5 mm., *i.e.* the image of a point would be a diffraction pattern with a central disc about 50 seconds diameter. According to Hooke, for two luminous points to be perceived separately there must be at least one unaffected cone between those receiving the images. The angular diameter of a cone at the centre of the fovea is about half a minute, so that the images of point sources were really points, the structure of the retina would permit resolution of points about 30 seconds apart. Since, however, the images are discs of appreciable area, the centres of such discs must be further separated in order that there may be a cone between them receiving substantially less light than those on either side.

Hooke found that for very good eyes the minimum separation for resolution is about a minute. This result was confirmed by v. Helmholtz, and is the general experience in the case of acute eyesight.

The size of the diffraction disc is proportional to the wave-length of the light, being nearly twice as great for red as for blue light.

The image of a point is not, however, determined by diffraction alone, being affected by spherical aberration, astigmatism, and chromatic aberration.

§ (24) Spherical Aberration. — The majority of eyes are "under-corrected" for spherical aberration, the marginal portions of the refracting system having shorter focal length than the centre, but various degrees of correction, sometimes even over-correction, are encountered. Frequently there are different degrees of correction in different zones or regions. For instance, aberration may be corrected for one meridian, but under- or over-corrected in the meridian at right angles. Where the pupil is excentrically placed, aberration of opposite signs may be encountered at opposite sides or at the top and bottom. During accommodation for near objects the flattening of the peripheral portions of the lens tends to correct the usual spherical aberration, and may even over-correct it when the degree of accommodation is considerable.

§ (25) Astigmatism.—Nearly all eyes show some astigmatism, or variation of power in different meridians. When at all marked, it results in the image of a point source being no longer a circular disc but a more or less elongated ellipse. Lines parallel and perpendicular to the axes of the ellipse cannot be simultaneously focussed, while lines at intermediate angles cannot be sharply focussed at all. Astigmatism can usually be corrected by means of cylindrical lenses of suitable power suitably orientated with respect to the astigmatic ellipse.

The chief seat of astigmatism is in the cornea, the anterior surface of which may have different curvatures in different directions. The astigmatism is termed *direct* if the greater power is in the vertical meridian, and *inverse* if it is in the horizontal. In other cases it is termed *oblique* astigmatism.

Among a number of persons examined by Nordenson,[1] 9 per cent had no astigmatism, 77 per cent had direct, 1 per cent inverse, and 12 per cent oblique astigmatism. It appears that astigmatism alters with age, the inverse variety becoming more frequent in older people, owing to the increasing tension of the cornea. There is no necessary relation between the astigmatism of the two eyes.

The term *irregular astigmatism* is applied

[1] "Recherches ophtalmométriques sur l'astigmatisme de la cornée," *Ann. d'Oc.*, 1883; *vide* also Tscherning's *Optique physiologique*, p. 117.

to cover any defect of refraction which cannot be corrected by means of a suitable lens. In many cases the image of a point is neither a circular nor elliptic patch, but may be of the most fantastic shapes. If such defects are pronounced the vision is poor and cannot be rendered normally acute with glasses.

We shall see later that astigmatism may seriously affect the judgment in certain optical measurements.

§ (26) Chromatic Aberration.—The eye is only slightly corrected for chromatic aberration. Its chromatic properties are very similar to what they would be if its contents were replaced by water.[1] Usually the actual curves connecting focal length and wave-length are slightly flatter from $\cdot 52\mu$ to $\cdot 66\mu$ than the curves for a simple water eye; but in many cases they are difficult to distinguish. The power for light near the mercury line at $\cdot 436\mu$ is usually about $1\frac{1}{2}$ diopters greater than for yellow light. In ordinary vision the effects of chromatic aberration are not noticed as the eye accommodates so that the brightest part of the spectrum—the yellow green—is in focus, the red and blue rays focussing behind and before the retina. There is therefore a bright image surrounded by a faint purple halo due to the superposed red and blue circles of diffusion. This halo is not noticeable under ordinary conditions; but if only part of the pupil is utilised, as, for instance, when half of it is obscured by a card, effects due to chromatic aberration become manifest. A bright point of light or a luminous line, such as the filament of an electric lamp, appears drawn out into a short spectrum with the red end *apparently* towards the screen, that is with the red rays striking the retina at the other side of the optic axis from the screen. The reason for this is at once apparent when it is borne in mind that the blue rays have crossed the axis before meeting the retina while the red rays have not.

§ (27) Chromatic Parallax.—The experiment just described is even more striking if, instead of employing half the pupil, a slit or "pinhole" about 1 mm. wide is placed in front of the pupil, as far to one side as possible, and two thicknesses of "Cobalt glass" are interposed. The glass transmits a little red light as well as blue, cutting out the central portions of the spectrum. Under these circumstances two separated images of the filament will be seen, one red and one blue. Their positions will obviously be reversed if the hole is moved to the other side of the pupil. Thus on moving the hole to and fro in front of the eye, or moving the eye behind the hole, the red and blue images will move to and fro. This effect has been termed *Internal Chromatic Parallax*,[2] because the separation of the different coloured rays takes place entirely within the eye, the incident pencils being coincident.

If, instead of a single source emitting two kinds of light, we have two sources, one blue and the other red, we may place them at such distances from the eye that both images are focussed on the retina. If the line joining the objects coincides with the line of sight, the images will also coincide. In this case, represented in *Fig.* 7 (*a*), the cones of coloured rays within the eye are coincident. Consequently there is no apparent displacement of the red and blue images on inserting an excentric pinhole in front of the pupil, as in *Fig.* 7 (*b*).

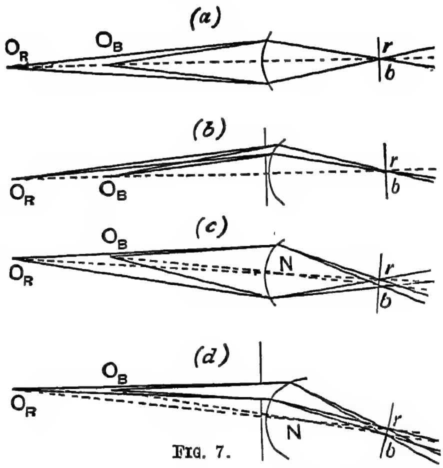

Fig. 7.

If, however, the eye is moved relative to the line joining the objects, a displacement of the images occurs, as is evident from *Fig.* 7 (*c*), each image lying on the line joining its respective object to the nodal point N. Since rays from all parts of the pupil converge to r and b their displacement is unaffected by the interposition of a pinhole; it therefore takes place even if the movement of the eye is behind a fixed stop, *Fig.* 7 (*d*). This phenomenon is termed *External Chromatic Parallax* to distinguish it from the previous case.

It might appear that external chromatic parallax, since it is only evident on moving the eye relative to the line joining two non-coincident objects, is simply the ordinary parallax always observed between objects at unequal distances; but they are in reality quite different, as the effect of a small stop is exactly opposite in the two cases. In the ordinary case when objects at unequal distances from the eye are seen by white light,

[1] P. G. Nutting, *Proc. Roy. Soc.* xc. 440.

[2] Guild, *Proc. Phys. Soc.*, 1917, xxix. 311.

or light of the same colour, the images are also at different distances, the image of the more remote object being in front of that of the nearer object. Also, rays which are coincident in the incident beam are equally refracted, and are therefore coincident within the eye. It follows from these two properties that ordinary parallax will be observed if a small stop is moved across the eye, even if the latter remains fixed, but will not be observed on moving the eye behind a fixed stop. External chromatic parallax, as we have seen, is observed on moving the eye behind a fixed stop, but is not observed on moving the stop before the fixed eye. Like internal chromatic parallax it arises wholly from the different refrangibilities of the two colours.

If we start with two coincident objects of different colours and gradually separate them until they are in the relative positions of *Fig.* 7, the amount of chromatic parallax observable *on moving the stop in front of the fixed eye* will gradually diminish to zero. The amount observable *on moving the eye behind the fixed stop* will be made up of a diminishing amount of internal and an increasing amount of external chromatic parallax. It is easy to show that the total parallax is constant wherever the two objects may be.[1] Chromatic parallax may give serious trouble in spectroscopic work when setting cross-lines on coloured spectrum lines. In well-designed instruments the power of the telescopes employed is about 15 to 20 magnifications for each inch (2·5 cm.) of effective aperture. The "exit pupil" of the telescope is therefore only from 1 to 2 mm. in diameter, and constitutes a small fixed stop through which the objects in the field of view are seen. In making observations on blue and violet lines the observer frequently depends on scattered extraneous light from the brighter portions of the spectrum to provide general illumination for the cross-lines. The cross-lines and spectrum line are therefore seen by light of different wave-lengths, and chromatic parallax effects are produced between them with slight movements of the eye. As we have just seen, this cannot be got over by focussing (that is, altering the relative distances from the eye of cross lines and spectrum line).

Suitable methods of overcoming the difficulty are mentioned in another article.[2]

§ (28) Visual Acuity.—The clearness with which the eye can see detail is termed its acuity. Even when the correctable defects of refraction, such as short or long sight and regular astigmatism, have been corrected by suitable spectacles, there are still considerable variations in the acuity of different eyes.

Acuity is usually tested by means of the Snellen Chart, which consists of a number of rows of letters of different sizes. For unit acuity a row of letters should be legible at such a distance that each letter subtends at the eye an angle of 5 minutes. The lines and spaces composing the letters subtend on an average 1 minute. If a row can just be read when the letters subtend x minutes, the acuity on the Snellen scale is $5/x$. This standard is somewhat low, good eyesight being represented by about 1·5.

The acuity depends on the brightness with which the object is illuminated. Druault found that with a test chart illuminated by 0·016 candle at a metre, the acuity was as low as 0·075. It increased with brightness, rapidly at first and then more slowly. It reached 1·0 for an illumination of 1·5 candle metres, 1·25 at 16·7 and 1·50 at 5400 candle metres. The variation is therefore very slight over an enormous range of brightness.

The diminution of acuity at low intensities is more rapid at the red than at the blue end of the spectrum.

§ (29) Coincidence of Objects in Field of View.—Many important optical and physical measurements depend on the determination of the coincidence of two suitable objects in the field of view of an optical instrument. The setting of telescope cross-lines on spectrum lines, or on the image of a distant staff, are cases in point. With suitable pairs of objects the eye is able to make adjustments of this type with very great precision indeed, provided the necessary precautions are taken to prevent avoidable errors. Many different types of setting are used for various purposes; but it will be sufficient, in order to illustrate the capabilities of the eye in this respect, to quote the accuracy with which want of alignment between two halves of a straight line can be detected. Settings of this kind are met with in the use of scales and verniers, and also in the coincidence type of rangefinder. The field of view of such an instrument is in general divided into two parts by a horizontal line of division. In the upper half one sees the same objects as in the lower half, but upside down. The measurement is carried out by adjusting the two images of the distant object—a flagstaff, for instance—so that one is exactly above the other as indicated by the coincidence of the images at the line of demarcation. J. W. French[3] has investigated the precision with which such settings can be made and the errors to which they are liable. Settings were made with various thicknesses and lengths of line and with various widths of dividing line between the two fields. It was found that under favourable conditions readings could be repeated so closely that the departure of an observation from the mean of a series

[1] Guild, *Proc. Phys. Soc.*, 1917, xxix. 311.
[2] "Spectroscopes and Refractometers."
[3] *Trans. Opt. Soc.*, 1920, xxi. 127.

was only about half a second of arc, or *less than a hundredth part of the displacement necessary for the resolution of two lines.* The precision varies with the angle which the length of the lines subtends at the eye, there being practically no aligning power for lines under 0·6 minute. As the length increases the precision improves up to a length of about 12 minutes, beyond which there is no further improvement. The thinner the lines the more rapidly the final precision is reached, but its actual value is nearly independent of the width of the lines.

The precision is reduced by increasing the width of the horizontal separating line. Thus for a separation of 4 seconds, the limiting value of the mean error was 1·1 seconds, while for a separating line of 19 minutes it was over 5 seconds.

The mechanism by which this close repetition of settings is effected is obscure. In the best case mentioned the two retinal images were evidently always brought into the same relative position to within a sixtieth of the diameter of a cone. This is all the more surprising inasmuch as the setting when made does not really correspond to exact alignment. This is at once revealed by making settings in opposite directions. The difference between such settings is greater the wider the separating line. It may be as little as two seconds for a very fine separation or as much as 40 seconds for a 20 minute separation. Not only so, but the mean of the settings made in opposite directions does not in general give the true setting for actual coincidence. There is thus a "personal equation" which may be many times as great as the maximum variation of individual settings. French traced this error to astigmatism in the eye of the observer. The error is zero when the direction of the astigmatism is parallel or perpendicular to the separating line, and greatest when it is at 45° to it.

It is therefore desirable in making all settings of this nature that the observer should be aware of the direction of any uncorrected astigmatism from which his eye may suffer, and that he should so orient his head as to bring this direction parallel or perpendicular to the lines whose collinearity has to be adjusted.

This aligning power of the eye does not appear to vary greatly with the acuity of vision. Thus French found that in certain experiments the brightness could be reduced 1000-fold without detracting from the precision. The actual illuminations were not stated, but the visual acuity was probably poor at the lower illuminations. This is in accordance with general experience with other types of coincidence setting, in which the definition may become surprisingly poor before the precision of setting is appreciably affected. There is still considerable obscurity as to what property of the eye is responsible for the precision with which these various settings can be made, but it is certain that in many cases the sense of symmetry plays an important part.

Eye, Adaptation of the, in Photometry. See "Photometry and Illumination," §§ (31) and (126).

EYEPIECES

§ (1) Introductory.—Ordinary optical instruments intended to be used as aids to vision, other than those designed to correct individual abnormalities in the eye, are for the most part divisible into at least two portions, the first, called the objective, forming a real image of the object to be examined, and the second, which is used in close proximity to the eye, the eyepiece. Eyepieces in normal use always form virtual images of the real image produced by the earlier part of the instrument, though it is to be observed that regarded as an eyepiece object the earlier image may be virtual. As might be expected from the similar conditions desirable in the emergent rays, very similar constructions in the eyepiece are suitable for use in a wide variety of instruments, and from this circumstance the eyepiece has come to be regarded as an independent optical system which can be transferred as a unit from one apparatus to another without detriment to the perfection of the visible image presented to the eye. For many purposes this is sufficiently nearly the case, and the same eyepiece may be used in a laboratory for widely differing work. When extreme conditions are encountered it is no longer the case that the best results are obtainable from an eyepiece of normal type. It is therefore only within limits that eyepieces may be regarded as separate instruments; beyond these limits the most satisfactory eyepieces must have peculiarities in their design which unfit them for general work while making them excellent for the special purpose for which they are intended. In these cases it is essential that the eyepiece should be regarded as an integral portion of the optical system to which it belongs, and the character of the corrections attained by it will depend upon the division of properties between the objective and eyepiece which the designer finds most convenient under the circumstances special to the particular instrument.

§ (2) Huygens' Eyepiece.—The most familiar apparatus in which separate eyepieces are used are the microscope and telescope, and the kinds of eyepiece most frequently

provided with these are known as the Huygenian and the Ramsden. In their simplest forms both are built of two separated plano-convex lenses. In the Huygenian eyepiece (*Fig.* 1) both lenses present their convex faces to the incident light, their separation is very nearly equal to half the sum of the focal lengths of the components, and the lens nearer the objective, called the field lens to distinguish it from the second lens, which is called the eye lens, is always of greater focal length than the eye lens. For eyepieces of short focal length, suitable for procuring high magnifications, the ratio of the two focal lengths is about 3 : 1, and as the focal length increases this ratio diminishes, until for the

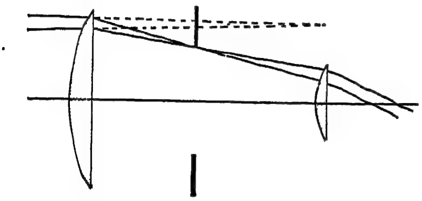

FIG. 1.—Huygens' Eyepiece.

eyepieces of greatest focal length it may be about 3 : 2. Since this inequality involves a real focus for incident parallel light travelling in the reverse direction through the instrument before the field lens is reached, and consequently a virtual final image for that light, this eyepiece cannot be used for the direct examination of a real object, and by analogy with simple lenses has therefore been termed a negative eyepiece. The term is quite inappropriate and misleading, for in so far as "positive" and "negative" are at all suitable for application to optical systems in general they must relate to the sign of the power, which is in this case positive as for each component lens. In fact, if the ratio of the focal lengths is $m : 1$, the elements from which a system of power κ must be constructed are

$$\text{Power of field lens } \frac{2\kappa}{m+1},$$

$$\text{Power of eye lens } \frac{2m\kappa}{m+1},$$

$$\text{Separation } \frac{(m+1)^2}{4m\kappa}.$$

The positions of the principal foci are distant respectively from the field and eye lenses

$$-\frac{m-1}{2\kappa} \text{ and } \frac{m-1}{2m\kappa},$$

the negative sign in the former case indicating that the focus is virtual.

§ (3) RAMSDEN'S EYEPIECE.—In Ramsden's eyepiece (*Fig.* 2) the two lenses are of equal focal length, their separation being somewhat less than the focal length of either, generally from $\frac{3}{4}$ to $\frac{2}{3}$. The most obvious difference,

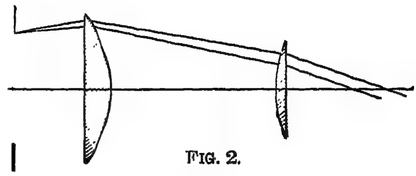

FIG. 2.

however, is that the field lens is reversed, thus presenting its plane side to the objective. If the ratio of the separation to the focal length of a component is n, the data for the construction of a system of power κ are

$$\text{Power of either component} = \frac{\kappa}{2-n},$$

$$\text{Separation} = \frac{n(2-n)}{\kappa}.$$

The principal foci lie outside the lenses at clear distances of approximately $(1-n)/\kappa$ and the eyepiece is very convenient for use in examining a real object. In particular, this property causes it to be generally used in conjunction with a thread micrometer for fine measurements of position.

§ (4) EYEPIECE THEORY.—These two eyepieces seem to have been evolved without the guidance of any adequate theory, and it is thus of interest to consider how they compare with the forms to which present theories would lead. It is to be remarked in the first place that for the attainment of a large field of view the presence of a field lens is necessary, the effect being to bend towards the eye lens rays that would otherwise reach the transverse plane in which this lens is situated at too great a distance from the axis to be transmitted out of the instrument. The eyepiece must thus consist of at least two well-separated lenses, and these will evidently both be of positive power. Another important consideration is that the eye is external to the instrument, and attention is directed to various parts of the field of view by rotating the eyeball in its socket without relative movement of the instrument and the observer's head. The useful rays, therefore, lie within cylinders which pass through the rim of the pupil and have axes through the centre of rotation of the eyeball. It follows that the useful rays from different object-points traverse different parts of the eyepiece, and each separate beam is about the diameter of the pupil, and occupies only a small part of the lens aperture. Under these conditions defects such as spherical aberration and coma, which are of outstanding importance for objectives, become of little moment in

comparison with the defects which do not depend on the width of the beam, such as curvature and astigmatism. Accordingly in eyepieces used under normal conditions, as for high-power telescopes, the primary requisite is a good balance in the curvature corrections, the eyepiece being required to correct the errors of this kind of the objective in addition to its own tendency to produce such defects, while the objective must if necessary be left with small outstanding errors of spherical aberration and coma to correct those of the eyepiece. As is well known, the corrected objective causes the rays to form the focal lines of the issuing beams on two surfaces of curvatures $-\kappa'(\delta'+\varpi')$ and $-\kappa'(3\delta'+\varpi')$, where κ' is the power of the objective and ϖ' is its Petzval coefficient, the value of which is about 0·7.

δ is the quantity denoted by δ_3 in § (17) of the article on "Optical Calculations," and on which the curvature of the image depends. For a lens free from spherical aberration and coma it may be shown that δ is unity. The quantity $\kappa\varpi$, which is given by the equation

$$\kappa\varpi=\Sigma\left(\frac{1}{\mu_{p-1}}-\frac{1}{\mu_p}\right)\frac{1}{r_p},$$

is known as the Petzval sum.[1] κ is the power of the system, and ϖ the Petzval coefficient, which is clearly a pure number. The above expressions should be compared with the quantities $-(\epsilon+\epsilon')/v_3$ and $-(3\epsilon+\epsilon')/v_3$ of the article on "Lens Systems, Aberrations of," and "Photographic Lenses."

Thus for a corrected objective the curvatures are $-\kappa'(1+\varpi')$ and $-\kappa'(3+\varpi')$. These errors would be entirely overcome if the corresponding curvatures of the eyepiece, $-\kappa(\delta+\varpi)$, $-\kappa(3\delta+\varpi)$, satisfied

$$\kappa'(1+\varpi')+\kappa(\delta+\varpi)=\kappa'(3+\varpi')+\kappa(3\delta+\varpi)=0,$$

or $$\kappa'+\kappa\delta=\kappa'\varpi'+\kappa\varpi=0.$$

In fact, the second of these conditions cannot be met, for κ, κ', ϖ, ϖ' are all necessarily positive. The best that can be done is to effect a compromise, and there is no general agreement on the precise form this should take. If the condition

$$\kappa'+\kappa\delta=0$$

is taken, the complete instrument will be corrected for astigmatism, but the field of view will appear to be convex to the observer. As κ' is small in comparison with κ in the cases we are considering, this condition implies a small negative value for δ. The outstanding curvature can be removed at the expense of astigmatism by making

$$\kappa'(2+\varpi')+\kappa(2\delta+\varpi)=0,$$

δ then having a larger negative value. Any particular type of correction may be obtained by securing an appropriate value for δ, but the values corresponding to all types of correction aimed at in eyepieces are invariably negative.

As the contributions to the curvature terms of the various lenses in an instrument are directly additive, it is seen that the condition is most readily met by securing negative contributions from both the field lens and the eye lens. From the result quoted in the case of the objective it appears that the presence of spherical aberration or coma in the eyepiece is a condition essential to the attainment of the required curvature correction.[2] Treating both lenses in the eyepiece as thin, the value of δ, apart from a coefficient which is necessarily positive, is

$$\gamma-2\beta(\mathfrak{S}+S)+2(1+\varpi)\mathfrak{S}S+S^2,$$

or if $s\kappa$ is the curvature added to each surface in deriving the shape of the lens from its standard form,

$$\gamma_0-2\beta_0(\mathfrak{S}+S)-\frac{1}{1+2\varpi}\{(1+\varpi)\mathfrak{S}-\varpi S\}^2$$
$$+\frac{1}{1+2\varpi}\{2(1+2\varpi)s-(1+\varpi)(\mathfrak{S}+S)\}^2.$$

Now for a single thin lens of refractive index μ

$$\varpi=\frac{1}{\mu},\quad \beta_0=0,\quad \gamma_0=\frac{1}{(1-\varpi)^2},$$

and with given values of $\mathfrak{S}$ and S this expression is algebraically a minimum when

$$2(1+2\varpi)s=(1+\varpi)(\mathfrak{S}+S).$$

Consider in the first place the eye lens. For simplicity the direction in which the light travels may be taken as the reverse of that in a complete instrument, so that we are dealing with parallel incident light and a front stop not far from the lens. These conditions give $\mathfrak{S}=1$, while S is negative and comparatively large. The minimum value is thus attained for a negative value for s, so that the surface of greater curvature is towards the objective. The limiting case when the contribution of the eye lens to δ is zero evidently occurs in a single lens when

$$s=\frac{1+\varpi}{2\varpi}\left\{\mathfrak{S}\pm\left(\frac{\gamma_0}{1+2\varpi}\right)^{\frac{1}{2}}\right\},$$

and the shallowest curvatures will be obtained by choosing the negative sign before the square root. If the glass is of refractive index 1·5, so that $\varpi=\frac{2}{3}$, the preferable solution is approximately

$$s=-1\cdot2.$$

[1] This may also be written as $\Sigma\varpi_m\kappa_{m,m+1}$. See "Optical Calculations," § (7), equation (39).

[2] For the values of the quantities β, γ, δ, see "Optical Calculations," § (7), equations (42), (45); § (8), equations (48), (49); and § (17); δ corresponds to the curvature coefficient δ_3 of that article. See also above.

so that the eye lens is meniscus with radii in the ratio 11 : 1, the corresponding value of $\mathfrak{S}$ being $-11/4$. For manufacturing purposes it is preferred to make the outer surface of the eye lens plane, and the small change thus introduced is easily compensated by a slight alteration in the value of $\mathfrak{S}$.

The discussion of the desirable shape for the field lens may follow similar lines. In this case $\mathfrak{S}$ is small and may usually be entirely neglected. The best conditions then require s and $\mathfrak{S}$ to agree in sign, that is to say, the greater curvature in the field lens must be on the side away from the real image. This simple theory thus accounts satisfactorily for the shapes of the lens when simple glasses are used. It will be noted that the determining factor is the positive value of γ_0. Since for ordinary achromatic lenses γ_0 is negative, it would be expected that the substitution of such lenses for the simpler lenses would be unsatisfactory, and this accounts for the unsatisfactory performance of the Kellner

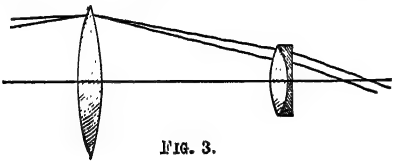

FIG. 3.

eyepiece (*Fig.* 3), which is a modified Ramsden with achromatic eye lens and double convex field (or sometimes plano-convex) lens situated in the plane of the real image. The unsatisfactory features of this objective could be removed by making use of a dense barium crown glass instead of a hard crown in the cemented eye lens, the high refractive index of the crown glass resulting in a suitable positive value for γ_0.

The method of correction which has been outlined obviously provides for the removal of spherical aberration and coma, and a large reduction in the amount of curvature and astigmatism. Of the spherical aberrations there remains distortion. The eccentric paths of the principal rays through the eyepiece inevitably result in the presence of distortion in the visible image, so that straight lines in the object are not represented by straight lines in the image. As long as the defect is not very obvious it is of no consequence, and when a Ramsden eyepiece is employed even pronounced apparent distortion is of no importance for exact measurements. This is evident when it is recollected that the image produced by the objective is free from distortion and that it is actually this image which is measured, the apparent distortion affecting the image and the measuring device equally. It is, however, of interest to remark that if the mathematical conditions for the removal of distortion were satisfied the image would appear distorted. This is because the judgment of the eye in examining the image is influenced by the presence of the unwonted circular boundary by which the visible field is limited, in consequence of which the apparent absence of distortion corresponds in fact to the presence of a very appreciable amount of real distortion.

§ (5) CHROMATIC DEFECTS.—In addition to the removal of the errors which have been mentioned, eyepieces must present to the eye images which appear to be corrected for colour. The complete correction of the system for colour would involve the employment of achromatic field and eye lenses, in addition to an achromatic objective. The insensitiveness of the eye under ordinary conditions to limited errors renders such elaboration unnecessary, and satisfactory results may be obtained for limited fields with the single glass lenses, the cost of which is naturally very much less than that of achromatic lenses. The use of the simple constructions means that only one colour condition can be satisfied. When the final image is at infinity, obviously it is only necessary that the images of different colours should subtend the same apparent angles at the eye. More generally the desirable condition is that the principal ray for a secondary colour should pass through the image for the fundamental colour. Consider now the properties of the Huygenian eyepiece for light of a colour for which the refraction is increased by one part in ν above that for the colour previously considered. The power of each lens is then obtained by multiplying the old value by $1+1/\nu$. The result is readily seen to be that the focal length of the combination is κ as for the original colour, but the focal planes are moved, their distances from the external surfaces being now

$$-\frac{\{m-1+(m+1)/\nu\}}{2\kappa}$$

and

$$\frac{\{m-1-(m+1)/\nu\}}{2m\kappa}.$$

The suggested condition for achromatism is thus met if the objective is at a great distance from the eyepiece when the emergent light is parallel. This is the condition appropriate in high-power telescopes, but for instruments in which the objective is not very distant the best results are obtained by a modified construction, and the altered eyepiece is known as a compensating eyepiece.

In the case of the Ramsden eyepiece the power is not the same for the new colour, the new value being

$$\kappa\left\{1+\frac{2(1-n)}{(2-n)\nu}\right\},$$

and the distance of the principal focus from the nearest lens is

$$\left\{1-n-\left(\frac{2}{2-n}-n\right)\frac{1}{\nu}\right\}\frac{1}{\kappa},$$

and the signs in the two changes are such that the desirable colour correction cannot be effected. The compensation required in the case of the Ramsden eyepiece is thus of a heavier character than with the Huygens, and this may be the reason why of the simpler eyepieces the Huygens is so decidedly favoured where it is possible to employ it, as, for example, in microscopy. For precise work where the Ramsden form is employed one lens is usually compound, an arrangement which enables the desirable conditions to be achieved with ease.

§ (6) Microscope Eyepieces.—The modifications which have been introduced into these lenses either consist in the substitution of a field lens of flint glass for the crown, or in a more elaborate construction. One modification of the Ramsden type has already been described. Another is the form used by Zeiss (*Fig.* 4), illustrated in the accompanying figure.

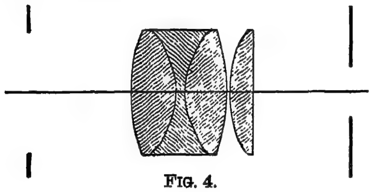

Fig. 4.

For microscopy it is frequently desired in high-power work to use a low-power eyepiece in the first place, and substitute another of high power for more critical examination of the specimen. This interchange is much facilitated if refocussing can be avoided, and Zeiss introduced the modern system of microscope eyepieces in which the image plane is in a corresponding position for all members of the series as they are placed in the draw tube. This convention is now generally followed.

When the magnification is very high the field of view is correspondingly small, and the need for a field lens disappears. Accordingly a number of high-power eyepieces are made of simple achromatic cemented lenses. For these very small fields the correction for curvature remains important, because the very powerful apochromatic objectives which are invariably used for such work suffer from curvature to a much greater extent than do objectives of other types.

§ (7) Erecting Eyepieces.—The eyepieces which have so far been described all yield an inverted image of an external object. For a telescope used for terrestrial objects this is unacceptable, and the image must either be erected by the use of reflecting prisms, in which case a Ramsden eyepiece is suitable, or an erecting eyepiece must be used. The latter consists, as a rule, of four separated lenses, and in the simplest cases these are all lenses of a single glass. When large fields of view are involved at least one of the lenses is of more complex construction. The first erecting eyepiece is due to Dollond, and the best form has been investigated by Sir George Airy (*Fig.* 5). The eyepiece which he recommends is illustrated in the figure, and the data he gives are as follows:

Lens.	Focal Length.	Shape.	Ratio of Radii.	Separations.
1	3	double convex	6 : 1	4
2	4	meniscus	25 : 11	6
3	4	convexo-plane	. .	5·13
4	3	double-convex	1 : 6	

The third and fourth lenses constitute a modified Huygens eyepiece, and their distance from the first two lenses is modified to remove any observable trace of colour in the image.

Airy also investigated in detail suitable forms for the Huygens and Ramsden eyepieces. For the former he concluded that the most desirable construction is

Field lens, $f=3$, meniscus; ratio of radii, 4 : 11,
Eye lens, $f=1$, double convex; ratio of radii, 1 : 6,

with a separation of 2.

§ (8) Special Forms of Eyepiece.—Many variations of these forms of eyepiece have been described, and there is no doubt that excellent results are obtainable by a great variety of constructions, provided these are more complicated than those which have been described here. There is, however, little to be gained by a discussion of such forms, for the best results in all cases will be obtained by considering the complete instrument as a whole. An idea of the forms assumed in cases where this is done may be obtained by reference to the article on "Telescopes." The most notable feature of the newer systems is that every effort is made to avoid the use of lenses for erecting the image, the employment of prisms for this purpose being highly preferable because the image is thereby more easily susceptible of correction for curvature and astigmatism. Whenever possible there is much to be said for the use of simple eyepieces, the brilliancy of the final image varying

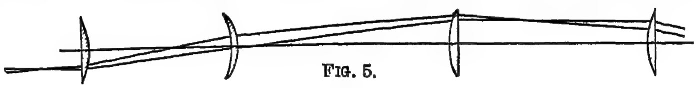

Fig. 5.

inversely with the number of lenses used in the system.

It will be evident from the trend of the foregoing discussion that the circumstances which call for special modifications of eyepiece are abnormally large fields of view and particularly low magnifying powers. In the latter case the conditions for the correction of the image are so different from those at high powers that it may easily occur that the least expensive construction will result from the use of an eyepiece over-corrected for colour and an uncorrected objective rather than the usual reverse arrangement.

The so-called diagonal eyepiece is obtained by inserting an inclined mirror into the path of rays in the eyepiece, the emergent direction of the light being thus inclined, usually at right angles, to the incident direction. It is employed only where a direct eyepiece is inconvenient.

For polarising eyepieces and autocollimating eyepieces see articles on "Microscope" and "Spectroscopes and Refractometers."

§ (9) Variable Power Eyepieces.—An entirely distinct class of eyepiece from any of the foregoing comprises the variable power systems. Their motion is controlled by the rotation of a sleeve in which suitably shaped slots are cut, these serving to give longitudinal movements to the lenses through the medium of feathers which engage in the slots. The lens carriers are, of course, prevented from rotating about the axis of the instrument. In at least one form there is no longitudinal movement of the eye lens as the power is changed, so that the over-all length of the instrument is constant and it becomes more simple than in other cases to prevent the ingress of water or other objectionable material into the interior of the instrument.

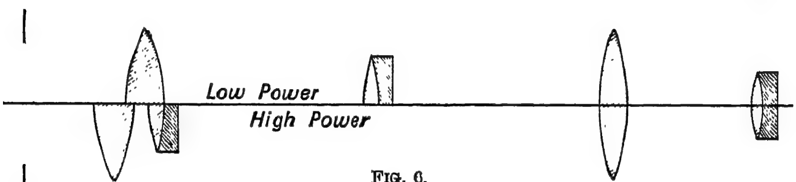

Fig. 6.

The moving systems of lenses which are used in some eyepieces of this class are more allied to photographic lenses than to most other optical systems, and the parallel in the work that has to be performed in the two cases will be realised. The diagrams show two eyepieces of this class, one made by Messrs. Ottway (*Fig.* 6), and the other by Messrs. Ross (*Fig.* 7).

The possibility of constructing a system with two moving parts to give a constant distance between object and image at various magnifications may be seen by considering a system of two lenses of focal lengths f_1 and f_2,

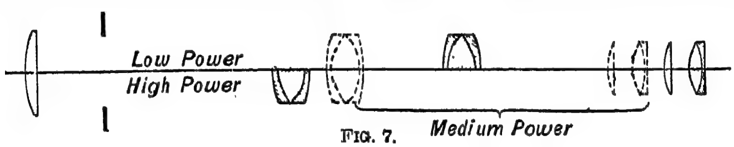

Fig. 7.

eyepieces, in which, by a suitable movement, the extent to which the image is magnified can be varied, the view remaining in good focus throughout the change. The ratio of the highest to the lowest magnifying power is usually from 3 : 1 to 4 : 1. The conditions which have to be fulfilled naturally vary considerably from one another at the extreme ends of the range, the correction of curvature being of outstanding importance at one end, while at the other the extent to which spherical aberration and coma can be tolerated is more limited. The lenses employed necessarily include achromatic combinations, and the power is varied by introducing large changes in the separations of the components. To avoid large changes in the external length of the instrument while maintaining constant focus there must be at least two independent moving the separation of whose inner principal surfaces is t, where

$$t = L \pm \{(L - f_1 - f_2)^2 - (f_1 + f_2G)(f_1 + f_2/G)\}^{\frac{1}{2}}.$$

When the magnification is G, the distance d_1 from the first principal point of the first lens to the object is

$$d_1 = \frac{f_1}{f_1 + f_2G}[L - f_2(1 - G) \mp \{(L - f_1 - f_2)^2 - (f_1 + f_2G)(f_1 + f_2/G)\}^{\frac{1}{2}}],$$

and similarly, the distance d_2 from the second principal point of the second lens to the image is given by

$$d_2 = \frac{f_2}{f_1 + f_2G}[LG + f_1(1 - G) \mp G\{(L - f_1 - f_2)^2 - (f_1 + f_2G)(f_1 + f_2/G)\}^{\frac{1}{2}}],$$

so that $$d_1 + t + d_2 = 2L.$$

These equations suffice for the theory of position of the moving parts when the over-all length is not restricted to a constant value if L is regarded as a variable quantity. It will be observed that in any case the magnification is determined by the focal lengths f_1 and f_2, and the distances of the object and image irrespective of the values of t and L, for

$$\frac{d_2}{f_2}-1=G\left(\frac{d_1}{f_1}-1\right).$$

As the moving lenses form the erecting portion of the eyepiece, G will be negative, so that for any magnification one lens produces a virtual and the other a real image. In the special case $d_1=f_1$, $d_2=f_2$, G is given by the ratio of the two focal lengths. T. S.

GLASS

I. DEFINITION AND CONSTITUTION

§ (1).—No satisfactory, concise definition has been suggested for the term glass, which we use, commonly, to denote vitreous, apparently amorphous, materials, brittle at ordinary temperatures, having a high softening point and possessing the general characteristics of an under-cooled liquid.

There is, however, a gradual accumulation of evidence which seems to suggest that glass, under normal conditions, consists, not merely of a single liquid phase, but of one or more solid phases in fine suspension in the liquid phase or, possibly, in colloidal solution.

We may regard glass, at high temperatures, as being a mutual solution of silicates or of oxides. As the temperature falls we approach a point where the glass becomes saturated with respect to one or more compounds stable at that temperature, and we might expect crystallisation to begin. The viscosity of glass, however, increases very rapidly with a fall in temperature (see "Annealing," § (19)), and it generally happens that the viscosity is too high and the rate of diffusion too low to admit of extensive crystal growth during the short time occupied by the cooling of the glass. If glass is cooled excessively slowly the crystals become visible to the eye: if cooled rapidly no visible crystals are formed, but it is improbable that the viscosity will totally inhibit the formation of crystal nuclei and incipient crystallisation when the saturation point of the glass with respect to one of its constituents is reached. (See also under "Physical Properties," § (21).)

Some glasses, which can be worked in the blow-pipe without crystallisation if they have never been allowed to cool (*i.e.* if the glass is gathered straight from the furnace), crystallise at once if worked after having been cooled and re-heated in the blow-pipe. This suggests that, during the cooling, crystal nuclei have been formed, and these tend to grow as soon as the viscosity falls.

It is found that glasses on cooling show a small evolution of heat when passing through a particular temperature. (This is reversible, an endothermic reaction occurring on heating.) The evolution and absorption is extremely small, and can only be detected with the most sensitive apparatus, but is sufficiently established to point to a small but definite change in the properties of the glass at this temperature.

Interesting evidence bearing on the crystalline nature of glass has been obtained by a study of the phosphorescence of glass when exposed to rays of short wave-length. Many glasses show phosphorescence to a marked extent when exposed to ultra-violet light or to cathodic discharge, and it is found that devitrified glass is strongly phosphorescent. If such a glass, however, is cooled rapidly from a high temperature the phosphorescence decreases, and, if chilled sufficiently to form the well-known phenomenon of a Rupert's drop, the skin appears to be free from phosphorescence although the centre of the drop still glows faintly. It seems probable, therefore, that glass in general contains crystalline nuclei in various stages of development, depending on the composition of the glass and the treatment it has received during manufacture. The effect of the crystalline phase will be considered below under different headings.

II. Historical Note

§ (2).—The discovery of glass has been ascribed both to Syria and to Egypt, and there is still some doubt as to the locality and date of the first glass-makers.

It is certain, however, that the Egyptians in 1400 B.C. were acquainted with the art of glass-making, and specimens of glass, blown with and without moulds, have been found dating from that time. They were also familiar with the technique of cutting and the production of coloured glasses. The art of glazing pottery-ware dates back probably to 4000 B.C.

The Greeks and Romans doubtless learned the art of glass-making from the Egyptians, but the glass industry never appeared to thrive in Greece, probably because of the excellence of their ceramic ware. The Romans, however, acquired considerable skill and were successful in mastering the technology of coloured glass, both clear and opal, although they continued for some time to import glass-ware from Sidon, Tyre, and Alexandria. The Romans worked with a glass of the soda-lime type. The Venetians may be credited with being the first to produce glass at a cost which allowed of its more general use. Venetian glass was characterised by the great beauty of form and lightness of the ware. Since the sixteenth century the Bohemians have also been great glass-makers.

The glass industry was first introduced into England in the thirteenth century, when French glass-workers settled in Surrey and Sussex. The industry flourished until the reign of Elizabeth, when restrictions on the use of timber as a fuel caused its temporary decline. In 1550 a factory making window-glass and drinking-vessels was started in London, and in 1619 the glass industry of Stourbridge sprang up. Stourbridge was particularly suited for glass-making owing to the presence of coal, together with the necessary clay for the manufacture of pots. The glass industry has now spread to all parts of England, but Stourbridge still remains one of the chief centres of the flint-glass industry.[1]

III. Composition

§ (3).—The following are the most common glass-forming oxides:

Acidic: Silica; Boric acid.

Basic: Sodium oxide (Na_2O); Potassium oxide (K_2O); Oxides of Barium, Calcium, Magnesium, Zinc, Manganese, Lead, Aluminium, Iron.

In addition to these, the oxides of arsenic, lithium, tin, and zirconium, and the elements fluorine and selenium, are introduced into

[1] See *Encyclopædia Britannica*, 11th edition.

glass for special purposes, and, for the manufacture of coloured glasses, the oxides of nickel, cobalt, chromium, copper, uranium, and the elements carbon, sulphur, silver, and gold are employed.

Probably over 99 per cent of the glass manufactured in the world is composed of a combination of silica with a mixture of two bases, an alkali (soda or potash), and either lead oxide or lime, 90 per cent being made from silica, soda, and lime only. Window glass, plate glass, and bottle glass-ware are made from silica, soda, and lime. Alumina is occasionally added to give greater strength and stability. Bohemian glass-ware is made from silica, potash, and lime, and flint glass for table-ware, cut glass, electric light bulbs, etc., contains silica, lead, and soda or potash. Occasionally magnesia or baryta is substituted for lime or baryta for lead oxide.

For glasses requiring special properties, resistance to attack by chemical reagents,[1] resistance to sudden changes of temperature, etc., magnesia, zinc oxide, and alumina are introduced and boric acid (B_2O_3) is substituted for part of the silica. Glasses free from silica are found to be insufficiently stable for general use. In following column is given a Table of Analyses of typical glasses.

	SiO_2.	B_2O_3.	Na_2O.	K_2O.	CaO.	MgO.	BaO.	ZnO.	Al_2O_3.	Fe_2O_3.	PbO.	As_2O_3.	P_2O_5.	MnO.	Sb_2O_3.	Total.

IV. Raw Materials

The sources of raw materials available for glass-making depend largely on the type of glass for which it is intended, since the small amount of impurities which can be permitted in better qualities of glass excludes a large quantity of material which would otherwise be suitable.

§ (4) Silica is almost invariably introduced into glass in the form of sand. Deposits of sand suitable for glass-making are found in many parts of the world. The chief requirements for a glass-making sand are freedom from iron and evenness and angularity of grain. For the manufacture of bottles, etc., uniformity in grading is the most important feature, the iron content being of less importance, whereas for "white" glass (or "flint" glass, the name now used to denote glass free from colour), such as chimneys, pressed ware, table glass, etc., chemical purity is equally essential. 90 per cent of the sand grains should lie between 0·5 and 0·1 mm. in diameter. Many sands are found containing 99 per cent between these limits. Sands graded between smaller limits 0·5 and 0·25 mm. are to be preferred, and it is not uncommon to find sands containing over 50 per cent between these limits. In America graded sands considerably coarser than this are sometimes used.

[1] See article "Glass, Chemical Decomposition of."

The best European deposits are at Fontainebleau near Paris, and Lippe, Saxony. These contain over 99·7 per cent of silica and less than 0·03 per cent of iron oxide; they are remarkably uniform in composition and grain size. Next in order of merit come the Belgian sands, notably at Epinal (below 0·05 per cent of iron oxide). Fair quality Dutch sands are also found.

Some of the British sands have a low iron content, but, in general, the sand is not so uniform in quality as that of Fontainebleau. Good deposits are found at Lynn, Aylesbury, Muckish Mount, Huttons Ambo, Burythorpe, and other places.[1]

For the manufacture of bottles sands rich in alumina are useful.

A number of good deposits of glass sands are found in America, notably in Illinois and West Virginia.

§ (5) ALKALIS.—(i.) *Sodium oxide* is generally derived from sodium carbonate ("soda ash") obtained from the Le Blanc or ammonia soda process, or sodium sulphate ("salt cake") obtained from the Le Blanc process. Until recently, owing to its relatively low cost, salt cake was largely used as a source of soda, but its use is attended by various disadvantages. It is usually contaminated with chlorides, and occasionally free sulphuric acid, and it is not easy to remove all the sulphates from the glass during manufacture. The chlorides and sulphates tend to produce a milky appearance in the glass. A high temperature is necessary to decompose the salt cake, the decomposition being assisted by the addition of carbon to the batch; the presence of carbon, however, makes the use of a "decoloriser" extremely difficult. Another disadvantage in the use of salt cake is that the walls of the furnace are seriously corroded along the "flux line" (at the surface of the glass) by the alkali which floats on the surface of the half-melted batch.

Soda ash, though formerly expensive, is now cheaper than salt cake and is becoming more popular owing to the inconveniences inherent in the use of salt cake. With soda ash as the source of alkali, however, it is difficult to melt glasses rich in silica and lime without the formation of a scum rich in silica which floats on the surface of the glass. A common practice is to use soda ash with the addition of the minimum amount of salt cake to prevent the formation of the scum.

Small quantities of soda are also introduced in the form of sodium nitrate for the purpose of oxidising any organic matter, ferrous iron, etc., that may be present in the glass, and of securing the oxidising conditions necessary for melting batches containing lead, which is easily reduced.

(ii.) *Potash* is universally added in the form of potassium carbonate ("pearl ash"). This can be obtained commercially in a state of reasonable purity. Pearl ash is highly hygroscopic, and careful analytical control is necessary if potash glasses are required to be of constant composition. Potassium nitrate (saltpetre) is also used in small quantities.

(iii.) *Felspar* (K_2O, $Al_2O_36SiO_2$) is occasionally used as a source of alkali where the presence of alumina is not considered disadvantageous, and, for cheap glass-ware, bottles, etc., rocks such as granite and basalt are sometimes used.

§ (6) LIME is usually added in the form of ground chalk, lime spar, or limestone rocks. In glasses containing magnesia dolomite provides a convenient source of lime and magnesia. Where greater purity is required, precipitated calcium carbonate can be obtained.

§ (7) BARYTA.—The cheapest source of barium oxide is the mineral witherite, $BaCO_3$, which can be obtained in sufficient purity for the manufacture of some glasses, pressed glass, etc. For optical glasses chemically prepared precipitated $BaCO_3$ or $Ba(NO_3)_2$ is used.

§ (8) LEAD OXIDE is usually added in the form of red lead (a mixture of PbO and Pb_2O_3, corresponding roughly to Pb_3O_4). Red lead varies somewhat in composition, free lead and lead sulphate are sometimes present, and the moisture content is variable. It is desirable that the maximum amount of Pb_2O_3 be present to facilitate oxidising conditions. Litharge, PbO, is sometimes used in the batch, but, owing to its low oxygen content, it is not desirable.

§ (9) MAGNESIA.—The chief sources of magnesia are dolomite (calcium and magnesium carbonates) and magnesite ($MgCO_3$). These minerals are obtainable in reasonable purity and are used in considerable quantities. For special purposes precipitated magnesia is used.

§ (10) ALUMINA.—For the best glasses the sources of alumina are plentiful, china clay, felspar, etc. There is some difficulty, however, in obtaining a cheap form of alumina for the manufacture of common glass bottles, where the low cost of the batch makes the addition of felspar too expensive. This is unfortunate, since the presence of alumina in glass increases the durability both mechanically and chemically.

§ (11) BORIC OXIDE (B_2O_3), an ingredient of many optical and resistance glasses, is introduced either as boric acid (H_3BO_3) or as borax.

§ (12) MISCELLANEOUS INGREDIENTS.—For the manufacture of opal glasses fluorspar (CaF_2) and cryolite (AlF_33NaF), both natural and artificial, are used. Calcium phosphate is also used for this purpose.

Other materials required in glass-making are used in the form of chemically prepared com-

[1] P. G. H. Boswell, "British Glass-making Sands"; C. J. Peddle, "British Glass-making Sands," *Jour. Soc. Glass Tech.* i. 27.

pounds, since they are only required in small quantities, and the cost is therefore unimportant.

§ (13) Arsenic.—White arsenic or arsenious oxide (As_2O_3) is the usual source of arsenic for the glass industry. Arsenic is introduced into both oxidising and reducing batches with apparently beneficial results. It appears to accelerate the removal of bubbles from the glass and, also, to assist "decolorisers" in their action.

It is probable that under oxidising conditions the arsenic is oxidised at low temperatures to As_2O_5, and at high temperatures this oxide tends to decompose, forming As_2O_3 and liberating oxygen which sweeps out the small bubbles from the glass and also oxidises the manganese and iron, giving the condition required for successful "decolorising." Under reducing conditions metallic selenium is generally used as a decoloriser. A part of the arsenic is reduced to metallic arsenic, which is volatile, and thus sweeps out the bubbles with a reducing vapour which tends to keep the selenium from becoming oxidised.

Analyses of glasses made from batches containing nitrates show that from 10 per cent to 20 per cent of the arsenic may be lost during melting, and, of the arsenic remaining in the glass, from 80 per cent to 90 per cent is in the pentavalent condition. Similar glasses melted without nitrates lose from 30 per cent to 40 per cent of the arsenic during the melting process, and only 60 per cent of the remaining arsenic is in the pentavalent condition.

V. The Manufacture of Glass

It is not possible here to describe in any detail the manufacture of glass, since the process varies very considerably with the type of glass made and the use for which it is intended. The general outlines are given below.

§ (14) The Preparation of the Batch.—The term "batch" is used to denote the ingredients of the glass mixed in the required proportions and ready for melting. The success of the melting operation and the quality of the glass obtained depends very largely on the care taken in the preparation of the batch. Many manufacturers do not sufficiently realise the importance of this side of the glass works. The raw materials should be well ground. Even grading is as important as the actual fineness of division. The sand, and occasionally other ingredients, are dried; in some works the sand is roasted to a red heat before use. The various constituents are then weighed out and fed into a mechanical mixing machine, which delivers the mixed, sieved batch into a container in which it is conveyed to the furnace. In some up-to-date, well-organised works elaborate plant is used to carry out these operations, and the weighing, mixing, and conveying of the batch is effected automatically. Many works are to be found, however, where the batch composition is estimated by volume—in some cases the shovel being the unit of volume—and the mixing carried out by hand.

§ (15) Furnaces and Melting Process.—Two entirely different methods of melting are employed according as the glass is contained in crucibles (or "pots") or in a tank.

(i.) *Melting in Pot Furnaces.*—The pots used to contain the glass during melting are of two kinds, open and closed. The open pot is a cup-shaped vessel, anything up to 5 ft. in diameter and 5 ft. high (or even larger), containing, when full, from 2 cwt. to 2 or even 3 tons of glass.

The closed pots are similar to the open ones except that they are fitted with a dome or hood which has an opening on one side through which the batch is charged, and the finished glass subsequently gathered. This hood, which projects through the wall of the furnace, serves to protect the glass from contamination by the furnace gases.

One furnace may contain several pots, from 2 up to 20 or more. The furnaces are usually fired with producer gas, although direct coal-fired furnaces are still found in some parts.

Great care has to be exercised in the manufacture and subsequent handling of the pots. These are made from carefully selected fire-clays (see "Glass-house Refractories," Vol. V.). The raw clays are mixed with a quantity of burnt clay, to reduce the shrinkage on firing, moistened, and allowed to mature for some months. The pot is then built up slowly by hand. The pot-maker first moulds a disc to form the bottom of the pot and then proceeds to build up the sides; not more than 6 in. or so of wall can be added at a time, since the plastic clay is not strong enough to support the weight of the whole side. The pot has, therefore, to be built in stages with an interval of a day or two between each stage. In some works plaster or wooden moulds are used to support the pots during their manufacture. Open pots are occasionally made by the casting process (see "Glass-house Refractories," Vol. V.). When the pot is completed it is allowed to dry slowly. The temperature of the drying-room is carefully regulated and precautions are taken to prevent draughts. When the pots are dry, a process which generally takes some months, they are removed from the drying-room when required for use and placed in a small kiln (the "pot arch"), in which they are brought slowly up to a red heat. Very great caution is required in the initial heating, and the correct rate of rise of temperature, which varies with different clays, must be maintained carefully. The temperature to which the pot is taken in the pot arch varies considerably in different

works, and frequently 900° C. is not exceeded. It is better practice, as a rule, to run to considerably higher temperatures. When the pot arch is at its maximum temperature, the pot is taken out and transferred as rapidly as possible to the melting furnace. For this purpose the brick work in the front of the melting furnace is removed, leaving a hole sufficiently large to admit the pot. When the pot is in position in the melting furnace, the wall is bricked up and the temperature raised. In the best practice the pot is heated to a temperature considerably higher than that required for the melting of the glass, since the life of the pot is prolonged if it is well "vitrified" before the glass is charged into it. In many works, however, the pot is not subjected to this preliminary heating and the glass is introduced as soon as the pot reaches the melting temperature of the glass, with the result that much unnecessary corrosion of the pot takes place.

The raw materials are mixed with a quantity of previously-melted glass of the same composition (cullet). This greatly facilitates the melting process. The pot, when ready for filling, is first glazed with cullet to protect it from the direct contact with the raw materials, particularly the alkali, which has a powerful fluxing action on the clay. The pot is then filled with the raw material and cullet. Since there is a considerable diminution in bulk when fusion takes place, several fillings are required to yield a pot full of molten glass. The method of filling varies somewhat in different works. Sometimes great care is taken to prevent the batch from touching and chilling the walls of the pot. In this case the batch is piled up in the form of a cone and as many as six or more fillings are made. In other works the batch is shovelled on quickly, two fillings, or occasionally, with lead batches, one filling, being considered sufficient.

The contact of the damp material with the walls of the pot and the consequent chilling of the inside frequently gives rise to small cracks in the pot walls (known as "batch cracks"). These increase in size at each filling and often cause the ultimate failure of the pot.

The reactions which occur during fusion are complex and imperfectly understood. The order in which the various changes take place is roughly as follows. The moisture and combined water is expelled from the batch:

Alkalis in the form of nitrates melt	320°
Magnesium carbonate decomposes	350°
Red lead decomposes, forming litharge	500°
Boric oxide melts	577°
Barium carbonate melts	795°
Potassium carbonate decomposes	810°
Calcium carbonate decomposes	825°
Sodium carbonate melts	849°
Litharge melts	877°
Potassium oxide melts	880°

Complex eutectics are formed, in which the oxides having high melting-points are slowly dissolved. The ease with which the glass melts depends largely on the viscosity of these eutectics. Owing to the low diffusivity of the mixture a very large temperature gradient is set up in the batch, and, in consequence, all the possible physical and chemical changes occur simultaneously in different parts of the pot, and many bubbles of gas, water, carbon dioxide, etc., are entrapped in the molten glass. The raw materials of the glass are eventually dissolved, and the bubbles of gas rise slowly to the surface at a rate depending on the square of their diameter, the viscosity and density of the glass. By a judicious choice of raw material and temperature of melting it is possible to arrange that only large bubbles remain in the glass at the end of the fusion, and these rise to the surface in a few hours and burst. If for any reason small bubbles (technically known as seed) are formed, the glass-maker frequently has to introduce large bubbles to sweep the small ones to the surface. For this purpose it is common practice to plunge a potato, on the end of an iron rod, to the bottom of the pot. The moisture and organic matter, which is given off violently, effectually removes the small seed. Nitrates and arsenic are sometimes used for this purpose.

To facilitate the removal of the bubbles (a process commonly known as "fining"), the temperature of the furnace is raised. With the diminution in the viscosity of the glass, the corrosion of the pot becomes severe. The glass in contact with the pot walls dissolves the material of the pot, the resulting glass having a density different from the mean density of the melt. Currents are therefore set up and, since the density of most glasses is greater than that of the pot used, these currents, caused by the solution of the pot in the glass, flow up the sides of the pot. As the glass rises, it becomes richer in pot material, and, consequently, less active as a solvent, with the result that the attack of the glass on the walls of the pot is greatest at the bottom and a taper is produced in the pot.[1]

There are other factors which affect the rate of corrosion (apart from the imperfections in the pot itself), *i.e.* the temperature distribution in the furnace, since it is possible for large convection currents to be set up if the bottom of the pot is heated locally. (See "Glass-house Refractories," Vol. V., for further details on the properties and behaviour of glass-house pots.) The presence of these convection currents is important, since the rate of solution of the

[1] Coad-Pryor, "Notes on Pot Attack," *Jour. Soc. Glass Tech.*, 1918, ii.; and Rosenhain, "Some Phenomena of Pot Attack," *Jour. Soc. Glass Tech.*, 1919, iii.

pot in the glass depends largely on the rate at which the glass rich in dissolved pot material can be removed from the vicinity of the pot and fresh glass brought in contact with it. The presence in the glass of an excess of silica and alumina derived from the pot increases the viscosity greatly, giving rise to a corresponding diminution in the rate of diffusion, and, but for this formation of currents, the pot might reasonably be expected to last for years instead of months as is actually the case.

The formation of sillimanite crystals (Al_2O_3, SiO_2) in the pot appears to exert a marked beneficial influence on the rate of solution.

During the "fining" process samples (proofs) are taken from the pot on an iron rod and, from these samples, the expert glass-maker can decide when the "metal" is ready for working or gathering. When the glass is fine (free from bubbles and raw material) the temperature is lowered until the viscosity suitable for gathering is reached. The glass is still far from being homogeneous, the lower portion being considerably denser than the upper, and the parts near the sides being richer in silica and alumina (derived from the pot) than the central portion of the pot. However, for all purposes except for optical instruments, the glass is considered good enough for use.

(ii.) *Melting in Tank Furnaces.*—For the production of cheaper kinds of glass where mass production is essential, "tanks" are invariably employed for melting purposes. A tank consists of a fire-brick chamber which may vary considerably in size according to the output required, their capacity ranging from two to over a thousand tons of glass. The ratio of length to breadth is roughly three to two, average dimensions being from 12 to 18 ft. wide, 24 to 36 ft. long, and from 30 to 44 in. deep. The bottom and sides of the tank are usually constructed of firebrick or refractory stone and the crown of silica brick. The gas and air enter by ports arranged along the side of the tank and the combustion takes place over the surface of the glass, the products of combustion passing out on the opposite side by flues leading to the regenerators, which are usually situated below the tank.

The dimensions of the tank and the distribution of temperature are so contrived that the raw materials are fed on at one end of the tank, melt and flow slowly down the tank, and, by the time the glass reaches the other end, it is fine and ready for working.

This procedure is more economical than melting in pots, since the glass is exposed to the direct heat of the flame. The process is continuous and the glass may be worked day and night without cessation. The refractory materials are more durable, since, in the places where they are in contact with the glass, they are always cooler than the glass, whereas, in a pot furnace, the heat has to be transmitted through the pot walls.

Frequently the most vulnerable parts of the tank are water- or air-cooled on the outside and, consequently, the tank is practically lined with a layer of glass too viscous to attack the refractories at an appreciable rate. In some works the whole of the furnace walls are water-cooled, and, in such furnaces, the rate of solution of the refractories is extremely slow.

No thermal convection currents are found in the glass in a tank, since the heating is from above, and we find, therefore, that the tank blocks wear away first near the surface of the glass, the attack on the blocks diminishing with the temperature as the depth below the surface of the glass increases. The blocks forming the bottom of the tank may last for some years, but the side walls, near the surface, seldom last for more than a year, often less.

In a furnace melting flint (colourless) glass the serious corrosion extends to a depth of perhaps 18 inches or 2 feet; with deeply coloured glass, an amber or dark green, the attack of the glass on the sides of the tank 8 or 10 inches below the glass level is slight.

During the melting process, in both pots and tanks, it is frequently found that a scum is formed on the surface of the glass. In pots, the glass is skimmed before the gathering of the glass is commenced; in tank furnaces, to meet this difficulty a wall or bridge is generally built across the tank, shutting off the working end from the melting. This bridge, which projects a few inches above the surface of the glass, retains the scum and the surface layer of the glass generally rich in silica, and allows the clear glass below to flow into the working end through a hole in the bridge near the bottom of the tank. The attack of the glass on the bridge is severe, and it is generally necessary to cool it by building it hollow and maintaining a circulation of air or steam in it. The cooling of the orifice through which the glass flows presents special difficulties, since severe chilling will cause obstruction due to high viscosity of the glass. Various devices have been adopted to separate the working end from the melting end of the furnace, since the temperature suitable for gathering the glass is lower than that required for melting. Thus the bridge is sometimes continued right up to the crown of the furnace, the part above the glass level being built in chequer work to cut down the radiation from the melting end. Again, a separate chamber connected to the melting tank by means of a clay syphon has been used. Sometimes small covered pots (generally known as "potettes") are built into the working end of the furnace with their hoods projecting through the furnace walls in a manner similar

to pot furnace practice. These potettes are drilled near the bottom, below the surface level of the glass, to allow the glass from the tank to flow into them. When working with potettes a bridge in the tank for skimming purposes can be dispensed with.

§ (16) DEFECTS. (i.) *Stones.*—If the process of manufacture outlined above has been carried out successfully, glass is obtained in the pot or working end of the tank free from bubbles and undissolved material and reasonably uniform in composition. There are various defects, however, which are frequently found which have arisen through accidental causes or through carelessness on the part of the operators. Of these perhaps the most common is the disease known as "stones." These consist of solid particles which have not been taken into solution in the glass, and may be caused by drips from the crown of the furnace or particles of refractories from the walls which have become undermined and detached. Stones may also be formed if parts of the furnace have been allowed to become too cool, when "devitrification" or crystallisation of the glass may result. These crystals, when once formed, are only dissolved with difficulty and, in consequence, give rise to stones. One of the most prolific sources of stones is the inclusion in the batch of coarse particles of raw material, such as limestone.

(ii.) *Striae.*—Another common defect is the presence of striae or "cords," which consist of veins of glass of a different refractive index from that of the rest of the glass. Strictly speaking, striae are always present in any but the best optical glass, although, for most purposes, they are sufficiently small to pass unnoticed. They are produced by imperfect mixing of the batch or contamination of the glass by the walls of the pot or tank. Stones always give rise to striae, which persist in the glass after the stones have disappeared. Striae are also found if the furnace has been allowed to run cold during the melting, when the high viscosity has hindered the diffusion of the constituents.

(iii.) *Seed.*—The presence of fine bubbles, or "seed" as they are called, in the finished glass is a defect sometimes found. Bubbles, which should have been removed during the fining process, are sometimes found in the glass owing to inadequate control of the temperature during founding or to an attempt to increase the rate of production beyond the working capacity of the furnace.

Seed may appear, however, at a later stage, after the glass has once been fine. This phenomenon is common in amber glasses where the colouring has been produced by carbon, probably in colloidal solution. Under certain conditions a rise in temperature or mechanical agitation may cause an evolution of gas. A similar effect is said to occur in cobalt blue glasses. Again, with some glasses, certain gases appear to be more soluble at high than at low temperatures, and on cooling bubbles are evolved. By successively cooling and heating the glass for a number of times the quantity of gas in solution can be diminished, and a marked improvement is observed in the tendency of the glass to devitrification. It has been shown that glass, under normal conditions, can hold in solution considerable quantities of gas. Allen and Zies obtained from 6·5 grms. of glass 6·5 c.c. of gas having the composition: oxygen, 64·2 per cent; carbon dioxide, 24·2 per cent; carbon monoxide, 3·5 per cent; hydrogen, 3·9 per cent; nitrogen, 4·1 per cent; and instances have been given where glass on cooling has liberated many times its own volume of gas. All glass, as usually made, contains a large amount of dissolved water vapour, far in excess of other gases found in glass. This is evolved copiously on heating the glass to 300°-400° C. or over, under reduced pressure.

So-called "vacuum bubbles" are formed where the surface of the glass is chilled rapidly, forming a surface crust, while the centre is still hot. As the interior of the glass shrinks a high state of tension is produced and minute bubbles may swell to a large size.

(iv.) *Colour.*—A frequent source of trouble to the glass-maker is the control of the colour of the glass. Iron is always present in the raw materials and refractories, and, when present in an excessive amount, produces a colour which varies from a yellowish green to blue according to the state of oxidation of the iron and the composition of the glass. The remedy for this is, of course, to use materials as pure as possible, but, for most commercial purposes, raw materials free from iron are much too costly. To mask the iron green, a colouring agent which gives the complementary colour, pink, is added to the batch. Of these "decolorisers," the most usual reagents are manganese (used with batches worked under oxidising conditions) and selenium (for reducing conditions), often in conjunction with small quantities of chromium, nickel, and cobalt. The colouring effect due to the presence of iron is less when the iron is in the trivalent condition, and hence the presence of nitrates in the batch improves the colour, since oxidising conditions are then attained. It is not usual to attempt to decolorise glasses containing more than 0·2 per cent of iron calculated as Fe_2O_3; a higher content of iron gives a glass which, when decolorised, has a perceptible grey tint.

A good "flint" soda-lime glass may contain

about 0·11 per cent Fe_2O_3, and a lead flint glass for cut glass table ware may contain 0·03 per cent Fe_2O_3 or even less.

Arsenic is also introduced into the glass to facilitate the action of decolorisers. The chemistry of this action presents some difficulties. (See "Raw Materials," "Arsenic.")

§ (17) Optical Glass.—The standard of quality required in glass for optical purposes makes the manufacture of optical glass a special process. The glass requires to be carefully stirred to produce the necessary homogeneity, and, even then, it is considered a good yield to obtain 20 per cent of good glass out of the pot. For this purpose a clay stirrer is introduced into the pot as soon as the glass is fine, or sometimes at an earlier stage, and the glass is slowly stirred. This operation is carried out mechanically, the clay stirrer being manipulated by means of an iron rod. It is necessary to stir as the temperature falls, until it is no longer possible to continue owing to the high viscosity. The stirrer is then either removed or allowed to remain in the glass near the side of the pot. The rate of stirring permissible varies within narrow limits, and has to be regulated carefully as the glass cools. At the end of the stirring operation the pot is removed from the furnace as quickly as possible and allowed to cool rapidly. With some glasses which tend to devitrify it is necessary to chill the glass by spraying water on to the outside of the pot. When sufficiently cold the pot is broken up and the glass carefully examined, those pieces which are considered free from striae and other defects being reheated to the softening point of the glass and moulded into rectangular blocks or lenses. The blocks are then annealed (see "Annealing," § (10)), and finally ground and subjected to further inspection.[1]

§ (18) Manipulation.—The general principles of glass-blowing are well known and have been described frequently.[2]

A brief outline of the processes in use at the present day is given below.

(i.) *Hollow Glass-ware.*—Although glass made by mechanical means has displaced in many cases the hand-blown articles, it is difficult to obtain by machinery the excellent finish which can be produced by a skilled glass-blower. The automatic production of unsymmetrical shapes, *i.e.* water jugs with handles and spouts, and complicated pieces such as wine-glasses, presents serious difficulties, and, at present at any rate, the supremacy of hand-blowing for such ware is unchallenged.

The blowing of a large glass article is generally carried out by a team of men or boys, who constitute a "chair." As a rule, two men and two boys make up a chair, although, for some work, only three persons are employed. In some works there is a tendency to increase the number of men to a chair, since, by so doing, the work becomes more highly specialised, and each man, in consequence, more efficient at his small contribution, and the highly skilled labour economised.

The glass-blower's equipment is simple, the most important item being the stool on which he sits. This consists essentially of a small wooden bench provided with arms on each side which project in front and behind him.

The "gatherer" first takes the blowing-iron, an iron tube about 5 ft. in length, which has previously been heated, and dips the end in the glass with a circular motion, withdrawing it with a ball of glass adhering to it. He then rolls the glass on an iron plate (the "marver") in such a way as to obtain a symmetrical shape in the glass on the blowing-iron. During this operation the glass has become chilled and stiff to work. He then dips it again in the pot, gathering more glass and marvering as before. This process is repeated until the required weight of glass has been collected on to the blowing-iron. From time to time the gatherer blows gently down the tube, expanding the glass on the iron into a pear-shaped mass. He then hands the iron to the glass-blower, the head of the "chair," who sits on his bench and places the blowing-iron across his knees, resting it on the arms of the chair. Since the glass is mobile during the blowing operation it is necessary to keep the iron constantly revolving to prevent the gathering from losing its symmetrical shape. The blower, by rolling the iron along the arms of the chair with one hand, is able to effect this, and, holding his tools in the other hand, he can shape the article as though the iron were in a lathe.

The glass-blower's outfit consists of a pair of shears or scissors, a palette or "battledore" (a small wooden board with a handle), a pair of tongs, calipers, a foot-rule, and an iron bar or file.

In the process of blowing hollow ware such as a jug or decanter, he rests the iron on one arm of the chair and blows until the desired size of bulb is obtained. He then shapes the bottom and sides of the jug by revolving it on the two arms, as indicated above, with one hand, and pressing the glass into the required shape with the palette, and checking the dimensions with the calipers.

[1] Series of papers issued from Geophysical Laboratory, Washington, on optical glass; Rosenhain, *Glass Manufacture*, ch. xiv.; Rosenhain, *Optical Glass: Cantor Lecture to Royal Soc. Arts*.

When he has trued the bottom of the jug, one of his assistants takes an iron rod—the punty (also known as the pontee, ponty, or puntee)—gathers a small amount of glass on the end of it, and then presses this on to the centre of the bottom of the jug. The glass on the punty adheres to the jug; at the same time the blower touches the glass at the end of his iron with the cold iron bar, and the jug breaks off the blowing-iron and remains attached to the punty. The assistant then reheats the jug, which has by this time become set, in a small furnace, the "glory hole," and when it has softened again returns it to the glass-blower, who revolves it rapidly on the bench. The centrifugal force causes the hole at the top of the jug (where it was originally attached to the blowing-iron) to open out. The blower trims the end with the shears, and then, rotating it, forms it into the desired shape with the help of his tongs. In this manner, with modifications suited to the type of article being made, all kinds of hollow glass-ware can be blown. In many cases the process of blowing may be simplified by the use of an iron mould made in two parts, with an opening at the top, so constructed that the blower can open and close the mould by means of a lever operated by his foot. He blows a pear-shaped bulb which he holds vertically for a second or so until an elongated neck is formed; he then introduces the bulb into the open mould with the neck protruding through the hole in the top. The mould is then closed, and the bulb blown up until it fills the mould. When the glass has set, the mould is opened and the finished article is removed and cracked off the blowing-iron. During the blowing up in the mould the blower spins his blowing-iron, rotating the glass in contact with the mould, and by this means prevents a mark from the joint in the mould being imprinted on the glass. Bottles, etc., not spun in this way always show a mould mark.

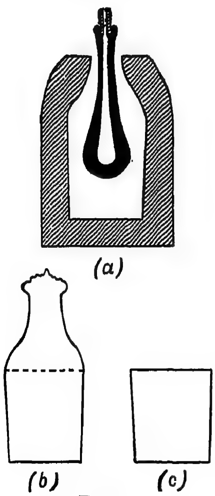

FIG. 1.

Fig. 1 (*a*) shows a diagram of a section through a mould for blowing a laboratory beaker or a tumbler, and (*b*) and (*c*) show the successive stages; (*b*) shows the tumbler as it leaves the mould. After annealing it is placed on a revolving disc, so arranged that a pointed flame plays on the glass (along the dotted line) as it revolves; the glass is then removed from the flame and touched with a cold, pointed, steel rod at any spot on the ring heated by the flame. If the glass has been well annealed, it will crack evenly along this line, leaving the tumbler as in *Fig.* 1 (*c*). It is then placed on a revolving disc or clamped to a rod which can be made to rotate horizontally, and the rim is heated until the glass softens and a smooth edge is produced by the surface tension. When the lip requires flanging the heating is carried further and the edge turned over with a tool to the amount required as the glass revolves. This operation introduces severe local strain round the rim of the glass, which has, in consequence, to be re-annealed.

(ii.) *Tube and Rod.*—In the manufacture of tubing, the gatherer prepares a large mass of glass on his blowing-iron, the size (as a rule from 5 to 20 lbs.) depending on the diameter and thickness of wall required in the tube. The gathering is carefully marvered and reheated in the glory hole. The blower then takes the blowing-iron and allows the glass to elongate by holding the iron vertically and giving it a gentle swing. His assistant then holds the punty in a convenient position, and the blower, by a dextrous movement, attaches the end of the gathering to the punty. The two men then move apart at a rate governed by the dimensions of the tube they are making. For small tubes it is necessary to run, but for tubing of medium diameter a slow walk is usual. With heavy tubing which tends to sag excessively it is necessary to chill it during the drawing with an air-blast, or, more usually, by fanning it. Solid rod is made in precisely the same manner, except that the gathering is made with an iron rod instead of a tube.

(iii.) *Glass Wool.*—By drawing out glass sufficiently quickly very fine fibres can be produced: thus, glass wool is made by winding glass drawn from the gathering on to a rapidly rotating drum.

(iv.) *Sheet Glass.*—A gathering of glass is made in the usual manner. The blower stands on a raised platform, so situated as to give him room to swing his iron vertically below him. He is usually provided with mechanical devices to assist the blowing operation, *i.e.* a flexible tube to enable him to use compressed air for blowing, and arrangements to relieve him of part of the weight of the gathering. He is also conveniently near a glory hole, for reheating during the blowing.

By means of specially shaped blocks and tools, the gatherer marvers a short, wide-bore cylinder having a thickened end, as in *Fig.* 2. By alternately heating the end of the cylinder and swinging it in a vertical plane, a cylinder,

about 4 ft. long or more, of reasonably uniform bore and thickness of wall, can be made. The end of the cylinder is then opened by bringing a small gathering of glass on the punty in contact with it; the glass of the cylinder softens at the point of contact, and a small hole is cut out with the shears. The end is then reheated, and, by rotating the cylinder, the hole becomes enlarged by the centrifugal force until its diameter is the same as that of the cylinder. The cylinder is then laid on a wooden stand, detached from the blowing-iron and the ends cracked off, generally by passing a thread of hot glass round it and touching it with a cold iron tool. A longitudinal scratch is then made from end to end on the inside surface, and a slight tap causes a crack to run down the side of the cylinder along the scratch. It is conveyed to the flattening kiln and placed on a smooth slab; the temperature is raised to the softening point of the glass, and the cylinder slowly opens out until it becomes approximately a plane sheet. The surface is rubbed with a wooden block to secure a smooth surface and intimate contact with the slab on which the sheet rests, and the finished sheet is then passed down the annealing lehr which adjoins the flattening kiln.

FIG. 2.

(v.) *Plate Glass.*—The manufacture of large sizes of the best plate glass is an expensive and wasteful process. Economical methods of making small-sized plates have been developed, but for very large sheets the casting and rolling process has not been supplanted.

A large mass of glass is poured on to an iron table; this is effected either by ladling the glass from a tank or pot into the casting pot in which it is carried to the table, or by removing the melting pot itself from the furnace. In either case the operation is carried out largely mechanically. The glass is then rolled with an iron roller running on rails at the edges of the casting table, the height of these rails determining the thickness of the plate. The roller is propelled mechanically, the width of the plate being controlled by guides which the roller pushes in front of it as it progresses down the table. After rolling, the sheets are annealed, either in a continuous lehr along which the sheets travel slowly, or in a kiln which is heated to receive the sheet and then allowed to cool down slowly, the sheet taking several days to reach a temperature at which it can be handled.

For certain purposes (roofing, etc.) sheet made in this way is sold without further treatment, but the surface is poor and the glass quite unfit for the purposes for which the best plate is required.

The plates have then to be ground to a true surface and polished. For this purpose they are clamped to a circular iron table, about 30 ft. in diameter, which is rotated, and the surface of the plate is rubbed down with iron slabs which are also rotated, eccentrically to the table. (The plates are usually set in plaster of Paris to ensure that the under surface is in intimate contact with the surface of the table.) The iron rubbers are fed with abrasives of successively finer grades (starting with coarse sand), until, finally, a fine ground surface is produced in the glass. During this process a large amount of glass (up to 30 per cent) is ground away and lost. The sheet is then polished, the iron "rubbers" being replaced by wooden blocks covered with cloth or felt and fed with rouge. If the previous grinding process has been carried out successfully, a brilliant surface is obtained with rouge in a short time—two hours or so. The sheet has then to be turned over and the whole process of grinding and polishing repeated on the other side. It is then washed and inspected, and cut to the required sizes, in such a manner as to exclude any defects which may be present.

Sheet known as figured rolled glass is made in large quantities. This is rolled in a somewhat different manner, four rollers being used. Instead of moving rollers such as are used in the method described above, these rollers are mounted in pairs and rotate about stationary axes, the glass being drawn between the two rollers. The sheet is formed by the first two rollers, and, passing through the second pair, receives the imprint of a pattern which has been cut on one of these rollers. Rolled sheet with simple patterns on it, such as parallel lines, etc., is also made by cutting the surface of a casting table to the desired pattern and rolling with a single roller as described above. The pattern is only pressed on one side, since the method adopted in cutting up the sheets, *i.e.* scratching with a diamond point and then breaking along the scratch, cannot be applied conveniently if the surface scratched is not plane.

Where plate glass having a curved surface is required (such as that sometimes used in large shop windows), the plate is heated on a mould having the desired curvature; the glass softens and takes the shape of the mould. Great care is necessary to keep the surface clean and free from defects during this operation, since any dust, etc., settling on the surface gets burnt in when the glass softens in bending. It is generally necessary to repolish parts of the surface, by hand, after the bending process.

(vi.) *Pressed Glass.*—Many kinds of cheap glass-ware, principally shallow vessels or solid objects, are made in presses, the glass being deposited in a mould and pressed into shape with a plunger.

A number of different types of machines have been developed for this purpose, some being operated by hand and others being automatic. Some machines combine the operations of pressing and blowing. Machines of this description are in common use for the manufacture of such articles as jam jars, heavy wide-mouth bottles of all kinds, tumblers, etc. The glass is fed, either by hand or by an automatic feeding device, into the first mould, the "parison" mould, and a plunger presses the glass into a symmetrical shape, this part of the process corresponding to the marvering in a hand-blown article. The parison is considerably smaller than the finishing mould except at the neck, where the glass is pressed at once to the full finished size and chilled, thus affording a means of conveying the half-formed jar to the finishing mould. The jar is taken from the parison mould and transferred (holding it by the chilled neck, the lower part of the jar being still plastic), either by hand or automatically, to the finishing mould, in which it is blown up to the full size. The finishing mould is then opened (it is generally made in two parts), and the jar is conveyed to the lehr.

The tendency of modern practice is to develop automatic processes, to increase and standardise production, and to cut down labour expenses. Thus in an up-to-date bottle works the entire process, batch-weighing, mixing, conveying, and charging into the furnace, is automatic, as is also the blowing of the bottles and the conveying of the bottles to the annealing kilns (known as "lehrs").

There are many types of machines in use for the manufacture of hollow ware, bottles, jars, electric light bulbs, etc., some entirely automatic and others semi-automatic, *i.e.* requiring the assistance of a "gatherer," who gathers the glass from the furnace by means of an iron rod or tube and keeps the machine supplied.

Of the fully automatic machines the Owens machine is perhaps the best known. This remarkable machine sucks the glass from the surface of a specially constructed tank into a mould (the parison mould), which it then withdraws from the tank, filled with glass, trimming off the glass adhering underneath the mould with a knife. The neck of the bottle is chilled and the parison mould opens, leaving the half-formed bottle hanging by the neck. The finishing mould then closes round the bottle, which is at the same time blown out to its full size. This mould then opens and the bottle is thrown out into a chute which conveys it to the lehr. Each mould is mounted on one of a number of rotating arms, and, by this means, gathers the glass as it passes the tank and discharges its bottle just before it completes one revolution or later, according to the type of machine. In order to present a continually fresh surface of the glass to the machine the hearth of the tank is revolved. The glass in the revolving tank is maintained at the same level, being fed continuously from the melting tank. The output from these machines is enormous, one 15-arm machine making up to 1000 gross of small bottles per day.[1]

There are many machines which are fed with a flow device, the glass flowing from the tank through a heated clay trough into the parison moulds. The rate of flow can be regulated by means of clay stoppers in the trough.

The manufacture of light articles, such as electric bulbs, is now extensively carried out automatically, the Westlake machine being perhaps the best known for this purpose. This machine gathers the glass, by means of a small cup, from a crucible into which the glass is ladled from the melting furnace. A 12-arm Westlake machine will produce up to 100,000 bulbs per day.[1]

Processes are also in operation for the automatic manufacture of window-glass and glass-tubing. In the window-glass process the glass flows or is ladled from the melting tank into a trough or basin, and a suitable "bait" is lowered on to the surface of the glass. The glass adheres to the bait, which is then slowly raised, drawing a sheet or tube (according to the shape of the bait) of glass from the trough. If the temperature is carefully controlled and the correct rate of drawing maintained, the process is continuous, the glass being drawn over rollers and through the lehrs to the sorting-house. In the tube process, when the required length has been drawn, the bait is raised quickly and the glass detached from the basin. The ends of the cylinder are then cracked off by passing a wire round it, and it is then scratched longitudinally and opened out in a manner similar to the familiar hand process of making window-glass.

Tank furnaces are now employed for melting glasses which, a few years ago, were invariably melted in pot furnaces; for example, glass for electric-light bulbs, tumblers, chemical ware, tubing, table-ware, opal glass; and it is claimed that lead glasses have been successfully melted in tanks.

The old rule-of-thumb methods are gradually being displaced in favour of more scientific

[1] For a description of some of the principal glass-making machines in use see *Journ. Soc. Glass Tech.*, 1917, p. 203; 1918, p. 19; 1919, p. 182.

control, and we find, for instance, pyrometers and polariscopes in common use. However, in spite of the rapid advance in the engineering aspect of glass technology, there will always be a demand for the highly-skilled glass-blower for the manufacture of artistic table-ware, cut glass, and so on.

§ (19) ANNEALING.—The viscosity of glass rises very rapidly with a fall in temperature. It is estimated that up to, say, 650° the viscosity is doubled for every 6° to 12° fall in temperature.

(i.) *Formation of Strain.*—When a block of glass is cooling uniformly from all sides there will be a temperature gradient from the outside to the inside which will depend on the thermal conductivity of the glass and the rate of cooling. Since the thermal conductivity of glass is low, very large temperature gradients are found if the heat be removed rapidly from the surface. As long as the glass is mobile no strain will be introduced. When, however, the viscosity of the outer layer becomes sufficiently high to resist the compression due to the shrinking of the inner layers, permanent strain may be produced. Let us suppose that when this viscosity is reached the outer layer is 600°. The centre of the block is then at, say, 650°. It is clear therefore that, if a is the mean linear coefficient of expansion of the glass, the inside layers will tend to shrink approximately $650a$ per unit length when cooled to 0°, whereas the outer layer would only shrink $600a$. When the whole block reaches room temperature the inside must, therefore, be in a state of tension and the outside in compression, the strain being roughly proportional to $50a$ per unit length, 50° being the difference in temperature between the outside and the inside of the block at the time when the outside became hard. Such a block would be considerably stronger and the surface harder than if free from strain.

Now let us consider the case of a plate of glass allowed to cool rapidly from the upper surface. A temperature gradient will be set up, the lower surface being, say, 50° hotter than the upper. The upper surface will set hard at, say, 600° and shrink as it sets, and the lower, being still soft, will flow under the compression due to the shrinkage of the upper.

There appears to be a discontinuity in the coefficient of expansion which increases by six or more times its normal value over a small range of temperature corresponding to the "setting" temperature. When the bottom of the block reaches 600° and begins to set hard, the upper surface will have reached 550°. If the temperature gradient has remained constant no strain will be present in the plate. At this point the whole plate has become "set," and any change of temperature gradient will consequently produce strain. As the whole plate cools the temperature gradient will diminish and, finally, the whole block will approximate to room temperature. The lower surface will then be in a state of tension and the upper in compression. If the maximum tension exceeds the tensile strength of the glass, a crack will develop in the lower surface and the glass will break.

(ii.) *Properties of Strained Glass.*—This plate will be strong to an upward force tending to produce concavity in the lower surface and weak to a downward force. Similarly, if scratched with a diamond on the bottom surface it will break easily, but not if scratched on the top. It is, therefore, desirable that glass required for general use should be as free from strain as possible, since the surfaces in tension are very vulnerable. However, for certain purposes some strain would be an advantage; for example, in certain kinds of hollow ware which are not subjected to rough usage on the inside, or in the case of a lamp chimney which has to resist sudden heating from the inside, compression in the outer surface is desirable.

Since glass-ware cooling quickly generally loses heat from the outside, we usually find under-annealed glass with its external surfaces in compression. Thus, when glass tubing, which is seldom annealed after manufacture, is cut into standard lengths, arrangements are made, by means of a diamond suitably mounted on a rod, for scratching the inside of the tube, which then breaks easily along the scratch. This cracking off would present some difficulty in tubing of large bore if it were well annealed; in fact, it would be necessary to heat the glass to produce temporary strain.

(iii.) *Process of Annealing.*—In the process of annealing there are two critical temperatures. The lower critical temperature (600° in the cases cited above) may conveniently be defined as the temperature at which the glass is just deformed at an appreciable rate under a stress equal to its tensile strength when cold. The upper critical temperature may be defined as the temperature at which 95 per cent of the stress in the glass disappears in three minutes.[1] These definitions are, of course, purely arbitrary.

The magnitude of the stresses in the glass will depend on the temperature gradient in the glass as it passes the lower critical temperature.

All glass-ware, with a few exceptions, is annealed after manufacture, generally by passing it through tunnel kilns (lehrs) which are heated at one end. The temperature gradient of these lehrs is so arranged that the glass, when passing through, is heated to

[1] For methods of determining the critical temperatures see *Journ. Soc. Glass Tech.* i. 61 and ii. 90.

its upper critical temperature and cooled slowly down to normal temperatures. For the success of the annealing operation it is, of course, essential that the rate of cooling be slow between the upper and lower critical temperatures, particularly in the neighbourhood of the lower. The rate permissible varies, of course, with the thickness of the ware and the degree of freedom from strain required.

Below the lower critical temperature the rate of cooling is immaterial, provided always that the temperature gradient is not sufficient to cause cracking of the ware.

The annealing temperatures vary largely with the composition of the glass. In the case of lead glasses the upper temperature is about 450° C. and the lower about 300° C.; with soda-lime glasses the upper temperature lies between 500° C. and 600° C. with a lower temperature between 320° C. and 340° C. Some hard resistance glasses require to be annealed at 630° C. to 640° C. and have a lower temperature of about 350° C.

The rate of cooling permissible depends on the thickness of the glass. Near the upper critical temperature the rate of cooling may be fairly rapid, but it must be diminished while passing the lower critical temperature. With a lead glass, a vessel with a thickness of wall, say ¼ in., can be cooled through its critical range at a rate of 50° per hour, whereas an electric-light bulb can be completely annealed and cooled to room temperature in 3 minutes. A soda-lime glass ¼ in. thick can be cooled through its critical range at about 15° per hour, and a complex resistance glass of that thickness would require cooling at less than 10° per hour; in fact, it is extremely difficult to obtain thick samples of the latter glass entirely free from strain, even in the laboratory.

In badly annealed articles it is quite usual to find tensile stresses of 1000 lbs. per sq. in. and often considerably greater.

(iv.) *Detection of Strain.*—Strain may conveniently be detected by means of a polariscope, since glass is doubly refracting when strained. When viewed through a quarter-wave plate between crossed Nicols a slight strain in a glass article may readily be located and the degree of strain estimated.[1]

§ (20) Devitrification.—The term devitrification denotes the formation of an appreciable quantity of a crystalline phase in the glass. The condition which favours devitrification in a glass is supersaturation with respect to one of its constituents or compounds at a temperature at which the viscosity is sufficiently low to permit of rapid crystal growth. The tendency of a glass to devitrify is influenced by factors which are as yet imperfectly understood. There is evidence that gases dissolved in the glass exert a marked influence in this respect; certain glasses, made with raw materials which have been carefully dried before use do not devitrify when worked in the blow-pipe, whereas similar glasses made from a batch not specially dried devitrify readily.

Certain constituents appear to inhibit crystal growth, whereas others appear to act as catalysts in accelerating it. Of the former, alumina is a notable case; boric acid, in certain cases, is also effective. Of the latter class, sulphur trioxide, chlorine, and fluorine are examples.

Of the crystalline phases which are formed, silica, in the form of tridymite, is the most common. In glasses rich in lime, calcium silicate ($CaOSiO_2$) is formed, and, in barium glasses, crystals of barium-disilicate ($BaO2SiO_2$) are deposited. Tridymite generally separates out from lead glasses, but in dense lead flints lead silicate is formed. These crystals may easily be distinguished by their refractive indices:

Tridymite . . .	1·469-1·473
$BaO(SiO_2)_2$ . . .	1·598-1·617
$CaOSiO_2$ . . .	1·621-1·633

Glasses containing soda are, in general, more liable to devitrification than similar glasses containing an equivalent amount of potash.

For the prevention of devitrification in any particular glass the factors controlling the crystal growth must be considered. For example, in the case of a soda-lime glass rich in calcium we may expect the glass to become supersaturated with respect to calcium silicate. The addition of alkali to this glass will increase the devitrification owing to the increased fluidity of the glass at any given temperature, but the addition of silica will increase the viscosity and diminish the devitrification. In the case of a glass rich in silica, say over 73 per cent, the dangerous crystalline phase will be tridymite. The addition of lime to this glass will inhibit devitrification for the reasons given above. The addition of alumina to most glasses prevents devitrification. The formation of crystals is frequently observed on the surface of glasses which show no evidence of crystal growth in the centre of the glass. In some cases this may be due to the volatilisation of alkali from the surface, giving rise to a thin surface film supersaturated with respect to silica. Glasses containing no appreciably volatile constituents show scums, however; for example, a glass containing only CaO, MgO, and SiO_2 gives a scum of crystalline $(MgO)_2SiO$.

Many glasses, when heated in the blowpipe, show a ring, of faintly opalescent appearance

[1] "Annealing of Glass," *Journ. Franklin Inst.* Nos. 5 and 6, cxc.

a short distance from the point where the flame impinges on the glass. This phenomenon is known as "bloom." It has been shown[1] to be due to the reaction of sulphur compounds in the gas with the alkali in the glass. The reaction is at first superficial only and the Na_2SO_4 formed can be wiped off. If the glass is subjected to prolonged heating, a permanent opalescence is produced and can only be removed by melting the glass in the blowpipe, when the product of the reaction is dissolved.

VI. Physical Properties

§ (21).—The measurement of the physical and mechanical properties of glass, as may be expected from the nature of the material, is a matter of some difficulty. The classic researches of Winkelmann and Schott pointed the way to the further study of glass, but it is only in recent years that serious attempts have been made to cover the ground.

In the first place, the properties vary very considerably with the composition of the glass, and it is difficult to obtain specimens with the desired degree of uniformity. Again, the presence of strain exerts a marked influence. We have a further difficulty in that methods of measurement applicable to glass at ordinary temperatures, when for most purposes one may regard it as a solid, have to be abandoned at higher temperatures in favour of those suitable for dealing with liquids. We have therefore a gap in our knowledge of the properties in the neighbourhood of the softening point, where, at any rate from the point of view of the manufacturer and those who have to manipulate glass at high temperatures, exact data is most needed.

In this range there is evidence of a discontinuity in the properties (see "Coefficient of Expansion," § (27)). Heating and cooling curves show that all glasses give an endothermic reaction on heating and an exothermic reaction on cooling. To detect this it is necessary to use a sensitive differential thermocouple, the evolution and absorption of heat being extremely small. This phenomenon occurs at a point when the glass acquires a particular viscosity, and is coincident with the discontinuity in the coefficient of expansion of the glass.[2]

An explanation of these phenomena is suggested by the work of Griffith,[3] which appears to indicate that, near the annealing range, the atoms or groups of atoms which above that temperature are arranged at random rapidly form nuclei possessing a definite orientation. These nuclei or chains of molecules are formed slowly at room temperature.

It is suggested that this arrangement of atoms causes local strain which may produce surface flaws. This theory assumes that the attraction between the molecules is a function of the orientation, since the grouping, to form a crack, must cause a decrease in the potential energy of the system to counterbalance the surface energy of the crack.

Experiments on glass fibres show that a fibre, drawn rapidly from a bead at a high temperature (*i.e.* chilled quickly through the annealing range) has an abnormal strength—10^6 lbs. per sq. in.—of the same order as the "intrinsic pressure," calculated from the energy required for volatilisation.

After a short time, a few hours, this strength decreases, reaching a stable value which depends on the diameter of the fibre. This fall in strength is accompanied by a change in dimensions. With fibres in the stable state, strengths have been obtained from 50,000 lbs per sq. in. in a fibre ·0027″ diameter to 490,000 lbs. per sq. in. in a fibre ·0001″ diameter. By extrapolation, for a fibre of zero diameter—*i.e.* of molecular dimensions—we obtain a figure of about 10^6 lbs. per sq. in.

These strong fibres are only obtained if the glass be drawn hot. If drawn out too cold we have a skin of chilled glass formed surrounding a fluid core; further extension will cause fracture of this skin, giving rise to surface flaws.

The slow decrease of tensile strength at room temperatures, ascribed to molecular rearrangement with the attendant surface flaws, explains the spontaneous cracking of glass articles which sometimes occurs long after they have been made.

Winkelmann and Schott attempted to correlate the physical properties with the chemical composition and, assuming additive relations, to assign factors to the constituents by means of which the physcial constants of any glass could be predicted. The factors obtained were not by any means satisfactory for quantitative work, but, in general, we have been able to discover from them the comparative effects of the constituent oxides on the properties.[4]

§ (22) Density.—The density of glass is approximately an additive function of the composition, and can be expressed in the form of $100/S = \Sigma(p/a)$, where S is the density of the glass, p the percentage of a constituent in the glass, and a is a constant for that constituent. The values of a are not identical with the densities

[1] Travers, *Journ. Soc. Glass Tech.* v. 61.

[2] This affords a convenient method for the determination of the upper critical annealing temperature of an opaque glass. See Scientific Papers of Bureau of Standards, No. 358, "Concerning Annealing and Characteristics of Glass," Tool and Valasek.

[3] "The Phenomena of Rupture and Flow in Solids." *Roy. Soc. Phil. Trans.* A, ccxxi. 163.

[4] Reference should be made to the summary of their work by Hovestadt in his book *Jena Glass*, translated by Everett.

of the oxides; according to Winkelmann and Schott a being always greater. Winkelmann and Schott assigned the following values for a:

B_2O_3	1·9	Al_2O_3	4·1
SiO_2	2·3	As_2O_3	4 1
Na_2O	2·6	ZnO	5·9
K_2O	2·8	BaO	7·0
CaO	3·3	PbO	9·6
MgO	3·8		

The results obtained with these constants give values correct to within about 3 per cent of the observed densities for most glasses. More recent work has shown that the figure assigned to MgO is too high. Assuming a value of 2·3 for SiO_2, Turner obtained a factor of 2·9 for Na_2O and 2·9 for MgO. Tillotson has also calculated factors which give good results: SiO_2 2·3, CaO 4·1, MgO 4·0, Li_2O 3·7, Al_2O_3 2·75.

The presence of strain in glass may cause a variation in the density of one in the second decimal place.

Optical glasses range from 2·3, a light crown, to 5·9, a dense flint.[1]

Common bottle glass	2·46-2·47
Plate glass	2·49
Heavy flint table-ware	3·5

The alkalis and RO group give a low dispersion relative to n_D (and have a high ν), lead oxide gives a high dispersion.

Boric oxide lengthens the red end of the spectrum relative to the blue. Fluorine, sodium, and potassium lengthen the blue end. Barium, while giving a high n_D, gives a low dispersion, and by its use we can obtain glasses with a high ν value relative to their refractive indices. This property is of great service to the optician.

The presence of strain lowers the refractive index. The greater the density of the glass the greater the variation in refractive index due to strain. It is therefore necessary that optical glasses be annealed with the greatest care. In the best glasses, the retardation due to double refraction should not exceed one-sixteenth of a wave-length.

Below are given the optical constants of a few typical optical glasses. The figures given in the last column (taken from Messrs. Chance's list of optical glasses) show the wave-length at which the transmission is reduced to 50 per cent through a plate 1 cm. thick.

Type.	n_D.	n_C-n_F.	ν.	C-D.	D-F.	F-G′.	Density.	Wave-length for 50 per cent abs.
Fluor. crown	1·4785	·00682	70·2	·00202	·00480	·00363	2·47	·301μ
Boro-silicate crown	1·5126	·00818	62·7	·00241	·00577	·00458	2·52	..
Barium crown	1·5881	·00962	61·1	·00284	·00678	·00544	3·31	·358μ

§ (23) Optical Properties.—For optical purposes the refractive index for light of wave-lengths ·6563μ, ·5893μ, ·4862μ, and ·4341μ, the C, D, F, G′ lines, is determined, and it is usual to specify the refractive index for the D line n_D and the partial dispersions. The ratio of (n_D-1) to the "mean dispersion" is also generally stated. This quantity $(n_D-1)/(n_C-n_F)$ is known as ν.

For most glasses the refractive index increases with the density and mean dispersion, while the value of ν decreases. Glasses having a high ν are generally designated crown glasses and those with a low ν flint glasses, the dividing line being a ν value of 55.

[1] Winkelmann and Schott, Larsen, *Amer. Journ. Sci.*, 1909, xxviii. 236; Tillotson, *Journ. Ind. Eng. Chem.*, 1912, iv. 246; *Journ. Amer. Cer. Soc.*, 1918, i. 76; Turner and English, *Journ. Soc. Glass Tech.*, iv. 126 and 153.

§ (24) Strength.—The strength of glass varies very considerably with the composition and degree of annealing. The difficulty of handling so brittle a substance when testing has led to very divergent results from different observers.

The tensile strength probably varies between 2½ and 10 tons per sq. in. Under certain conditions glass fibres have been prepared—·00013″ in diameter—having a tensile strength exceeding 214 tons per sq. in.[2]

Crushing strength, 10 to 15 tons per square inch.

Winkelmann and Schott placed the oxides in the following order, as regards their influence on the glass in tension: CaO, ZnO, SiO_2, P_2O_5, B_2O_3, BaO, Al_2O_3, As_2O_5, PbO, Na_2O, K_2O, MgO; in compression, SiO_2, MgO_2, Al_2O_3, B_2O_3, ZnO, PbO, BaO, K_2O, Na_2O, in descend-

[2] Griffith, *Phil. Trans.* A, ccxxi.

ing order of strength. (The positions of CaO and MgO are doubtful.)

§ (25) Hardness.—The hardness of annealed glass on Mohs' scale varies between quartz and fluorspar. Various attempts have been made to assign factors to the constituent by means of which absolute hardness may be calculated, but they have met with little success.

All glasses will scratch any other glass. Auerbach attempted, by measuring the size of the scratches, to arrange glasses in order of their scratching powers and their resistance to scratching. It was found that the order obtained by an estimation of their scratching powers was not by any means identical with their resistance to scratching.

The hardness of a glass surface depends very largely on the heat treatment it has received, surfaces in compression being considerably harder than those in tension (see "Annealing," § (19)). It is claimed that by extremely rapid chilling it is possible to obtain a glass which cannot be scratched by a diamond.

Various processes have been patented for hardening sheet glass by chilling the surface. Rapid chilling can be obtained by pressing the hot glass sheet between copper plates. Glass so treated is said to withstand eight times the shock which would fracture a similar sheet if annealed. The success of such a process depends on the uniformity with which the chilling is effected.

§ (26) Elasticity. (i.) *Young's Modulus.*—Young's Modulus varies from 4·9 to 5·9 dynes per sq. cm. for flint glass and from 5·9 to 7·8 for crown glasses.

Clarke and Turner have calculated factors for various oxides which satisfy the equation E (Young's Modulus) $=\Sigma pz$, p being the percentage of the oxide in the glass and z a constant. This formula gives good results for soda-lime glasses.

Oxide.	Value of z (giving E in kg. per sq. cm.).
SiO_2	40
Na_2O	110
(Al_2O_3)	120
(Fe_2O_3)	120
CaO	240
(MgO)	300

The values for the oxides in brackets require further verification.

(ii.) *Rigidity (Torsion Modulus).*—

Flint glass	$2·0\text{-}2·5\times10^{11}$ (dynes per sq. cm.)
Crown glass	$2·6\text{-}3·2\times10^{11}$ (dynes per sq. cm.)

(iii.) *Volume Elasticity (Bulk Modulus).*—

Flint glass	$3·6\text{-}3·8\times10^{11}$ (dynes per sq. cm.)
Crown glass	$4·0\text{-}5·0\times10^{11}$ (dynes per sq. cm.)

(iv.) *Poisson's Ratio.*—

0·21-0·28.

§ (27) Coefficient of Expansion.—The linear coefficient of expansion varies from $3·3\times10^{-6}$ to 14×10^{-6}, that of fused silica being $0·4\times10^{-6}$.

Typical Glasses.	Linear Coefficient (0°-100°)$\times10^{-6}$.
Heat-resisting glass (cooking ware, etc.)	3·3
Jena 59‴	5·7
Jena 16‴	7·8
English laboratory ware	7·4
Flint glass	7 to 8
Soda-lime glass	7·5 to 9·5 and over.

Turner and English have suggested factors for the calculation of the coefficients of expansion by the formula $a=\Sigma pz\times10^{-7}$, p being the percentage of any constituent and z a constant assigned to it.

Oxide.	Value of Z.
SiO_2	0·05
Na_2O	4·32
CaO	1·63
MgO	0·45

It will be seen that the coefficient of expansion is sensitive to a small change in the alkali content of the glass; an increase of 1 per cent in the alkali may cause an increase of 5 per cent in the expansion.

The expansion is affected considerably by the presence of strain in the glass. Values obtained from strained glass may be 5 per cent higher than those from the same glass after annealing.

The coefficient of expansion rises steadily with the temperature, a linear relation holding over a small range of temperature. With all glasses, however, there is a discontinuity in the expansion near the annealing temperature of the glass, the coefficient increasing by six or even more times its normal value. This abnormality only persists over a short range of temperature, the coefficient of expansion falling at higher temperatures.[1]

§ (28) Specific Heat.—The specific heat of glass at normal temperature may be calculated to within 1 per cent from the specific heats of the constituent oxides, the specific heat $c=1/100\Sigma PC'$, P being the percentage of the constituent and C′ its specific heat. Winkelmann assigns the following values of C′:

SiO_2	·1913	BaO	·06728
B_2O_3	·2272	Na_2O	·2674
ZnO	·1248	K_2O	·1860
PbO	·05118	Li_2O	·5497
MgO	·2439	CaO	·1903
Al_2O_3	·2074	P_2O_5	·1902
As_2O_3	·1276	Mn_2O_3	·1661

The thermal capacity per unit volume shows

[1] "Measurement of Thermal Dilation at High Temperatures," Peters and Cragoe, Bureau of Standards Scientific Papers, No. 393.

only an approximate approach to constancy, varying from about 4·7 to 5·1.

Lead flint, specific heat	·14
Soda lime, specific heat	·19

The specific heat rises with the temperature.[1] Glasses have a specific heat only slightly higher in the amorphous state than in the crystalline (devitrified), with the exception of glasses rich in alkali, where the difference is considerable.

§ (29) Thermal Conductivity. — ·0015-·0025 C.G.S. units. These figures may be taken as approximate for room temperature.

§ (30) Electrical Conductivity and Specific Inductive Capacity.—The conductivity of glass depends largely on the alkali content of the glass. Glasses rich in soda have a high conductivity. The substitution of potash for soda reduces the conductivity.

Ambronn[2] states that the conductivity can be expressed in the form $L = L_0 e^{-\beta/\theta}$, L_0 and β being constants, L the conductivity, θ the absolute temperature. L_0 can be expressed as a linear function of the soda and lime in the glass.

Type of Glass.	Specific Resistance×10[10].	Temperature, °C.
Soda lime .	531·05	55
	89·15	72
	11·901	93
	1·874	116
	0·202	149
	Specific Inductive Cap.	
	6·26	11
	6·79	129
	Specific Resistance.	
Soda lead .	215·13	73
	144·64	83
	20·82	104
	4·93	120
	1·89	140
	Specific Inductive Cap.	
	7·36	19
	8·44	130
	Specific Resistance.	
Potash lead.	1328·6	142
	Specific Inductive Cap.	
	6·76	18

According to Gray and Dobbie,[3] annealing reduces the conductivity of glass by many times its value in the unannealed state.

§ (31) Thermal Endurance. — Winkelmann and Schott adopted the formula

$$F = \frac{P}{aE}\sqrt{\frac{K}{SC}},$$

F being the resistance to a sudden change of temperature,
P = tensile strength,
a = coefficient of expansion,
E = Young's Modulus,
K = thermal conductivity,
S = density,
C = specific heat.

Values calculated by this formula are more or less in accordance with experimental results.

Since the coefficient of expansion changes more rapidly with composition than do the other physical constants, the thermal endurance is therefore largely governed by the value of a. Glasses rich in alkali are therefore the most liable to break with changes of temperature. Glass being considerably stronger in compression than in tension, it follows that it will be more resistant to sudden uniform heating than to sudden cooling. Glasses which will not withstand a rapid fall of 50° without cracking can be heated rapidly to several hundreds of degrees without risk. It is probable that the condition of the surface of the glass plays an important part in the thermal endurance.

Tests of the thermal endurance of hollow glass-ware may be carried out as follows: A beaker or flask of the glass under test is filled with wax and heated to a degree or so above the temperature of testing. It is then allowed to cool, keeping the wax well stirred, until the required temperature is reached, when it is plunged into iced water. This operation is repeated at successively higher temperatures until the beaker cracks. This test can usually be made to repeat to within 15° C.

Good beakers should stand 150° C. without cracking under this test. Laboratory ware containing striae are found not to be inferior to those free from cords, although the former must be in a state of considerable strain.

§ (32) Surface Tension.—The surface tension of glass[4] has been measured by Griffith at temperatures up to 1100° C. and a value at 15° C. obtained by extrapolation.[5]

Temperature, °C.	Surface Tension in lb. per Inch.
1100	·00230
905	·00239
801	·00257
745	·00251
15 (extrapolated) . .	·0031

[4] The glass used had the following composition: SiO_2, 69·2 per cent; K_2O, 12 per cent; Na_2O, 0·9 per cent; Al_2O_3, 11·8 per cent; CaO, 4·5 per cent; MnO, 0·9 per cent.
[5] Griffith, *Phil. Trans. Roy. Soc.* A, ccxxi.

§ (33) Viscosity. — The viscosity of glass falls rapidly with a rise in temperature. There are great experimental difficulties associated with the measurement of viscosity at high temperatures, and there is but little data on the absolute viscosity of glass at present available. Practical glass-makers have, however, collected information as to the general effect of certain constituents on the melting temperature and rate of setting, *i.e.* the temperature coefficient of viscosity. Thus, the addition of silica decreases the temperature coefficient, *i.e.* glasses rich in silica have a long working range, whereas the addition of lime increases the temperature coefficient. Alumina and baryta are also said to impart a high temperature coefficient to glass.

The viscosity of glass at the "fining" temperature is of the order of 50 (absolute units). At the gathering temperature the viscosity is from 1500 to 3500, depending on the size of the ware manufactured and the method of blowing. With automatic blowing devices the glass is gathered at a much lower viscosity. The viscosity at the annealing temperature is 10^{13}-10^{14}.

The measurement of viscosity has been used for the determination of the annealing temperature, the method adopted being the observation of the rate of twisting of a glass rod under a known torque.[1]

VII. Coloured and Opal Glasses

§ (34).—Coloured glasses may be divided into two groups, according as the colouring agent is (i.) apparently in true solution in the glass or (ii.) suspended in a fine state of division resembling a colloidal solution. As in the case of aqueous solutions, there is no sharp line of demarcation between the two groups.

Coloured glasses in the category (i.) are produced by the oxides of iron, titanium, manganese, cobalt, nickel, chromium, copper, etc., and in the second group (ii.) by the elements carbon, copper, gold, and selenium, etc. The opal glasses may be considered as coming under the heading (ii.).

(i.).—The colours produced by the various oxides vary somewhat with the composition of the glass and the conditions of melting (*i.e.* oxidising or reducing). In the case of the green glasses, the soda glasses tend to a bluish-green and the potash to a yellowish-green.

(*a*) *Iron.*—In the divalent state iron imparts a bluish-green colour, in the trivalent condition a greenish-yellow is produced. The colour from the divalent iron is much more intense than that from the trivalent, and hence oxidising conditions of melting are conducive to freedom from colour.

(*b*) *Titanium* oxide in combination with iron is used for the production of amber glass; very beautiful shades of amber may be obtained.

(*c*) *Manganese.* — Manganous compounds have very little colouring action on glass, giving a faintly green colour in small concentrations and a brown colour in large. When oxidised, colours ranging from pink to purple are produced. In small quantities manganic compounds neutralise the blue-green colour due to iron and are, accordingly, frequently used for this purpose, where oxidising conditions prevail. Used in larger quantities with iron, amber glasses are produced. Manganese is used extensively in combination with other oxides where a purple tint is required.

(*d*) *Nickel.*—The colouring effects of nickel are very variable; in fact, it has been claimed that with this oxide alone all the colours in the spectrum can be produced, with suitable modifications of the batch mixture and firing conditions. Nickel is little used, therefore, commercially, although it is sometimes used with considerable success as a decoloriser to neutralise the effects of ferric iron.

(*e*) *Cobalt* yields intense blue glasses. 0·01 per cent of the oxide is sufficient to produce a pale blue and 0·1 per cent a medium blue glass. The action of cobalt is similar in reducing and in oxidising conditions, and it is used almost exclusively for the production of blue glasses. Cobalt glasses, however, transmit an appreciable proportion of red rays. The addition of a small quantity of chromium cuts out the red rays (1 part of Cr to 10 Co).

(*f*) *Chromium* produces intense green glasses, but the colouring effect is not so strong as in the case of cobalt. It is used extensively in the industry, since the chromium colours are little affected by melting conditions. Chromium is generally introduced in the form of potassium bichromate.

(*g*) *Copper.* — Divalent copper gives tints varying between blue and green. Under reducing conditions ruby glass can be obtained (see below).

(*h*) *Iridium* imparts a neutral grey tint. In large quantities a black glass can be obtained.

(*i*) *Cadmium*, in the form of the sulphide, produces a rich yellow glass.

(*j*) *Uranium* also gives a yellow glass, characterised by a marked fluorescence in any but lead glasses.

[1] Littleton and Roberts, *Journ. Opt. Soc. of Amer.* iv. 4; Trouton and Andrews, *Proc. Phys. Soc. Lond.* xix. 47.

For data on the viscosity of glass and slags see Arndt, *Zeit. für Electrochemie*, 1907, p. 572; *Chem. Apparatenkunde*, 1903, No. 3; Field, *Trans. Far. Soc.*, 1917–1918, xiii.; Washburn, *Phys. Rev.*, Feb. 1920, xv. 2.

(*k*) *Antimony* may produce yellow glasses when used with lead batches.

(ii.).—In the second group of colouring agents copper, gold, and selenium are used commercially for the production of ruby glass. The manufacturing process presents some technical difficulty.

(*a*) The copper ruby is the cheapest to make, but the process requires great care, and frequently inferior colours are produced. It is necessary that the copper be reduced to the metallic state, and the presence of a reducing agent is necessary. Partial oxidation imparts a muddy green colour to the glass. The copper is usually introduced into the batch in the form of the oxide. When the glass is fine the copper is apparently in complete solution, and proofs taken from the pot and chilled quickly may be colourless. The glass is then gathered and blown to the required shape. The article is then reheated and the ruby colour comes up (the glass being said to "strike"). With the copper ruby the colour is so intense that it is necessary to use the ruby glass in thin sheets only, the articles required being "flashed" with ruby (*i.e.* made from colourless glass and covered with a thin coating of ruby; this is effected by gathering the glass for blowing the article from a pot containing "white" glass and then, before blowing, dipping the gather in the ruby glass; by this means glass-ware can be made with an extremely thin coating of ruby glass). When the glass is reheated the particles begin to aggregate, and when the glass "strikes" they have attained a sufficient size to produce scattering of the light. If the ruby glass is heated further the colour will change to purple, and from purple to blue as the particles increase in size. Finally, if heated for a sufficient time at a suitable temperature, the particles become visible and the well-known copper aventurine glass is produced. To obtain a good ruby the degree of dispersion of the metallic copper lies within fairly narrow limits.

(*b*) The gold ruby is made in the same manner, but the glass is much easier to handle, since there is not the same tendency to oxidation as in the case of the copper ruby, and it is possible to work with small concentrations of gold. It is therefore not necessary to "flash" gold ruby. The gold is usually introduced in the form of gold chloride.

The presence of tin oxide greatly facilitates the striking of the ruby and is almost invariably used in the industry with the copper ruby, and generally with the gold ruby.

(*c*) Selenium in the metallic state is also used for the production of ruby glass. In small quantities selenium is used as a "decoloriser" under conditions sufficiently reducing to ensure that the selenium remains in the metallic state. It is used for this purpose in tank furnaces. The oxide of selenium exerts no colouring action.

(*d*) Carbon, in suspension in glass, gives colours ranging from yellow to amber.

(*e*) Many special glasses have been made for the transmission and absorption of light of particular wave-length. Thus there are at present on the market a large variety of glasses similar to Crookes' glasses, the principal constituent of which is cerium oxide, which transmit nearly all the light in the visible spectrum, but are particularly opaque to ultra-violet light and cut down the infra-red light considerably. The absorption of these glasses for ultra-violet light is said to be improved by exposure to a strong source of ultra-violet. Similarly, nickel glasses are made which are opaque to visible radiation but are highly transparent to ultra-violet light.

(*f*) The colour of glass is modified by the prolonged action of sunlight and ultra-violet light. Glasses containing manganese rapidly develop a purple colour on exposure to intense ultra-violet light. This colour disappears if the glass is heated to its softening point, but reappears again if exposed further to ultra-violet light. Soda-lime glass tends to develop a blue colour, nickel and selenium a yellow.

(*g*) A rise in temperature displaces the absorption in coloured glasses towards the red end of the spectrum.

§ (35) OPAL GLASSES.—Opal glasses are made under conditions somewhat similar to the manufacture of ruby glass, the opalescence being due to the presence of small particles in suspension. Some of the opals, however, are regarded as being emulsoids rather than suspensoids, the disperse phase being a glass insoluble at low temperatures.

(i.) *Fluoride Opals.*—The most common opacifying agent is fluorine. This may be introduced as fluorspar (CaF_2), sodium fluoride (NaF), or cryolite ($3NaF, AlF_3$). In practice the presence of alumina serves to facilitate the production of the fluoride opals, although these can be made without alumina. The most usual ingredients in an opal batch are a mixture of fluorspar and felspar or cryolite alone, or a mixture of the three. Up to 20 per cent of cryolite may be used in an opal batch. The character of the opal varies somewhat with the form in which the fluorine is introduced. Thus, the NaF opal is faintly opalescent over a long range, whereas the cryolite opal strikes rapidly. By a careful control of the quantity of fluorine present opals can be made to remain clear when cooled quickly and to strike when reheated. Various ornamental effects are thus introduced into artistic ware by judicious local

heating. The composition of the suspended particles is not yet known with certainty.

(ii.) *Phosphates.*—Good opal glasses are also made with calcium phosphate (bone ash) as the opacifying agent. These opals strike at a higher temperature than the fluoride opals; they require a higher temperature to melt, and are not so easy to manipulate. They have the advantage, however, that they do not tend to "boil" readily if overheated, as do the fluoride opals, which evolve fluorine copiously if the temperature be allowed to exceed 1300° C.

(iii.).—There are other materials sometimes used in the manufacture of opals. Arsenic yields a good opal, and oxide of tin is used, especially in the enamelling industry.

The opal glasses are usually fragile and break easily if exposed to a rapid change of temperature. If reheated for any length of time, or worked in the blow-pipe, the suspended particles grow, especially if the concentration of the opacifying agent in the glass is high, and the glass has the appearance of devitrification, the surface losing its gloss. If examined microscopically it is seen that the particles consist of globules of a glass having, as can be determined by manipulation in the blow-pipe, approximately the same softening point as the matrix.

Opalescent effects are often found as the result of incipient devitrification, the crystallisation of silica sometimes producing this effect.

VIII. Miscellaneous and Ornamental Glasses

§ (36) Cut Glass.—Cut glass is in common use for many purposes—table-ware, massive glass-ware, etc. This industry is larger than is generally supposed. The preparation of cut glass-ware is a laborious operation requiring considerable skill. The first step is the preparation of the "blank," which may either be pressed or blown, generally the latter. The pattern to be cut is then painted on the blank; these patterns are often very complicated. Sometimes a transfer is used for this purpose. The ware is then taken to the grinding shop and ground on a coarse stone or an iron wheel fed with sand. After the coarse grinding the glass is finished on a finer grade of emery or carborundum wheel, and finally polished on a wooden wheel fed with putty powder (tin oxide). In the case of heavy articles this work is very laborious, a heavily cut piece taking some weeks to complete.

After the fine grinding the polishing is sometimes effected by "acid polishing," thereby avoiding the use of the wooden wheel and putty powder. In this process the ware is dipped into a solution containing hydrofluoric acid. If the composition of the solution is properly controlled a beautiful finish is produced on the glass—with a great saving of time and labour.

§ (37) Engraving.—This form of decoration is frequently applied to "flashed" glass, but is also employed for colourless glass. The engraving is carried out by means of a small soft iron or copper disc, usually revolving at a high speed, fed with fine emery or carborundum powder. In the hands of a highly skilled engraver very beautiful and delicate effects may be produced.

§ (38) Etching and Embossing.—Most glass-ware may be etched by means of a solution of hydrofluoric acid or sodium fluoride. A weak solution of hydrofluoric acid leaves a polished surface; strong hydrofluoric and sodium fluoride give matt surfaces, the latter reagent yielding a finer grained surface than the former.

In the etching process the glass is first coated with Brunswick black or wax, leaving the parts to be etched uncovered. This is effected either by means of a transfer or by coating the whole surface with wax and cutting away the part to be etched. For small designs a pantograph is sometimes used for this purpose. The glass is then immersed in the etching solution and afterwards washed. The wax may then be washed off with hot soap and water, the Brunswick black being removed by washing with turpentine or a solution of caustic soda.

The solvent action of a weak solution of hydrofluoric acid affords an excellent method for cleaning glass surfaces. Glass rinsed with a weak solution is cleaned almost instantaneously without an appreciable loss in weight.

§ (39) Sand-blasting.—This is the cheapest method for preparing a ground-glass pattern on glass surfaces. It is commonly used for labelling bottles, etc. A stream of sharp-

grained sand is blown against the glass by means of a steam- or air-blast, and a ground surface is rapidly produced on those parts not protected. The glass to be sand-blasted is covered with a stencil plate cut, from metal foil or parchment, to the desired pattern. For elaborate patterns dextrine, applied by means of a stencil, is sometimes used as a protection.

§ (40) Frosted Glass. — So-called frosted glass is made by coating the surface of glass, which has previously been sand-blasted, with glue, which, on drying, contracts and chips off flakes of glass, producing the appearance of a frosted window-pane.

§ (41) Beads.—Small glass beads are usually made from thick-walled tubing. Short lengths are cut from the tubing and these are heated in a revolving drum until the edges are rounded off. To prevent the beads from adhering to each other and the holes through them closing up, they are kneaded with clay or talc before heating. They are subsequently polished by being shaken with bran. Glass marbles are made in a similar way, using rod instead of tubing.

Opaque glass for making beads is sometimes obtained by stirring the glass rapidly before drawing the tube. By this means a large number of small bubbles are introduced into the glass, which somewhat resembles mother-of-pearl.

Larger beads and imitation pearls are made by blowing small bulbs from tubing. Coloured pigments are then introduced inside the bulbs. In the manufacture of imitation pearls "essence of pearl" is used. This is made from scales of fish ground to an impalpable powder. The silver and coloured balls (associated with Christmas trees) are made by silvering the inside of the bulbs and then painting the outside with a transparent enamel.

§ (42) Drilling and Slicing.—Glass may be drilled by means of a sand-blast. For finer work, a hard steel drill, lubricated with turpentine, or a copper or brass tube, fed with carborundum or emery, may be used.

Blocks of glass may be cut rapidly by means of a diamond circular saw—a soft iron or mild steel disc armed with diamond dust.

§ (43) Reinforced Glass. — Various processes have been employed for strengthening sheet glass. Of these, the most common is the use of wire-netting embedded in the glass. The wire, which is pre-heated, is rolled into the glass during the manufacture of the sheet.

Another process now in operation consists in cementing together thin glass sheets by means of a thin layer of celluloid. A composite sheet made in this way will not splinter when broken.

§ (44) Fused Silica.—For the properties and uses of fused silica, or quartz glass, see article on "Refractories." E. A. C.-P.

Bibliography

The bibliography of glass is scattered widely throughout scientific literature. References have been given, under separate heading above, to the most reliable sources of information. Below is a list of the principal works on glass:

Glass, Action of Steam on. See "Glass, Chemical Decomposition of," § (2).

GLASS, CHEMICAL DECOMPOSITION OF

§ (1) Devitrification and Colour Changes. (i.) *Atmospheric Agents.*—All glass is to a greater or less degree subject to change after manufacture. These changes may arise from chemical transformations occurring in the body of the glass itself, or may be produced by agencies outside giving rise to modifications of the surface of the glass; in both cases the glass is considerably altered, and where the transparency is of prime importance the glass may be rendered quite unserviceable.

The chief change arising in the body of the glass itself is known as devitrification, and is caused by the crystallisation of various metallic silicates, or more rarely silica, giving rise to definite crystalline aggregates, or in extreme cases a micro-crystalline structure affecting the whole mass of glass and rendering it opaque. These phenomena are usually noticed in batches of glass which have been allowed to remain for prolonged periods at too low a temperature during melting, or on reheating for the purposes of working or annealing; during any of which operations the range of temperature for the formation of the various silicates has been maintained for prolonged periods, thus favouring their crystallisation and separation. Recent researches made on the cooling of molten silicate mixtures and the thermal effects observed during the process have enabled some of these critical ranges to be avoided, with the result that devitrification has become a less serious problem. Various impurities appear to induce devitrification, while the favourable influence of others in preventing the trouble (*e.g.* alumina) have been known for a long time.

Glass also undergoes certain chemical changes from within due to other causes than those of devitrification.

In the manufacture of glass of the highest quality for optical purposes, or for use where the maximum transparency and lack of colour is of prime importance, the greatest care has to be taken to ensure that all the materials used are of the highest degree of purity. For example, it has been found that the presence of chlorides or sulphate in the alkali used in the manufacture of potash lead glass is capable of producing cloudy glass unless certain precautions are observed during the process of manufacture. By employing a high temperature, or by the addition of borax to the melt, the trouble may be obviated. It is, however, not impossible to obtain alkali which is practically free from these impurities, and this course is to be preferred.

Another impurity which is impossible to remove entirely, and which when present in any but the most minute proportions (0·03 per cent) produces a distinct coloration, is oxide of iron. The coloration can be destroyed by the addition of peroxide of manganese. The addition, however, frequently causes a secondary change to supervene, giving rise to the formation of a pink colour. Several explanations have been given of the phenomenon. The first action of the oxide of manganese is to oxidise the iron, producing a nearly colourless ferric silicate, which under the influence of sunlight, or the ultra-violet rays, is capable of again becoming deoxidised, giving rise to a higher and coloured oxide of manganese. It has also been supposed that the colour is due to the formation of alkaline permanganates. The strong pink colour arising from this change is commonly noticed in old window glass. In the manufacture of the best optical glasses little or no manganese is added, but every precaution is taken to ensure that all the materials are as free from iron as possible. Glass which has become coloured by manganese in this way is rendered colourless on again remelting. The presence of some base which is capable of forming a higher and lower oxide seems necessary before the influence of manganese makes itself felt.

(ii.) *Action of Water*.—In addition to the changes arising in the mass of the glass itself, there are others which are caused by outside agencies and affect its surface, resulting in the production of tarnish, or actual disintegration of the glass material. The most important substance which is capable of producing these changes in glass is undoubtedly water, and in some cases its action has been so pronounced that otherwise useful optical glasses have had to be discarded, or to be enclosed between layers of more durable glass to make them suitable for employing in optical instruments. In the case of glass used for optical purposes it is found that moisture is actually absorbed from the atmosphere, due to the hygroscopic nature of the glass; the water is capable of causing solution of the glass with a simultaneous liberation of alkali, which on combination with the carbon dioxide of the air produces a layer of alkaline carbonates. It has been observed[1] that glasses containing potash, lime, and silica are very much more hygroscopic, and therefore more susceptible to attack by this means, than are the corresponding soda glasses. The presence of increasing amounts of lime decreases this disparity to a great degree. Glasses containing oxide of lead are on the other hand far less hygroscopic than either, and are therefore not so liable to decomposition by this means.

The changes produced by water on glass are more pronounced as the opportunity for contact is greater, and in consequence glass exposed to water is attacked more rapidly than when moist air only is in question. Rise of temperature, particularly if accompanied by rise of pressure, as in the case of water-gauge glasses, considerably increases the rate of the attack. Glasses containing boric acid, alumina, or zinc, with soda as alkali, have proved to be particularly resistant to the attack by water at all temperatures, and are, moreover, capable of withstanding prolonged contact with water at high temperatures and pressures, without undergoing marked deterioration, or becoming obscured by the liberation of opaque insoluble basic silicates, as in the case of the lime alkali glasses. The two well-known Jena glasses 16‴ and 59‴ are of this type. Another change affecting optical glass in which water undoubtedly plays a part, but at the same time is not the sole cause of the phenomenon, is what is generally alluded to as "filming." It is found that the interior lenses, prisms, and other glass parts of optical instruments occasionally become veiled, causing a diminution of the light transmitted, and in extreme cases almost complete opacity. The exact cause, or causes, has not been clearly elucidated, but whatever they may be, there appears little doubt that the glass has suffered some chemical decomposition.

When "filmed" glass is examined under low magnifications, at least two distinct types of films are noticed; in the one, distinct globules may be distinguished, while in the other the glass is obscured by a bloom which under higher magnifications is also seen to be globular. The "film" is frequently noticed to be grouped round minute scratches or unevennesses; on the other hand it may very

[1] Foerster, *Berichte der Deutsch. Chem. Ges.*, 1893, xxvi. 2920.

markedly avoid them. On exposure to air the film does not spontaneously evaporate, but does so on heating, leaving a residue and usually a tarnish of the glass surface, with or without actual pitting. It has been proved that the lubricants used in the lens threads, and the varnishes or blacking compounds used on the interiors of the cells or chambers, play some part in the process, and that such compounds which give off volatile constituents at ordinary or slightly elevated temperatures are unsuitable for use in optical instruments. Absolute cleanliness in the polishing and subsequent treatment of the lens, together with drying of the air in the chambers before sealing up, and the use of suitable lubricants, appear to prevent filming to a great degree. The treatment of the lens with hot water after polishing is also claimed to act as a palliative, but with all these precautions the prevention of filming cannot yet be said to be certain, and more research is required. One thing, however, seems conclusively proved, namely, that water plays a large part in the process.[1] Atmospheric dust is also capable of causing the decomposition of the polished surfaces of glass lenses. The degree of attack depends in the case of glasses free from lead on the amount of alkali present. When this is below 10 per cent it is found on microscopic examination that each dust particle has become a centre of decomposition, while in the case of glasses richer in alkali the whole surface may undergo a homogeneous decomposition with the liberation of alkaline salts, forming deliquescent globules in the case of potash glasses, and a dry dusty deposit in the case of soda glass. In glasses containing more than 20 per cent alkali the deposit becomes visible to the naked eye.

Lead glasses containing more than 20 per cent oxide of lead exhibit what are known as lead spots; these on microscopic examination are seen to originate from dust particles, each of which forms the centre of a mass of minute brown or blackish scales. They are presumably lead mirrors produced by the reducing action of the dust on the solution of the glass formed by traces of moisture.[2]

§ (2) DECOMPOSITION CAUSED BY CHEMICAL REAGENTS.—It will be seen from what has been said above of the various factors affecting the stability of glass, that it becomes necessary to subject that intended for optical or other scientific purposes to test before use in order to prove whether it is suitable for the purposes for which it is intended.

The optical glasses offer particular difficulties, since it is by the variation of the chemical constituents that the special optical features are obtained; consequently the determination of what changes are permissible without seriously affecting the chemical stability becomes a matter of prime importance. Where the optical constants or slight colour can be ignored there is more scope for variation, and it becomes possible to make glasses which are more resistant to atmospheric agents, and at the same time to manufacture those possessing in a high degree resistance to the more violent attack of chemical reagents.

Before passing on to the testing of glassware, it will be advisable to consider briefly the influence of the various constituents of the glass on the resistance to attack by chemical reagents.

(i.) *Action of Water and Steam.*—In addition to ordinary atmospheric moisture, glass for many purposes has to withstand the action of hot and cold water, and also steam, sometimes under high pressures.

The attack proceeds in a similar manner as in the case of atmospheric moisture, but at a greater rapidity. Glasses containing boric acid with either zinc or alumina, and soda as the alkali, have, as mentioned above, proved to be by far the best glasses. When glasses containing these elements are examined it is found that some which may be superior at low temperatures (20° C.) may not be so good as others (at, say, 80° C.), while at still higher temperatures the superiority may be assumed by another glass. For ordinary chemical ware the most useful proportion of boric acid appears to be 9-10 molecules to 100 SiO_2, while for gauge glasses a slightly greater proportion is advisable. The lime alkali glasses are very much inferior, the degree of attack depending largely on the ratio of lime to alkali; the richer the glass is in alkali the less the degree of resistance. Glasses containing more than 20 per cent alkali cannot be regarded as suitable for use with water under any circumstances. The proportion of lime has a marked effect in increasing the resistant powers, and more particularly if the soda is partly replaced by potash, as in the glass used by Stas in his classic researches, in which case the glass compares favourably with the boric glasses.

Lead glasses are intermediate in position between the boro-silicate and lime alkali glasses, the resistant power increasing with the lead content.

(ii.) *Action of Acids.*—Sulphuric, nitric, and hydrochloric acids when concentrated have very little action on most good glasses of the lime soda or lead types, but when the acids are weaker the action becomes slightly more pronounced, and increases on further dilution. This observation has led to the opinion that

[1] Ryland, *Trans. Optical Society*, 1918, xix. 178; Martin and Griffiths, *Trans. Optical Society*, 1919, xx. 135.

[2] Zschimmer, *Chemiker Zeitung*, 1901, xxv. 69.

the attack proceeds from the contained water rather than from the acid itself, and is less than in the case of pure water under similar circumstances, owing chiefly to the neutralisation of the liberated alkali by the acid. The alkali would normally in the case of the action by water be instrumental in further increasing the attack.[1] The boric acid glasses are not so resistant to hydrochloric as to sulphuric acid, and more recent work than Foerster's has tended to emphasise the importance and significance of the attack by acids, more particularly hydrochloric. It has been shown that fuming hydrochloric acid has a very pronounced action on zinc and lime borosilicates, and that high boric acid content tends to promote this attack.[2] On the other hand, glasses containing lime and alumina with soda, and some potash, are much more resistant. A high silica content (70 - 72 per cent) appears to confer great resistant properties.

The conclusion arrived at by Foerster, that in the case of dilute acids the action appears to be due to the contained water, rather than to the acid itself, is confirmed by recent work. The reason why hydrochloric acid should be so much more active than other acids is somewhat obscure.

Lead crystal glass (33 per cent oxide of lead) is very slightly attacked by acids and its resistant power is increased on prolonged contact. The very rich lead glasses are rather severely attacked. The rate of increase of attack with rise of temperature is not so pronounced in the case of acids as with water.

(iii.) *Action of Caustic Alkalies.*—The action of water on glass results in the production of an alkaline solution; we should therefore expect that there is no clear line of demarcation between the results obtained with water and solutions of the caustic alkalies. In the case of dilute solutions this is the case, and the boro-silicates again occupy the premier position as regards resisting power. If, however, the boric acid is greater than 5-7 per cent the resistance diminishes and becomes more pronounced with increasing concentration of alkali.

The lime alkali glasses are attacked by dilute alkalies with the formation of basic lime silicates which appear as opaque layers on the glass, while the solution is found to contain silica and some lime. When the concentration of the alkali increases and exceeds 2N the glass is dissolved as a whole and very little tarnish occurs. The effect of rise in temperature is very marked in the case of the caustic alkalies, more particularly above 80° C. Soda is the most violent in its attack of all the caustic alkalies. Ammonia also has a slight action on glass, but its action has not been so systematically studied; in general, however, glasses which are most resistant to attack by caustic soda are also found to exhibit the same order when ammonia is substituted.

(iv.) *Action of Alkaline Carbonates.*—The attack by alkaline carbonates proceeds in a similar manner as with the caustic alkalies, but in the case of the lime alkali glasses, varieties containing alumina are far more resistant than those which do not contain it. In fact, the alumina-free lime alkali glasses are more strongly attacked by sodium carbonate than by sodium hydroxide of equivalent strength, which is not the case with any others. In explanation of this it has been suggested that as alumina is soluble in caustic soda, but not in sodium carbonate, this is sufficient to account for the difference in behaviour. There appear to be other factors which modify the results, the nature of which is not exactly known.

Solutions of salts also have a slight solvent action on glass, but the degree of attack is in no case comparable to that observed with the reagents considered above.

When the chief factors affecting the stability of glass which is required to withstand the attack of chemical reagents are considered, it will be found that the introduction of one element may, while conferring stability as regards one mode of attack, be conducive to more accelerated attack by a different reagent It therefore becomes a matter of some difficulty to indicate the ideal glass for all purposes, but nevertheless, as a result of exhaustive tests, certain definite conclusions have been reached. Boric acid, for example, besides conferring on a glass great powers of resistance to the influence of water, at the same time confers very valuable mechanical properties, such as power to withstand sudden changes of temperature, which is of great service in all glass articles. It will therefore be found that, in spite of certain minor disadvantages, nearly all glass required to be used for chemical purposes contains a certain proportion of boric acid. The influence of a high silica percentage in conferring acid-resisting powers, and of alumina in restraining the attack by sodium carbonate, have also been alluded to. It will thus be seen that sufficient information is available for selecting the most suitable type of glass for use with any *single* chemical reagent, and considerable progress has been made in the manufacture of glasses which successfully withstand the attack by most chemical reagents to a very high degree.

§ (3) Testing of Glass. (i.) *Optical Glass.*—Glass intended for optical purposes must, in

[1] Foerster, *Zeitsch. anal. Chem.*, 1894, xxxiii. 299.
[2] Cauwood English and Turner, *Journal Society of Glass Technology*, 1917, p. 189.

addition to possessing the properties necessary for the construction of the best optical instruments, be capable of retaining its polish and transparency under ordinary conditions of use. As has been pointed out above, the chief agent in promoting the changes in optical glass is atmospheric moisture, and all tests which are in use for testing optical glasses have been devised to measure directly, or indirectly, the degree of attack.

In the early experiments powdered glass was heated in water and the amount of alkali and total solid material dissolved was determined. This method is not an ideal one, owing to the fact that it is impossible to ensure uniformity in the degree of fineness of the various samples of glass. As a result of these experiments, however, it was found that the less stable glasses gave up a greater amount of alkali and total solid matter, and that the ratio of alkali to silica in the dissolved glass material was invariably higher than in the original glass. Mylius and Foerster,[1] who were the first to investigate this question systematically, were led to conclude that a determination of the alkali removed would give a measure of the relative stability of glasses. They were therefore led to investigate methods for the detection of minute quantities of alkali. As a result they developed the use of a reagent which is now invariably employed for the purpose of classifying optical glasses.

Iodeosin (tetra iodo fluorescein), the reagent in question, is a red solid which is soluble in aqueous ether, but insoluble in water. The aqueous ether solution when shaken up with a solution of an alkali produces a solution of the salt of iodeosin which is soluble in water, giving rise to an intense red colour. The alkali may be determined either by comparing the solution with one containing a definite quantity of the alkaline salt of iodeosin, or by titration with N/100 or N/1000 acid. In the latter case the acid is added to the solution, which must also contain an excess of an aqueous ether solution of reagent, and the two layers shaken together until the water solution is rendered colourless. The extreme sensitiveness of this reaction has enabled the test to be applied to quite small areas of glass, and there is no longer any necessity to use powdered glass for the purpose.

The method as finally developed for the testing of optical glass will now be briefly described, but for a more detailed description the original[2] papers should be consulted.

For the purpose of the test, polished samples of optical glass measuring $6 \times 10 \times 0{\cdot}8$ cm. are used. These are very carefully cleaned and then broken into two portions by making a fine file mark parallel to the longest side and placing a red-hot rod along the cut, followed by a damp piece of filter paper. Any glass dust is removed from the fractured surface by means of a clean brush, and the specimens are now placed in a closed vessel containing water and arranged that the fractured surfaces of the glass are supported in a horizontal position on a platform above the water. The glass vessel and its contents is now maintained at a constant temperature of 18° C. for one week. The glass surfaces are attacked by the moist air to a greater or lesser degree with liberation of alkali, and in the case of very poor glasses it is sometimes found that the surface becomes covered with visible spots of alkaline salts. The specimens of glass are now removed with a clean pair of forceps, and held broken edge downwards in a bath of the iodeosin reagent for one minute. The iodeosin reagent is usually prepared from the sodium salt, in which form it occurs in commerce. It is sometimes found to be adulterated with other salts and dyes, and care should be taken that only the purest samples are used. A weighed quantity of the salt (0·53 gm.) is dissolved in 30 c.c. distilled water and treated with 15 c.c. $(N/I)H_2SO_4$ in a separating funnel. The acid liberates the free dye in the form of orange-red scales. One litre of aqueous ether of the highest purity saturated with water at 18° C. is now added, and the lower colourless acid layer separated. The remaining acid is removed by shaking with three or four successive quantities of 30 c.c. distilled water, or until the lower aqueous layer becomes coloured a strong pink. The reagent is now poured into a bottle of resistant glass together with 1/10th of its volume of a 1 per cent solution of the sodium salt and a few fragments of broken glass. The bottle should be completely filled and should be kept in a cool dark place. The reagent gradually becomes acid, but owing to the presence of the sodium salt, neutrality is restored by double decomposition. The alkali set free by the action of the moist air on the glass combines with the iodeosin, producing the corresponding salt, which, being insoluble in the aqueous ether, is left as a pink deposit on the glass. To remove the excess of iodeosin the glass is rapidly rinsed in another bath of anhydrous ether. After drying, the sides of the glass slabs are cleansed, leaving the broken surface untouched. The next process is to determine the actual amount of alkali liberated.

The glass is washed in 3 c.c. of water containing 0·1 gm. anhydrous sodium carbonate per litre, and the solution transferred to a small porcelain vessel of about 10 c.c. capacity divided into two equal chambers by a watertight porcelain partition. The dish is rinsed with a further 2 c.c. of water, and this is added to the first wash water. To the second chamber is next added 5 c.c. water, and from a pipette graduated to 1/100 c.c. a solution of sodium iodeosin containing 0·01053 gm. per litre, each cubic centimetre of which contains 0·01 mgm. free iodeosin, until the colours of the two solutions are similar.

[1] Mylius and Foerster, *Berichte der Deutsch. Chem. Ges.*, 1889, xxii. 1092; *Zeitschrift für Instrumentenkunde*, 1889, ix. 117; and *Zeitschrift für Instrumentenkunde*, 1891, xi. 311.

[2] Mylius, *Silikat Zeitsch.*, 1913, 1, 2, 25, 45, contains latest working details; Mylius, *Zeitsch. für Instrumentenkunde*, 1889, ix. 50; Mylius and Foerster, *Berichte der Deutsch. Chem. Ges.*, 1891, xxiv. 1482; Mylius, *Zeit. anorg. Chem.*, 1907, lv. 233, also 1910, lxvii. 200.

For a useful résumé of work by Mylius and Foerster see *Jena Glass*, Hovestadt, Eng. Trans. by Everett (Macmillan).

The area of the fractured surface is now calculated and the amount of iodeosin which would combine with the alkali set free from 1 sq. metre determined.

The following classification has been adopted to express the results of the tests :

Class.	Mgm. of Iodeosin per sq. metre.
H_1	0 – 5
H_2	5 – 10
H_3	10 – 20
H_4	20 – 40
H_5	40 – 80

Glasses in the first three classes are considered to withstand the action of the atmosphere and not to suffer tarnish, while those in classes 4 and 5 should not be used in exposed positions. At the present time this is the only method capable of quantitative treatment, and is therefore exclusively used for comparing and classifying optical glasses. Other methods in which the skill and judgment of the experimenter are the sole criterion are occasionally used. One of these devised by Weber consists in exposing pieces of glass to the action of hydrochloric acid fumes for twenty-four hours and then removing to the air. The less stable glasses will be found to become coated with a rime of alkaline chlorides, and from the appearance it is possible to make some form of classification. The method requires a great amount of experience and skill.

Another method due to Zschimmer, which has been recently modified by subsequent workers, seems likely to be of service in predicting the susceptibility of glasses to "filming."[1] The polished slabs of glass, together with polished slabs of transparent silica, are placed in a glass tube in a thermostat and heated to 80° C. A current of pure moist air is passed through, and after some time the heat is withdrawn, thus allowing the tube to cool; it is found on removing the large tube that some glasses are more bedewed than others, while the silica plates are usually dry. The rate of disappearance of the dew is observed by placing the samples in separate closed tubes, and on drying they are again carefully examined. In this test the good glasses are very little changed, while those which the iodeosin test has shown to be poor are frequently found to be actually pitted. Superheated steam has also been used, but the results obtained require to be viewed with caution.

(ii.) *The Testing of Chemical and other Glassware.* — This problem has been the subject of very numerous researches since the time of Scheele and Lavoisier, but owing to the fact that it is only in recent times that highly resistant glass has been manufactured, the early researches become merely of historic importance. The later workers have unfortunately not adopted a uniform method of test, and it becomes a matter of some difficulty to correlate the numerical data obtained. The conclusions, however, are on the whole fairly unanimous, and are summarised in a preceding section.

Mylius and Foerster, who were the first to study systematically the modern types of glass, were inclined to attach too great importance to the attack by water, and to consider the differences obtained with other reagents as of minor significance. Later investigations have taken more comprehensive views, and as a result a great improvement has been made in the manufacture of resistant glasses.

The action of water at ordinary temperatures, *e.g.* 20° C., also at higher temperatures, 80° C., and also boiling water and steam, both under atmospheric and high pressure, is usually determined.

The last method has recently come very much into vogue. For many glasses the test is a useful one, while for others the conditions are perhaps too severe, and the conclusions drawn may conceivably lead to erroneous results.

The action of acids, alkalies both strong and dilute, also ammonia and ammonium chloride, should also be tested, and great care should be taken that the temperatures are carefully maintained, more especially with the caustic alkalies, since the rate of attack increases very rapidly with small rises of temperature. It is impossible to give the full details of all the tests, and for fuller information the memoirs mentioned below should be consulted.

GLASS, OPTICAL PROPERTIES OF: Table. See "Optical Glass," § (4).

GLASS, PLATINISED

PLATINISED glass has not hitherto found much use in Applied Optics, for the following reasons. When the platinised surface is produced by deposition, or by "spluttering" methods, it is easily rubbed off, and requires protection, thus showing no advantage over silvering methods. When produced by the so-called "burning-in" process, the resulting layer is more or less granular and diffuses the light very considerably. In recent years,

[1] Elsden Roberts and Jones, *Journal Society of Glass Technology*, 1919, iii. 52.

however, Messrs. Rheinberg & Co., London, have introduced platinised and semi-platinised surface mirrors, in which the platinum is incorporated in the surface layer of the glass, so as to be irremovable, and which show no grain and are remarkably free from diffusion. They also withstand the action of all ordinary solvents, except those which attack the glass itself. Notwithstanding the fact that the intrinsic reflective power of a platinised surface is between one-third and one-fourth less than that of a perfect silvered surface, they supplant the latter, because silvered surface mirrors are liable to tarnish, are very delicate, and deteriorate fairly rapidly, whilst the platinised surface mirrors will wear, require no protection and do not suffer deterioration.

Amongst the applications of such platinised surface mirrors are reversing mirrors for process cameras, in replacement of large and expensive prisms; reflex camera mirrors, and, generally speaking, mirrors where first surface reflections only are required. They likewise find employment for dental and surgical mirrors, on account of the freedom with which they can be subjected to hot water or sterilising fluids without deterioration.

Semi-platinised mirrors find application in or with optical apparatus as light filters, since they have a neutral grey tint, and may be placed in any position where they are subjected to heat, without liability to damage or change. They are also employed in the types of optical instruments where some definite part of the light is reflected by the surface, and part transmitted through the glass.

Platinised mirrors by the Rheinberg process reflect the red end of the spectrum proportionately more than the blue end to a *very slight* extent as compared with silvered mirrors. This is easily observable by comparing the image of a person in both, the difference being just sufficient to impart to the face the appearance of being slightly ruddier and healthier. The platinum mirror, however, also reflects the ultra-violet rays just beyond the visual spectrum to a greater extent than silvered mirrors, as the latter absorb these rays more strongly. This has been demonstrated by spectrographs taken by reflection from platinised mirrors and freshly silvered surface mirrors under the same conditions.

Platinised mirrors can be used as back surface as well as front surface mirrors, but the reflection from the back surface suffers slightly in brilliancy.

The Rheinberg process employs a high temperature,[1] and its success depends on:

(1) The special coating mixtures used.

(2) Careful pyrometric regulation of the electric furnaces.

(3) The precautions used to ensure retention of the plane or curved surfaces of the glass to be platinised.

[1] See patent N. 156,472, Jan. 13, 1921.

(4) Precise regulations according to the particular composition of the glasses used.

Flint glasses are unsuitable for this process, as the platinum interacts with the lead in the glass. Whilst a large variety of glasses can be successfully platinised, the best results are obtained with those of the crown glass and plate glass description.

Fuller particulars will be found in a paper read before the Optical Society in November 1920.

GLASSES, COLOURED

THE physical nature of a glass closely resembles that of a rapidly solidified liquid, which has the power of holding metallic oxides, metals, and other matter in combination, solution, or suspension. There are many varieties of glass of very varied composition, but nearly all possess the property referred to. In Germany several scientific papers have been published dealing with the relation of glasses to effects of colour, but English contributions to the subject have been, with very few exceptions, aesthetic rather than scientific. It may, however, be claimed that in practical glass-making, especially in the recapture of the colours of mediaeval windows, English manufacturers have been quite as successful as their foreign competitors.

Variation in the chemical composition of glasses produces varied effects in their action on light. The influence of the variation on the refractive power and dispersive power of glasses is dealt with elsewhere. Variation in colour is also due to variation in chemical composition. Colour effects are caused by the power possessed by glasses of absorbing some of the constituent rays of white light and of transmitting or partly transmitting and partly scattering the remainder. Even the most colourless optical glasses show noticeable colour when a considerable thickness is traversed by

light. Glazed window glass, of good quality, appears to be colourless, but a tinge of colour shows when a sheet of similar glass is placed on white paper, and if the edge of the sheet is viewed it appears to possess a deep sea-green colour.

Coloured glasses may be transparent, translucent, or opaque: transparent, if practically all the incident rays, not absorbed, are transmitted; translucent, if the non-absorbed rays are partly transmitted and partly scattered by minute, opaque, embedded particles; opaque, if all the non-absorbed rays are reflected.

Colours are produced by introducing into glass mixtures certain ingredients, usually metallic oxides, and melting them in crucibles or tanks. The resultant colours depend on the colouring ingredient and its condition, on the ingredients of the glass mixture, on the atmosphere surrounding the molten mixture, and, in some cases, on the temperature to which it is exposed.

The *glass mixture* generally used as a basis for the production of coloured glasses is either A or B:

A—sand, carbonate of potash, and red lead.

B—sand, carbonate of soda, and carbonate of lime.

§ (1) MANUFACTURING PRACTICE.—The following is a record of some results obtained on a fairly large scale in a manufactory:

Copper, used in the form of *copper scales*:[1] with A mixture, 0·8 per cent, light blue colour, like that of cupric sulphate; with A mixture, 5 per cent, dark green colour; with B mixture, 0·2 per cent, bright blue; with a sand-potash-lime mixture, to which stannic oxide, red tartar,[2] 0·3 per cent copper scales, and 0·1 per cent of ferric oxide have been added—a colourless glass which gradually becomes very dark ruby when reheated. If the atmosphere surrounding the molten glass has not had a sufficiently reducing effect, it appears, when cold, to be rusty, and transmits a blue colour.

A similar mixture, but with carbonate of soda substituted for carbonate of potash, in a strongly reducing atmosphere, develops visible crystals of metallic copper, and a glass closely resembling the mineral aventurine. The crucible containing the molten mixture must be cooled extremely slowly.

Gold, dissolved in aqua regia: with a sand-potash-lead mixture to which crushed metallic antimony, stannic oxide, antimony trioxide, charcoal, and 0·03 per cent gold have been added — a colourless glass which gradually develops a dark ruby colour when reheated. If the atmosphere during melting has not had a sufficiently reducing effect, the glass appears to be rusty-red and transmits a violet-blue colour.

Iron, usually used in the form of ferric oxide: ferric oxide with A mixture, 5 per cent, a rich yellow colour; 1 per cent of black oxide of manganese is usually added to give the yellow an amber tint. Iron scales[3] with B mixture, 0·1 per cent, a pale blue colour. With a larger proportion of iron scales, a grey-green.

Ordinary bottle-green colour is usually obtained by adding a small proportion of cobalt oxide to from 3 to 5 per cent of ferric oxide.

Manganese, used as manganese dioxide: with either A or B mixture, about 1 per cent, a violet colour. The oxide is used as a decolorant for A glasses. It acts partly by converting any iron in the glass mixture into ferric oxide, and partly by producing a tint of colour complementary to the green due to ferrous oxide.

The oxide used as a decolorant with B glasses, *e.g.* ordinary window glass, although the glass may be colourless when first made, develops a pink colour in the glass after long exposure to light. The addition of a colouring ingredient to neutralise colour in a glass mixture reduces the transparency of the glass.

Cobalt, used as black oxide: with A or B mixture, 0·4 to 1 per cent, a bright purple-blue, less purple with B than A. Cobalt glasses with large proportion of the oxide, or in considerable thickness, transmit a ruby colour. The effect can be neutralised by the addition of chromic oxide or cupric oxide.

Nickel, used as nickel monoxide: with A mixture, 0·2 per cent, a strong violet colour; with B mixture, a brown colour.

Sir Herbert Jackson, F.R.S., has found that the same proportion of the oxide with a lithia glass gives a yellowish-brown colour.

Chromium, used as sesquioxide: 0·4 per cent, with both A and B mixtures, gives a greenish-yellow colour.

Uranium, used as uranate of soda: 0·5 per cent with A or B mixture, fluorescent yellow colour. Colour and fluorescence better developed with B than with A mixture.

Carbon, used as finely divided wood charcoal: with B mixture, 0·02 per cent, a clear yellow colour. As the proportion of carbon is increased the colour passes from yellow to brown, brown to black.

Arsenic trioxide: with A mixture, 5 per cent, gives an opaque white enamel; a thin film of the enamel transmits a strong amber-red colour.

Fluor spar: with A mixture, 4 per cent, gives a deep opal effect.

[1] Copper scales = crude red cuprous oxide, Cu_2O.
[2] Red tartar = crude bitartrate of potash.
[3] Iron scales: a thin black film formed when iron is heated in air = Fe_3O_4 ferroso-ferric oxide.

Silver: used in the form of oxide, as a pigment. It is mixed with some finely divided difficultly fusible material, such as kaolin, applied to the surface of a colourless glass, and strongly heated. It gives a yellow transparent colour, with a slight bluish lustre. The colour is best developed on a soda-lime glass, of which phosphate of lime is an ingredient.

§ (2) Experimental Meltings.—*Platinum black*: with A mixture, 0·3 per cent, is diffused through the glass, giving a grey translucent effect.

Oxide of iridium: with A mixture, 3 per cent, gives a dense black.

Carbonate of thallium: with A mixture, 6 per cent, gives a greenish-yellow colour.

Antimony trioxide: with A mixture, 3 per cent, gives a pale translucent yellow.

Vanadium, as pentoxide: with A mixture, a yellow-green; with B mixture, a blue-green.

Selenium, as a selenate: with A mixture, a pink amber.

§ (3) Crookes' Glasses.—Sir William Crookes' prolonged researches[1] to discover satisfactory eye-preserving glasses for spectacles throw light not only on the effects produced by special ingredients introduced into glasses in cutting off ultra-violet and heat rays, but also in the production of effects of colour. The base used for all of his experiments was a soda-lime glass, and the thickness of the plates of glass, when prepared for use, was 2 mm. The results of his experiments with regard to colour are as follows:

Cerium nitrate 17 per cent, pale reddish-amber tint; chromic oxide 1 per cent, green; copper sulphate about 2 per cent, blue; ferrous oxalate 10 per cent, a smoky green colour; ferric oxide 2 per cent, yellow; ferroso-ferric oxide, 2·85 per cent, with the addition of carbon 0·35 per cent, pale blue. Manganese gives a reddish-purple colour, cobalt sulphate a rich blue, nickel sulphate a brown, cobalt mixed with nickel a neutral grey, praseodymium a greenish-yellow, neodymium a lilac.

The conclusions arrived at with regard to eye preservation were that a glass containing cerium is most effective in cutting off injurious ultra-violet rays, and a glass containing iron, in a ferrous or metallic condition, is most effective in cutting off heat rays. A glass composed of 83 per cent of fused soda glass and of 17 per cent cerium nitrate was found to be practically opaque to ultra-violet radiation, the limit being $\lambda 3650$; a glass composed of 90 per cent raw soda glass mixture, and 10 per cent ferrous oxalate, with small additions of red tartar and wood charcoal, gave a sage-green glass which cut off 98 per cent of heat radiation; whilst a glass composed of 96·80 fused soda glass, 2·85 ferroso-ferric oxide, and 0·35 carbon had a pale blue colour, and cut off 96 per cent of heat radiation.

[1] *Phil. Trans. R. Society*, Series A, 1913, ccxiv.

§ (4) Absorption of Light by Coloured Glasses.—R. Zsigmondy's papers on the absorption of light by coloured glasses,[2] and on the use of coloured glasses for scientific and technical purposes,[3] have some bearing on the subject of this article. He rightly insists that the colour of a glass depends not only on the colouring material, but on the glass mixture or batch to which it is added and on the atmosphere in which it is melted. As examples he gives (1) the brown- and violet-coloured glasses produced, respectively, by a soda-lime and potash-lead glass mixture with the same proportion of the same oxide of nickel; and (2) the change in colour from yellow to yellow-green, and from yellow-green to blue-green, of a glass mixture containing ferric oxide when, in the process of melting, an oxidising atmosphere changes to a reducing one. He calls attention to the action of manganese in reducing the green part of the spectrum and to the increase of the red part of the spectrum when a small proportion of manganic oxide is added to the ferric oxide of a mixture for yellow glass. In dealing with copper he found that if the proportion of cupric oxide be increased from 2 per cent, which gives a blue glass, to three or five times that value, green glasses are obtained differing widely in their absorption from that of a copper-blue glass. In his first research the following bases and glass mixtures were used; borax, sodium silicate, potassium silicate, lead silicate, soda-lime glass, potash-lime glass, soda-lead-lime glass, potash-lead glass, soda-zinc-lime glass, soda-borosilicate glass, and barium-borosilicate glass. The colouring agents were calculated as oxides, and the proportions ranged, except for the green-copper glasses, from 0·1 per cent to 2 per cent. The mixtures were melted and stirred in an oxidising atmosphere; the molten glasses were poured, and the plates, thus formed, after annealing, were cut and polished for examination. A "Glan" spectrophotometer was used, and the coefficients of extinction, having been determined, were used for the construction of representative curves, of which illustrations are given. It is regrettable that in this research the ordinary soda-lime and potash-lead glasses were so rarely used that it is difficult to compare their effects. The objects of the second research on the use of coloured glasses for scientific and technical purposes were (1) to provide a ray-filter, which would transmit one part of the spectrum whilst absorbing the remainder; (2) to obtain light filters for three-colour photography;

[2] *Ann. d. Phys.*, 1901, iv. 60.
[3] *Zeitschr. f. Instrumen.*, 1901, xxi. 97.

and (3) to find a glass to absorb all parts of the spectrum equally. A Pulfrich comparison spectroscope was used for examining the glasses, and the following is an abridged table of the results. It is unfortunate that in the account of this research the compositions of the glass mixtures are not given.

Glass.	Colour.	Spectral Rays transmitted.
Copper-ruby glass	Deep red	Only red.
Gold-ruby glass	Red	Red, yellow; in thin sample, blue and violet.
Uranium glass	Bright yellow	Red, yellow, green; in thin sample, blue.
Nickel glass, soda base	Yellowish-brown	Red-yellow, traces of green and blue.
Nickel glass, potash base	Dark violet	Violet (G – H), extreme red.
Copper glass, blue	Blue, like copper sulphate	Green, blue, violet.
Copper glass, green	Green	Green, yellow, traces of red and blue.
Chrome glass	Yellowish-green	Yellowish-green, traces of red.
Cobalt glass	Blue	Blue, violet, extreme red.
Manganese glass	Dark violet	Violet (G – H), extreme red.
Smoke-grey glass	Grey	Whole spectrum weakened.

The following results with specimens of mediaeval glass were obtained by the author of this paper:

Glass.	Colour	Spectral Rays transmitted.
Copper-ruby of thirteenth century	Deep red	Red, bluish-green and trace of yellow.
Copper-ruby of fourteenth century	Deep red	Red and some blue.
Blue of thirteenth century	Greyish-blue	Blue, violet, traces of red and yellow, but no green.
Carbon-yellow of thirteenth century	Pale yellow	Passes all rays except blue, violet, and extreme red.

§ (5) Suggested Explanations of Effects of Colour of Transparent Glasses.—The behaviour of metallic oxides introduced into a glass seems to correspond exactly with their behaviour when added to an acid solution. Thus cupric oxide, dissolved in hydrochloric acid of moderate concentration, gives a green solution of cupric chloride, which contains in addition to the undissociated salt a number of blue cupric and colourless chlorine ions. If this solution is largely diluted with water the ionisation is increased, and the colour of the cupric ions predominates over that of the undissociated residue, the solution becoming blue. Precisely the same result is obtained when cupric oxide is added to glass, which it must be remembered always contains a large excess of the acidic oxide, silica. When present in comparatively large quantities the cupric oxide gives a green glass, but if only a minute amount is added a blue glass results. Similar resemblances can be traced in the behaviour of other metallic oxides. It is probable then that ionic dissociation of the metallic silicates takes place on melting. It might be thought that the existence of this ionisation would render a coloured glass a conductor of electricity. This, however, cannot be the case since the ions in a solid have no mobility, with the result that a blue cupric glass is as good an insulator as a dry crystal of copper sulphate, in which ions are present in large numbers, but without the power of moving through the crystal.

There is another group of coloured glasses in which the origin of the colour is entirely different, examples of which are the ruby glasses made by the formation of reduced gold and cuprous oxide in the mass of the glass. Here again we may see a close resemblance between the behaviour of a salt solution and a glass. Carey Lea in 1884 showed that if a very dilute solution of gold were treated with a reducing agent a bright red solution, apparently quite transparent, was produced. With increased concentration a purple solution was formed, and in still stronger solutions a yellow colour resulted. These solutions, so-called colloidal, are now known to be not solutions at all, but suspensions of particles so small that their presence can only be demonstrated by the ultra-microscope.[1] In gold and cuprous oxide ruby glasses this method of viewing them renders it quite certain that they owe their colour to the presence of fine particles, the size of which, by their action on the light of different wave-lengths, determines the colour of the transmitted and reflected light. It may also be assumed that the yellow and brown colour of carbon glass, for which many different causes have been suggested, is really due to ultra-

[1] See also paper by J. C. Maxwell Garnett, *Phil. Trans. Royal Society*, A, 1904.

microscopic particles of silicon, comparable to the particles of metallic gold and cuprous oxide, which are the cause of colour, respectively, in gold-ruby and copper-ruby glass.

GONIOMETRY

§ (1) Spectrometer Methods.—The measurement of the angles between the flat surfaces of prisms is one which for many purposes requires to be performed with the greatest possible accuracy. The refracting angle of a prism to be used for refractive index measurements, for example, must be known to within about one second if the index measurements are to be correct to the fifth decimal place; and some of the angles of prisms used in rangefinders, dial sights, and similar instruments must approximate to specified values to within about the same amount. We shall first treat the general methods, and then refer to special methods suitable for special cases. For the general methods a spectrometer is required. The features of such an instrument adapted to the most precise work are discussed in another article [1] and the various adjustments described.

The two best-known methods of measuring an angle on the spectrometer are the following:

Method 1.—The prism is placed on the spectrometer table with the vertex of the angle in question over the centre (*Fig.* 1 (*a*)), and the table is adjusted until the edge of the prism is parallel to the axis of rotation.[1] The parallel beam from the collimator is divided into two by reflection at the faces of the prism. If the telescope is placed in the position T_1, one of the reflected images can be brought to the cross-lines, and in the position T_2 the other. The angle between the two positions of the telescope is twice the angle of the prism.

Method 2.—The prism is placed with its centre over the centre of the table and rotated so that the reflected image from one face is on the cross-lines of the telescope T (*Fig.* 1 (*b*)). The table is then turned until the reflection from the other face of the required angle is on the cross-lines. The second face is now in exactly the position previously occupied by the first; and the angle through which the table has been turned is 180° minus the angle of the prism.

[1] "Spectroscopes and Refractometers," § (8).

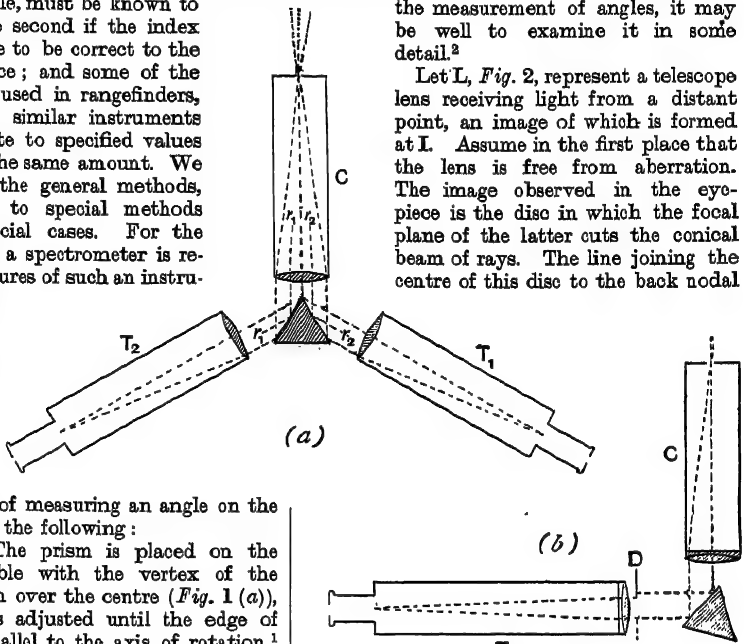

Fig. 1.

For work of only moderate accuracy—say 10 seconds or so—there is little to choose between these methods; but when high accuracy is aimed at Method 1 is quite useless. This arises from the fact that in practice it is impossible, except by accident, to obtain perfect collimation or perfect focussing. There is always a range, known as the depth of focus, within which the definition of an optical instrument appears uniformly good, and there is consequently a certain degree of latitude in all adjustments of collimation or focus. As this error vitiates quite a large proportion of the methods which have been published for the measurement of angles, it may be well to examine it in some detail.[2]

Let L, *Fig.* 2, represent a telescope lens receiving light from a distant point, an image of which is formed at I. Assume in the first place that the lens is free from aberration. The image observed in the eyepiece is the disc in which the focal plane of the latter cuts the conical beam of rays. The line joining the centre of this disc to the back nodal point of the objective is the direction of the incident beam as indicated by the telescope. Clearly, provided the aperture is symmetrical about the back nodal point of the lens, the apparent direction is not affected by errors of focus; for if the plane of the cross-wires is not accurately at I but is at I′, the centre of the disc of confusion is still on the line IN. If, however, one half of the object-glass is covered by a screen, as in *Fig.* 2 (*b*), the centroid of the disc of confusion at I′ is below the line IN, while at I″ it is above it. In the first case the cross-lines will be set to the left of their proper position, while in the second case

[2] See also Guild, *Proc. Phys. Soc.*, 1916, xxviii. 242.

they will be set too far to the right. If the other half of the objective be employed the errors will be reversed. In general, unless the centroid of the section of the beam by the principal plane of the lens coincides with the nodal point, the centroid of the image will be displaced from its true position unless the focus is absolutely exact. If then the focus is not quite accurate, and different parts of the aperture are employed for different component measurements of a determination, the results will be in error. In the presence of spherical aberration there is no position of focus at all for which the centroid of the image is unaffected by cutting off part of the aperture unsymmetrically. In *Fig.* 2 (c) the case of a lens with under-corrected spherical aberration is shown (much exaggerated). f_a is the focus for rays near the axis, and f_p for those near the periphery. F is the position of best focus when the whole aperture is used, while if either half is used separately, the disc of least confusion would be displaced appreciably towards F′ or F″. The effect on the displacement of the image from its true position on the line NA for different positions of the focal plane of the eyepiece is easily followed from the diagram.

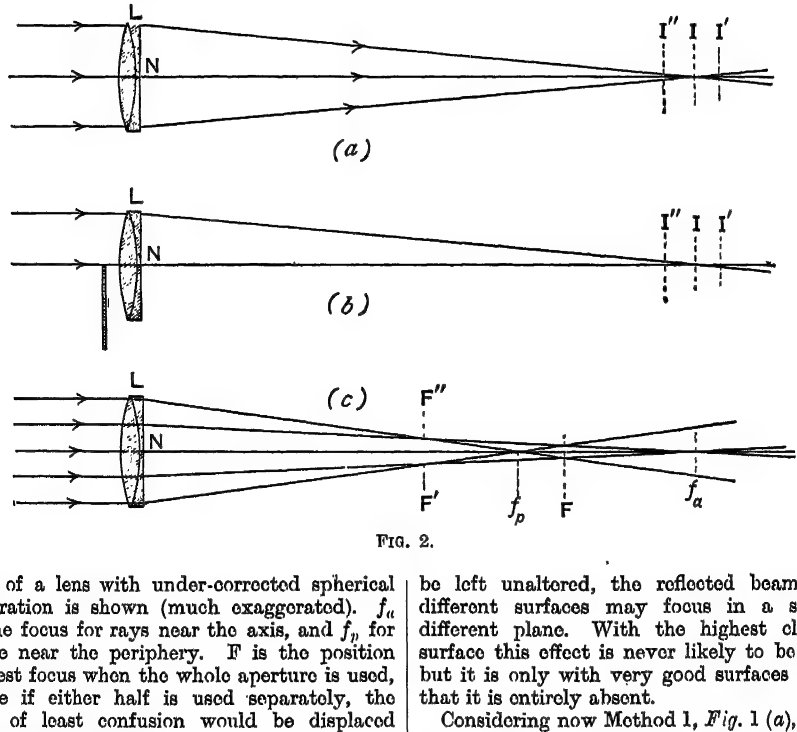

FIG. 2.

In practice, if an object be sighted with a telescope with partially obscured aperture, the movement of the image across the field as the focus is adjusted is very easily observed. Within a certain range there is no means of judging when to stop. Even with very sharp focussing it is easy for errors of several seconds to be made, while under conditions by no means abnormal in laboratory work errors as great as half a minute may arise. It is obvious, of course, that the error is in a plane perpendicular to the line of division of the objective, and that measurements in the horizontal plane will not be affected, provided the aperture is symmetrical with respect to the vertical diameter of the lens.

Thus an essential condition to the accuracy of measurements of angles with a telescope is that the aperture employed should be symmetrical with respect to that diameter of the lens which is perpendicular to the plane of measurement. It is not safe to use an excentric aperture, even though the same region be used for all the measurements; for, although the focal adjustment of the telescope be left unaltered, the reflected beam from different surfaces may focus in a slightly different plane. With the highest class of surface this effect is never likely to be great, but it is only with very good surfaces indeed that it is entirely absent.

Considering now Method 1, *Fig.* 1 (*a*), in the light of these considerations, it is evident that in changing from position T_1 to T_2 the full effect of errors of focus or spherical aberration will be felt, since opposite halves of the objective are used for the two measurements. If to obviate this we place the prism in such a position that the aperture of the telescope is symmetrically filled, the ray from the vertex no longer passes through the nodal point, and the directions actually measured by the telescope are those of the rays r_1r_1 and r_2r_2. There is therefore liability to error on account of imperfect focus of the collimator; since, unless collimation is perfect, r_1 and r_2

do not emerge quite parallel, and the angle between the reflected rays is not equal to twice the prism angle. It is therefore immaterial where the prism is placed, when inaccuracies due not only to the collimation but to the focussing of the telescope as well are taken into consideration. It is impossible to arrange the method to be simultaneously free from both effects, and it cannot be used for accurate work.

Method 2, on the other hand, is free from this defect. By means of an iris diaphragm D,[1] which is closed down until a circular aperture completely filled with light is obtained, exact symmetry may be assured. As it is desirable to use the biggest available aperture, the telescope axis should be rotated, if possible, out of its usual position (directed to the centre) and directed to the middle of the side of the prism. The fact that the collimator is not symmetrically employed is clearly of no consequence under the conditions of the experiment, provided the prism is mounted with the bisector of the angle over the axis of rotation, so that the two surfaces are in the same plane when the light is reflected from them.

This is the most convenient method for general use, provided the rotation of the table can be determined with the same accuracy as that of the telescope. If, however, as is too frequently the case, no provision exists for the *accurate* measurement of table rotations, it is necessary to resort to the next method, which involves the use of an auto-collimating eyepiece.

Method 3.—The telescope is fitted with an eyepiece arranged so that the cross-lines may be illuminated from behind and the telescope itself may be used as a collimator. When its axis is approximately normal to a plane surface, a reflected image of the cross-lines will be seen in the focal plane. When these are accurately set to coincide with the actual cross-lines, the axis of the telescope is normal to the surface. The determination of an angle consists, therefore, in setting the telescope normal first to one surface and then to the other. The angle between these positions is equal to 180° minus the angle of the prism.

There are several forms of auto-collimating eyepiece, but not all of them are useful. Those forms in which the reflector is behind any of the lenses of the eyepiece are most troublesome to use, on account of the flooding of the eye with light reflected from the surfaces of these lenses. The most satisfactory form of auto-collimating eyepiece is that due to Abbe. It is illustrated in *Fig.* 3. A small slab of glass, *p*, bevelled at one end to form a 45° reflecting prism, is mounted behind part of the cross-lines. This prism, when illuminated by a lamp placed above it, acts as a bright background to the cross-lines in front of it. When the telescope is approximately normal to a reflecting surface the appearance of the field may resemble *Fig.* 3 (*c*). The whole field will probably be faintly illuminated by the

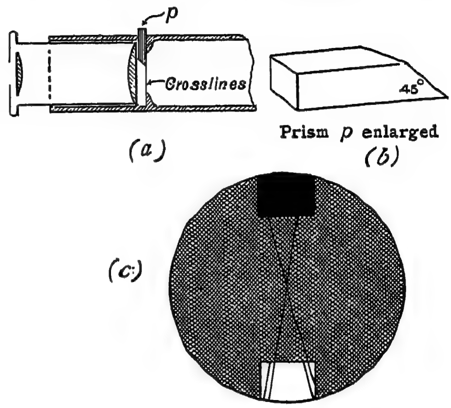

FIG. 3.

general light of the room, except for the area occupied by the back of the prism *p*, which will be quite dark. At the opposite side of the field to this will be the brightly illuminated image of the face of *p*, with the image of the cross-lines showing up against it. When the normality is exact, both horizontally and vertically, the actual cross-lines and those of the image will coincide. It improves the accuracy of setting considerably if the axis of the telescope is *slightly* inclined in the vertical direction. In that case the image lines are a little wider or closer than the actual cross-lines at the same distance from the centre of the field, and instead of a somewhat insensitive coincidence setting a symmetrical setting is made with the image lines a little outside or inside the others.

This is a very fine eyepiece to work with. Its only drawback is the difficulty of using a high-power ocular, on account of the distance between the cross-lines and the field lens necessitated by the insertion of the illuminating prism.

Another arrangement which may be employed is not a true auto-collimating eyepiece but serves the same purpose. It is shown in *Fig.* 4. A side tube is attached to the telescope just in front of the eyepiece, and serves to carry a short draw-tube at the end of which can be attached a pinhole, a fine slit, or a graduated scale, or whatever type of object may be most convenient for the purpose on hand. A semi-transparent reflector, which may be a microscope cover-slip thinly coated

[1] It is a great convenience to have iris diaphragms fitted to spectrometer telescopes and collimators.

with silver or platinum,[1] is mounted at R by some suitable means. When the telescope is nearly normal to a reflecting surface, an image of P is seen in the field of the eyepiece. For use in Method 3, above, the most suitable object is a moderate-sized hole with a vertical fibre and two horizontal fibres. These latter should be about $\frac{1}{2}$ mm. apart, and settings are made on the vertical fibre half-way between them.

In carrying out measurements by Methods

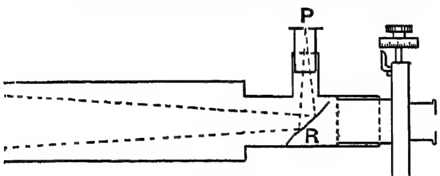

FIG. 4.

2 or 3, every care must be taken to eliminate all the sources of error to which even the best spectrometers are liable. The article on "Spectroscopes and Refractometers" should be consulted for a discussion of these errors. In Method 2 it will be found advantageous to employ a broad slit and fibre, as described in the article just referred to, rather than a narrow slit. It is advantageous to employ a light green filter in front of the light source in all goniometric measurements as this eliminates chromatic aberration and improves definition.

§ (2) Method of Substitution.—With an exceptionally fine spectrometer it is possible to measure angles by Methods 2 or 3 to within a second, provided extreme care is taken. Spectrometers of this quality are few; and it is not every observer who is fortunate enough to have access to one.

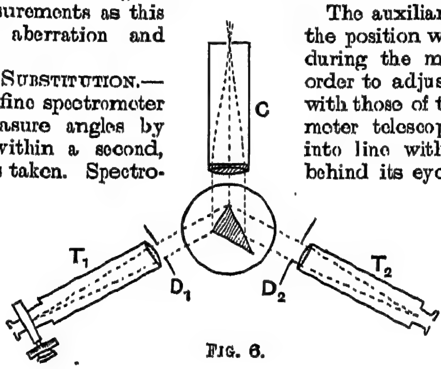

FIG. 6.

The overwhelming majority of angles in optical prisms are sub-multiples of 180°; and of these the great bulk are 45°, 60°, or 90°. For such angles special methods of high accuracy can be employed which do not involve the measurement of an angle on the spectrometer at all. It is therefore possible to have standard angles of these values, and the actual testing of an unknown angle is reduced to a measurement of the small difference between it and the corresponding standard. We shall first describe the method of substitution, and then refer to the methods of obtaining the standards. If a spectrometer is available, the only additional apparatus required is a second telescope on a separate stand. This telescope should be similar to that of the spectrometer, but only one of them requires to have a micrometer eyepiece.

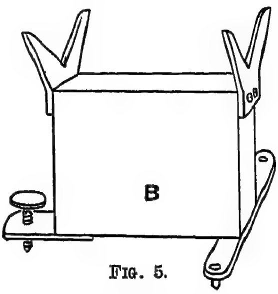

FIG. 5.

Such an auxiliary telescope is of great use in many ways,[2] and there should be one associated with every spectrometer. A cheaply constructed stand of perfect rigidity can easily be made as in *Fig.* 5. The body, B, is a slab of hard wood which carries metal Vs in which the telescope rests. The method is carried out as follows:

The auxiliary telescope T_2 is placed in the position which it is going to occupy during the measurements, *Fig.* 6. In order to adjust its axis to be coplanar with those of the collimator and spectrometer telescope, the latter is rotated into line with T_2 and a lamp placed behind its eyepiece. The cross-lines of T_1 are then visible in the field of T_2, and the latter is adjusted until both sets of cross-wires are at the same height. This procedure assumes of course that the axes of T_1 and C are already in adjustment with respect to the centre. If this is not so the complete adjustment must be made for all three at once, as described in "Spectroscopes and Refractometers," § (8).

One of the nearly equal angles which have to be compared is placed on the table so that light from one of its faces is directed into the auxiliary telescope T_2. The other telescope T_1 is brought to receive the image from the other face. The table is levelled until both images are at the correct height with respect to the cross-lines. This is most rapidly done if one of the faces is perpendicular to the line joining

[1] A small piece of glass may be very conveniently semi-platinised by using the preparation known as "liquid platinum." This is painted on the surface *very thinly* and the liquid evaporated off over a hot-plate. To get a semi-transparent film, the painted surface should appear of a light amber colour when held between the eye and a light.

[2] See "Spectroscopes and Refractometers," §§ (8), (10).

two of the adjustment screws, this face being adjusted last.

When the preliminary adjustments have been made, the image in T_2 is brought to the cross-lines by means of the tangent screw which rotates the table. The micrometer eyepiece of T_1 is employed to set on the other image. This angle is then removed, and the other is laid as nearly in the same position on the table as possible and levelled in the same way as the other. The image in T_2 is again set on the cross-lines by rotation of the table. It is evident that if the angle were precisely equal to the previous one, the image in T_1 would now also be on the cross-lines. If the angles are not quite equal, the image in T_1 will be displaced by twice their difference, which is measurable with considerable precision on the micrometer. The settings *both* on T_2 and T_1 should be repeated several times.

The determination takes very little time, and with telescopes of about 30 cm. focal length should be accurate to less than 1 second. The method is clearly applicable to any size of angle for which there is a standard available.

The precautions concerning the symmetrical filling of the telescope apertures and the use of the diaphragms D_1 and D_2 must be observed, lest the focus of the reflected beams should differ slightly with the two prisms. It is also essential that the spectrometer and auxiliary telescope should stand on a more rigid support than the ordinary laboratory table, otherwise relative movements of the two will take place as the observer moves about. A convenient plan is to set them on a slab of slate or stout plate glass, which is raised off the surface of the table by three pieces of indiarubber or thick card. The auxiliary telescope then retains its position as accurately as if it were part of the spectrometer.

If much measurement of angles has to be done, it is advantageous to dispense with the spectrometer altogether and build up a simple apparatus specially for the purpose. Both telescopes and the collimator can be supported by separate stands similar to *Fig.* 5. The only additional requisite is a prism table, capable of a small amount of rotation by means of a tangent screw, and having the usual adjustments for levelling the prism. All the apparatus should stand on a slab of slate or thick glass as described above. To adjust the axes of the telescopes to be coplanar, the following procedure should be followed. Place first one and then the other telescope in line with the collimator, and adjust so that the centre of the slit is at the height of the cross-wires. If the axis of the collimator were parallel to the supporting slab to begin with, the telescope axes would now also be parallel to it, and the three axes would be coplanar in any position. If however the collimator was tilted, say downwards, each telescope will be tilted upwards. Place the telescopes in line with each other, and illuminate the cross-lines of one by means of a lamp behind the eyepiece. On looking into the other, both sets of cross-lines will be seen, differing in height by twice the amount that the axes are inclined to the base. Bring them together, making half the adjustment with each telescope. They should now both be parallel to the base. Place one of them in line with the collimator again and adjust the latter. If the initial error was considerable the adjustment should be repeated. When all three are so adjusted that their axes are parallel when taken two by two in this way, they are also parallel to the base-plate and so are coplanar in any position. They can then be set up in the relative positions of *Fig.* 6, and the prism set on the table and adjusted as already described. If it is not convenient to provide the table with the necessary fine motion for bringing the image to the cross-lines of T_2, this can be dispensed with by providing a micrometer eyepiece for T_2 as well as for T_1. A comparison is then made by placing the two prisms as nearly as possible in the same position on the table and making settings with both micrometers.

With this simple apparatus, small differences of angle can be measured with exceedingly high accuracy.

A variant of the method, which eliminates the use of a collimator, employs auto-collimating telescopes. The type of *Fig.* 4 should be used, as this is convenient for use with micrometer eyepieces. The telescopes in this case are set normal to the faces, the difference in the micrometer readings when one angle is replaced by the other being equal to twice the difference in the angles as before.

§ (3) Determination of Standards.—The substitution method of § (2) gives the easiest and most accurate method of determining an angle, provided a standard angle is available from which it only differs by a small amount. The method itself enables us to determine standards for the most usual cases which occur in practical optics. *For a* 60° *standard*, for instance, a prism with all three surfaces polished is required. By taking the differences of the three angles in pairs and assuming the sum to be 180°, each angle is obtained absolutely.

For a 90° *standard* a square prism should be employed. Here again the substitution method provides the differences of the angles in pairs, and the sum, 360°, being known, the value of each angle is obtained.

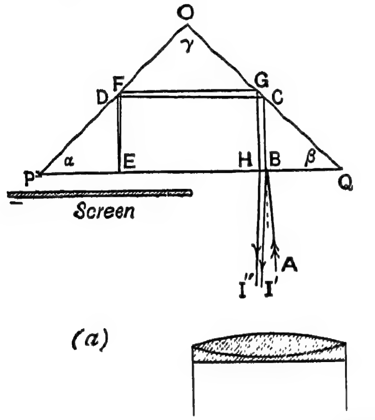
For a 45° *standard*, which may most conveniently take the form of an ordinary total reflecting prism, the difference in the 45° angle is measured by the substitution method,

and the right angle compared with the 90° standard. Thus the actual values of the 45° angles can be obtained.

For a 30° *standard* a prism of 30°, 60°, and 90° should be used. The last two angles are directly compared with the appropriate standards, 180° minus their sum giving the value of the remaining angle.

Thus the substitution method is self-contained, inasmuch as it can be employed to determine absolutely the standards required for ordinary test work.

§ (4) Auto-collimation Methods.—There are many methods of determining the commonly occurring angles in which the auto-collimating telescope is employed.[1] The most suitable telescope to employ is a small astronomical telescope of about $2\frac{1}{2}$ or 3 inch aperture, fitted with a micrometer eyepiece and the illuminating device of *Fig.* 4. The general method will be understood from *Fig.* 7 (a), which shows the arrangement for measuring the right angle of a 45° prism. The prism is placed in the position shown relative to the auto-collimating telescope, from which an incident beam AB, approximately normal to the hypotenuse of the prism, emerges. Two images will be seen in the field of the eyepiece, one due to rays such as BI′ reflected from the front face, the other due to rays which have passed through the prism by the path BCDE, being reflected approximately normally and returned along the path EFGHI″. The angular displacement of these two images depends only on the value of the right angle. The formula is easily deduced directly; but the following general method of treatment will be found useful. T. Smith[2] pointed out the great advantage, when dealing with the passage of rays through prisms, of "rectifying" the path of the ray. If one looks into a prism in any direction, he appears to be looking straight through a series of chambers which are reflections of the prism itself at the various surfaces encountered by the light rays. If these reflected prisms are drawn until a surface parallel to the front surface is reached, the path of any ray between these two surfaces is a straight line. When this is done for the cases which we are about to consider, it is found that they all reduce to the case of reflection from the front and back surface of a slightly prismatic plate. The deviation between such rays is $2\mu\theta$, μ being the refractive index and θ the inclination of the surfaces of the equivalent plate. The internally reflected ray is deviated away from the vertex of θ. The prism is developed in this way in *Fig.* 7 (b), the path of the ray within the prism being BEH. Let $\gamma = 90° + \delta$, δ being the error of the right angle. Then $\alpha + \beta = 90° - \delta$. The inclination between PQ and P′Q′ $= 180° - (P\hat{Q}P' + QP'Q') = 180° - 2(\alpha + \beta) = 2\delta$, the convergence being towards the left. The inclination of HI″ to BI_1 is therefore $4\mu\delta$. If the inclination were in the other direction, it would indicate that γ was less than 90°.



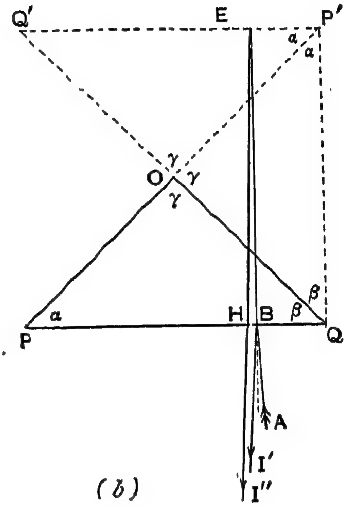


Fig. 7.

In *Fig.* 8 a number of other cases are drawn. A few words about each will suffice.

(a) To measure the difference between the 45° angles of a right-angled prism. $\theta = \alpha - \beta$. Deviation $= 2\mu(\alpha - \beta)$. In direction shown if $\alpha > \beta$.

[1] See Guild, *Proc. Phys. Soc.*, 1916, xxviii. 242; S. D. Chalmers and H. S. Ryland, *Trans. Opt. Soc.*, 1904–1905, p. 34.

[2] *Trans. Opt. Soc.*, 1918, xix. 120.

(*b*) Difference of two angles of equilateral prism. Deviation $=2\mu(\alpha-\beta)$.

(*c*) Prism of 90°, 60°, and 30°. Light incident on shortest face. $\theta=\pi-(3\beta+\gamma), =3p+q$ if $\gamma=90°-q$, and $\beta=30°-p$. Deviation $=2\mu(3p+q)$.

In general for a prism of this character in which one angle is $90°-q$ and another is $90°/n-p$, p and q being small errors, the divergence is $2\mu(np+q)$.

The defect of the auto-collimating methods for precise work is that the beam which traverses the interior of the prism is almost always thrown out of focus on account of slight want of homogeneity of the glass, and the accuracy of which the method would otherwise be capable is thus discounted. A second serious defect is that if the prism has pyramidal error (see next paragraph) the two images are at different heights in the field. This complicates the measurement very considerably. The difficulty is sometimes got over by modifications of the arrangements described, in which the condition of symmetrical use of the telescope objective is violated. In general practice therefore, in accuracy as well as convenience, the auto-collimating methods are inferior to the method of substitution.

§ (5) Defects of Prisms.—In the treatment of the previous paragraphs we have assumed perfect prisms, *i.e.* perfectly plane surfaces with the three edges parallel. In practice the surfaces are rarely absolutely flat and the edges generally converge slightly, *i.e.* the prism is part of an elongated pyramid. Clearly the measurements will only be of the highest accuracy provided the surfaces are flat enough for such accuracy to have any meaning. If the different parts of the surfaces vary in direction by several seconds, it is meaningless to attribute a more closely specified value to the angle between them. Prism surfaces are frequently convex or concave, being really long radius curves. This in practice may give rise to unexpected discrepancies between results obtained by different methods, in which, owing to the exigencies of the apparatus, different portions of the surface may be employed.

(i.) *Pyramidal Error.*—When the three edges are not parallel the prism is said to have "pyramidal error." With the exception of the general methods of § (1), the methods of precise goniometry which we have considered involve the assumption of the value of the sum of the angles of a prism. In the presence

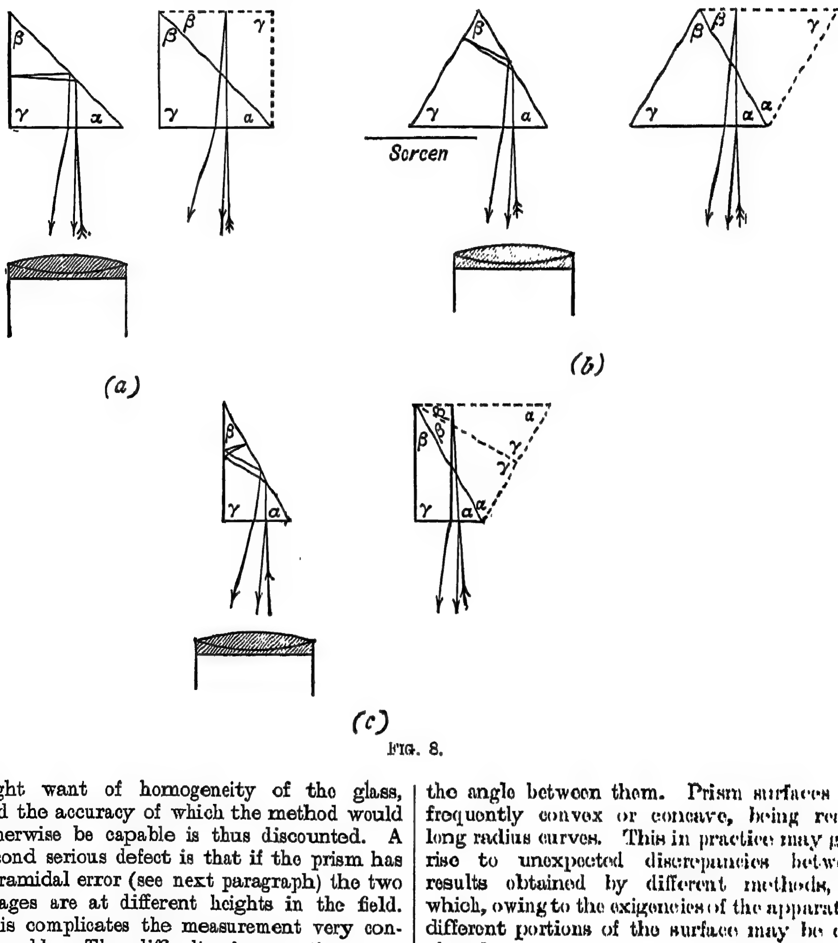

Fig. 8.

of pyramidal error this is not exactly 180°, since the angles measured are the actual angles between the faces, and these are only equal to the angles of a plane triangle when the normals are coplanar. The methods of defining pyramidal error vary considerably, but we shall define it here as the angle between one of the surfaces and the opposite edge. In the case of an equilateral prism the value is the same whichever face is considered, but in other cases it is not so. For any isosceles prism it is convenient to take as the pyramidal error the angle between the unique face and the opposite edge.

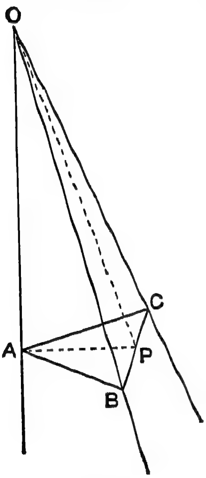

FIG. 9.

Let OBC, *Fig.* 9, be the plane of the face in question, and OA the opposite edge. Let ABC be a section by a plane perpendicular to OA. Draw AP perpendicular to BC. Then AOP is the pyramidal error, p, as above defined. $B\hat{A}C$ is the angle between the planes AOB and AOC $=\hat{A}$ say; but angle ABC is not the angle between the planes AOB and BOC, because AB and BC are not perpendicular to OB. If the angle between the planes is $\hat{B}$, $\hat{B} > A\hat{B}C$. Similarly $\hat{C} > A\hat{C}B$. Thus $\hat{A}+\hat{B}+\hat{C} > \hat{A}+A\hat{B}C+A\hat{C}B$. These are the angles of a plane triangle, $\therefore\ \hat{A}+\hat{B}+\hat{C} > 180°$. Denote $O\hat{B}A$, $O\hat{B}C$, and $A\hat{B}C$ by α, β, and γ respectively; then from the geometry of the solid angle of which α, β, γ, and $\hat{B}$ are elements,

$$\cos\gamma = \cos\alpha\cos\beta + \sin\alpha\sin\beta\cos\hat{B},$$

$$\therefore\ \cos\hat{B} = \cos\gamma\operatorname{cosec}\alpha\operatorname{cosec}\beta - \cot\alpha\cot\beta,$$

$$= \cos\gamma\,(1+\tfrac{1}{2}\cot^2\alpha+\tfrac{1}{2}\cot^2\beta) - \cot\alpha\cot\beta,$$

since α and β are nearly right angles.

$$\cot\alpha = \frac{AB}{AO} = \frac{AB}{AP}\cdot\frac{AP}{AO} = \frac{p}{\sin\gamma};$$

similarly $$\cot\beta = \frac{p}{\tan\gamma}.$$

$$\therefore\ \cos\hat{B} = \cos\gamma\left\{1+\frac{p^2}{2}\left(\frac{1}{\sin^2\gamma}+\frac{1}{\tan^2\gamma}\right)\right\} - \frac{p^2}{\sin\gamma\tan\gamma}$$

$$= \cos\gamma - \frac{p^2}{2}\cos\gamma,$$

$$= \cos\left(\gamma + \frac{p^2}{2}\cot\gamma\right),$$

$$\therefore\ \hat{B} = \gamma + \frac{p^2}{2}\cot\gamma.$$

For an isosceles prism, it is clear from symmetry that $\hat{C} - A\hat{C}B$ is equal to $\hat{B} - \gamma$. Therefore ξ, the excess of the three prism angles over 180°, $=2(\hat{B}-\gamma) = p^2\cot\gamma$.

In *Fig.* 10 the values of ξ for various pyramidal errors are plotted for the two

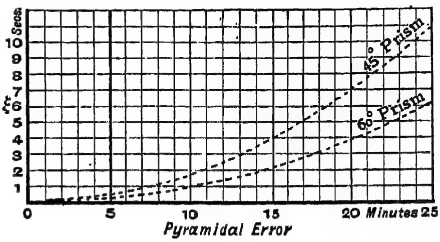

FIG. 10.

commonest prisms. We see that the sum of the angles may be taken as 180° without appreciable error if the value of p does not exceed 3 or 4 minutes. For larger values ξ increases rapidly and has to be taken into account in precise measurements. We may measure p on the spectrometer as follows. Let ABC, *Fig.* 11, be the prism, arranged as

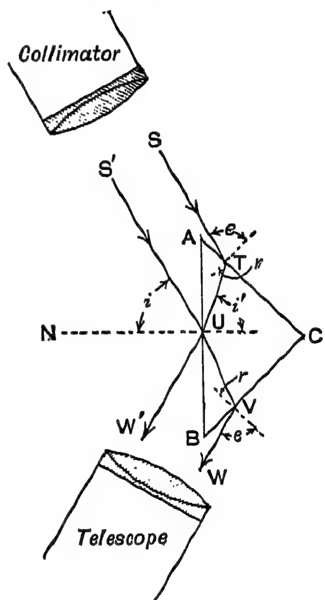

FIG. 11.

shown with respect to the collimator. Rays such as S′U are reflected from the face AB in the direction UW′. Rays such as ST follow the path STUVW, VW being parallel to UW′ if $\hat{A}=\hat{B}$ and $p=0$. In the presence of pyramidal error one will slope upwards and

the other downwards. Their vertical displacements can be measured with the micrometer eyepiece suitably oriented. Take as reference plane a plane perpendicular to the edge C, and let the incident light be in this plane. The normal NU will have an inclination p to the plane. Suppose it slopes downwards towards the left. Then the reflected ray UW′ slopes downwards by an angle $\phi=2p\cos i$. Since AC is perpendicular to the reference plane TU is also in this plane, so the ray UV slopes upwards by an angle $\phi'=2p\cos i'$. This ray meets BC, which is also perpendicular to the reference plane, and is refracted from glass to air. It is easily shown that ψ, the upward inclination of the emergent ray VW, is equal to $\mu\phi'$, where μ is the refractive index of the prism.

Thus the vertical displacement, δ, of VW with respect to UW′

$$=\phi+\psi=2p\,(\cos i+\mu\cos i').$$

We must substitute for i' in terms of the angles of the prism and the angle of incidence i.

$$i'=\hat{A}+r=\hat{A}+\sin^{-1}\frac{1}{\mu}\sin e,$$

$$=\hat{A}+\sin^{-1}\frac{1}{\mu}\sin\{\pi-(\hat{A}+i)\},$$

therefore

$$\delta=2p\left[\cos i+\mu\cos\left\{\hat{A}+\sin^{-1}\frac{1}{\mu}\sin(\pi-\hat{A}-i)\right\}\right],$$

whence p is obtained.

The advantage of this method is that δ is not appreciably affected by incorrect adjustment of the prism with respect to the plane of incidence; the effect is simply to introduce a cosine term. In carrying out the measurement, the two images of the slit will be superposed if $\hat{A}=\hat{B}$. To observe δ it is necessary to block out first the rays externally reflected and then those internally reflected.

Pyramidal error may also be measured by auto-collimating methods. In *Fig.* 7 (*b*), for instance, it is obvious that since the γ edges of the prism OPQ and its reflection OP′Q′ are coincident the faces PQ and P′Q′ have a *vertical* inclination of $2p$. Thus the vertical component of the displacement of HI″ with respect to AI′ $=4\mu p$. Similarly in *Fig.* 8 (*b*) the $\beta\gamma$ plane of the reflected prism is parallel to the β edge of the actual prism and is therefore inclined vertically with respect to the $\alpha\gamma$ face of the latter by p. Hence in this case the displacement of the two reflected beams has a vertical component $2\mu p$.

Grainless Photography, use for graticule production. See "Graticules."

Gramophone. See "Phonograph and Gramophone."

GRATICULES

Graticules, a term which came into common use during the Great War, may be defined as being the measuring marks or scales, usually on a glass plate or disc, placed in a focal plane of an optical instrument for determining the size, distance, direction, position, or number of the objects viewed coincidently with the scale itself. The term "graticule" comprises, therefore, the numerous appliances variously known as sighting scales, reticules, cross-lines, eyepiece, and stage micrometers, diaphragms, webs, etc., which are used in telescopes, microscopes, and other optical instruments, and it is usual to refer to the disc or plate with the marks on it as a "graticule."

Being normally viewed under considerable magnification, it is of primary importance that the lines or marks should be quite sharp and clean, whatever the thickness of the lines may be. The thickness may vary between ·0001″ and ·004″ according to the purpose for which they are used and the method of manufacture. The lines may be required to be opaque, or transparent, or to have special optical characteristics, and, except in the case of simple cross-lines, the divisions or spacing of the graticules usually demands the very highest degree of accuracy. Further, where the graticule takes the form of a circular disc inserted within an optical instrument, very exact centring of the pattern on the disc is an essential. Owing to these exacting demands in the way of accuracy and precision, the manufacture of graticules is not the simple matter which it would appear to be, and has been the subject of an immense amount of research.

The methods of manufacture may be classed under two main headings: (*a*) mechanical ruling, (*b*) photographic methods. The methods by mechanical ruling may be subdivided into—

(1) Ruling with a diamond on glass.

(2) Ruling with a diamond, and subsequently filling in the marks with graphite, or some other opaque substance, the latter being usually mixed for the purpose with copal varnish or some similar medium.

(3) Coating the glass with a transparent film of collodion or similar medium, and ruling the lines on this, subsequently cementing on a cover glass.

(4) Coating the glass with waxy or bituminous substances, ruling through this, then etching the lines by means of hydrofluoric acid gas, or by immersion in solutions containing hydrofluoric acid, and, lastly, filling in with opaque substances.

The photographic methods may be subdivided into—

(1) Photographs on plates or discs with

albumen or collodion emulsion having a grain as fine as possible.

(2) Photo-ceramic methods.

(3) Photo-etching methods.

(4) By Grainless Photography.

(5) By Filmless Photography.

Of these various methods Nos. 1 and 4 of the photographic methods require a cover glass cemented on to protect the film; all the others are " coverless " graticules.

In all countries the principal method of manufacture up to the year 1914 was the mechanical method, the marks being usually filled in with an opaque substance. Simple patterns, such as straight lines at equidistant intervals or cross-lines, can be produced very perfectly in this way, but the method becomes cumbersome when anything more elaborate is required, such as scales with varying line thickness, or curved lines or numbered lines. Further, where lines cross each other the glass is apt to be broken up, causing the critical point to be less good than the rest, and this has led to the practice, when ruling lines at right angles to each other, of stopping the line just short of the cross-line, and continuing it again a short distance from the other side. The sharpness and apparent opacity of diamond-ruled lines depend on the cleanness and fineness of the diamond cut and personal skill of the operator; the diamond points are apt to wear out fairly rapidly and then produce inferior work.

Ruling and etching methods are not so subject to wear and tear of the ruling point, because the waxy or bituminous substance ruled through is soft. Curved lines, numerals, or letters can be reproduced by a pantograph arrangement. In other respects they suffer from the same limitations in manufacture as diamond-ruled graticules, and it is exceedingly difficult to coat them with a resist so perfect that the hydrofluoric acid does not attack the glass here and there through the resist, occasioning tiny marks or spots on the glass which are objectionable.

Graticules produced by any method of mechanical ruling require separate testing for accuracy and finish, each being an individual piece of work standing on its own merits.

Graticules produced by photographic means have a great advantage in this respect, for any number of graticules can be produced exactly similar to one another, without requiring separate testing for accuracy of scales, always provided that the photographic method employed is one in which the film is given no chance of expanding or contracting during the process. The main security for this is by only employing such processes in which the film is not transferred from one glass to another, *i.e.* each graticule disc or plate must be coated separately and the film must be left *in situ* throughout the operations.

Many fine grain processes have been employed, collodion in general having been found to be the most suitable medium, since gelatine coatings almost invariably accumulate dust specks and are not sufficiently clear. Carbon processes on bichromated gelatine or fish glue have likewise been employed; in this case all except the image lines, which are rendered insoluble, is removed by washing. Such processes yield very fair results in the case of graticules with comparatively coarse lines, or which are subject only to low magnifications.

Photo-ceramic methods have been employed in Germany mainly for one particular purpose, viz. graticules for binoculars. These graticules have a transparent image, which is more or less faint—an advantage for the purpose in question. They show little evidence of grain. The process has been kept secret, but some ideas as to the methods by which they are produced may be inferred from German and Austrian photo-ceramic literature.[1]

Messrs. Adam Hilger, Ltd., of London, have also developed a photo-ceramic method. These graticules have a fine grain, the image lines being sufficiently firmly adherent to the glass surface to stand the necessary cleaning of the discs. They will also withstand ordinary solvents. This process would seem to have been employed mainly for graticules with fairly coarse lines, used with low magnification.

Photo-etching methods which were worked out by J. Rheinberg, London, in the early years of the War, by coating discs with an emulsion impervious to the action of hydrofluoric acid gas before exposure to light, but pervious to its action after exposure, have not hitherto proved successful, because the resist suffered from the same defects already referred to as liable to occur in the etching methods after mechanical ruling.

Methods of graticule production by photography on a sensitive collodion film, having a grain so fine as to stand considerable magnification, date back a considerable time, and until recent years were chiefly practised in Germany. The actual process has been kept secret, but there is evidence to show that it has followed on the lines of the old Taupenot Collodion Process, dating from 1855, or some modification of the process.[2]

Messrs. Rheinberg & Co., London, have in recent years introduced graticules made by a secret process styled " Grainless Photography," which differs widely from any

[1] *Die Photokeramik* by Julius Krüger and Jakob Husnik, published by A. Hartleben, Vienna and Leipzig.

[2] For an account of these processes readers are referred to Hardwick's *Photographic Chemistry*, 1859, and an article on "Fine Grain Photographic Plates," *British Journal of Photography*, September 13, 1912.

previous process, both as regards the composition of the film, the chemicals employed, and the methods of photographic treatment. Collodion is used as the vehicle of the image. By different modifications of the process, either black opaque lines are produced, or white opaque lines, or transparent lines in grey, amber, violet, or other tints. The lines remain clean and sharp under considerable magnification, the transparent ones show no vestige of grain under high magnifications.

Graticules produced by so-called "Filmless Photography," another secret process developed by the brothers Rheinberg during the Great War, represent the latest advance. These are similar in appearance and characteristics to those by "Grainless Photography," and may be opaque or transparent, but the image vehicle is the surface layer of the glass itself, in which the lines are formed in untarnishable metal. In a perfect filmless photograph the lines cannot be rubbed or cleaned off, and they are unaffected by solvents save one or two powerful acids, chiefly those which attack the glass itself.

In one special modification of this process, termed the "Silverline" process, a brilliant white image consisting of an extremely fine fibrillar interlaced network of granulated silver, is produced upon the glass surface, and not incorporated within the surface layer. This image, unlike that in any other kind of graticule, has the property of reflecting an approximately equal amount of light in all directions, no matter at what angle the light is incident upon it. The image, however, requires protection by means of a varnish.

In a paper on "Graticules" (*Transactions of the Optical Society*, May 1919) Mr. Julius Rheinberg has stated the general methods and considerations relating to their photographic production (with special reference to those made by Grainless and Filmless Photography), together with considerations as to their design in relation to the various purposes for which they are required, and in the main the following particulars are abstracted herefrom.

The usual way is to start with a greatly enlarged drawing, say from 12″ to 15″ diameter, from which an intermediate reduced negative is produced, and this is again reduced in a precision camera to the exact size. The positive so obtained serves for the production of the "Master negatives," from which the graticules are then made by "contact printing." Drawings should be on smooth, thick, Bristol board, not on thin paper or linen which has a tendency to cockle. For fine work the nature of the ink is important, and of a number of Indian inks tried, Messrs. Winsor & Newton's "Mandarin Black" was found to be the best.

Whilst it is not needful to draw the original to any particular scale of magnification, it is very needful to bear in mind that all photographic processes increase the relative thickness of lines, partly owing to the grain of the plate, partly owing to optical considerations, and, to compensate for this, the lines of the drawing should be finer than the actual scale of magnification of the drawing. Even in graticules produced by Grainless and Filmless Photography the intermediate negative has to be made on a fine *grain* plate, because grainless emulsions are too slow to admit of camera reductions from drawings on an opaque board, and lines intended ultimately to be—

1/500″ should be drawn about 5 per cent thinner than the scale magnification.
1/1000″ should be drawn about 10 per cent thinner than the scale magnification.
1/2500″ should be drawn about 50 per cent thinner than the scale magnification.

The optical considerations referred to above relate to the limits of accuracy germane to all reproductions by photographic lenses. No lens produces an equally sharp image on a flat plate over the whole field, but the deviations are small enough to be negligible with a good lens in ordinary photography because the lines are much coarser and the grain of the plate itself is usually the determining factor in setting the limit. When, however, lines of ·0005 inch and less are in question, the lens sets the limit, as it is difficult to secure these evenly over more than a comparatively narrow angular field.

Similarly the lenses themselves set a limit to the accuracy with which long scales can be reproduced by photographic reproduction, as slight errors may occur in the spacing of divisions owing to zonal differences of magnification.

For these reasons many kinds of graticules cannot be properly produced from large drawings by camera reduction at all, the "master negatives" being made by contact printing from originals mechanically ruled. Where figures, etc., are employed combinations of photographically reduced drawings and mechanically ruled scales can be used to produce the master negatives.

In this manner grainless photographs have been produced with lines as fine as 1/12500″, although lines finer than 1/5000″ are a matter of considerable difficulty.

In any photographic process of graticule production the order of accuracy between one scale and another, when large quantities of a scale are produced, is a matter of importance. This will depend entirely on the nature of the process, also whether any film transfer has taken place. In the case of Grainless and Filmless Photography a number of scales were sent to the National Physical Laboratory, taken from batches at random, which had all been produced from the same master negative, but not actually from the same negatives, as a master negative serves for making any number of the actual negatives used by means of intermediate positives, and the tests showed the maximum error of the scales, either as regards over-all length, or as regards the divisions, to be within one-twentieth per cent, and consequently since this error included any

actual error in the original master negative, the actual variations between one scale and another produced by either of the processes in question would be below that amount. The main test was made on scales of 10 mm. length; tests on smaller numbers of scales up to 100 mm. length gave similar results.

The vehicle bearing the image is an important consideration in graticules produced photographically. Collodion has in general been found to be the most suitable and is employed in the Grainless Photographic process as well as in the foreign-made graticules.

In Filmless Photography, however, the vehicle which bears the image is the surface layer of the glass itself, and the nature and composition of the glass play an important part, since the process is based on the idea that as glass is porous, though the pores may be ultra-microscopic, matter in a suitably fine state of division can be introduced into these pores by appropriate methods. The most suitable kinds of glass have been found to be the various descriptions of crown and plate glass. Glasses of a particularly dense nature, such as barium glasses and baryta light flints, have been found less suitable, although with more or less trouble filmless photographs can be produced thereon, particularly transparent photographs which do not necessitate the introduction of as much metal into the surface layer of the glass as opaque ones. Glasses containing any considerable proportion of lead, *i.e.* the ordinary description of flint glasses, are unsuited to the process, though this is due to the softness of these glasses and chemical combinations which take place rather than to any question of density.

The uses to which graticules are put are fairly numerous; they form a most essential part or adjunct of the optical instrument in or with which they are employed, and there are but few optical instruments used in peace or war in which they are not either permanently or temporarily used. A good example of the relative importance the graticule may assume in an optical instrument is afforded by the Aldis Unit Telescopic Sight for aeroplanes, the whole instrument being merely a device for seeing the graticule image sharply, coincidently with the target which is viewed without any magnification whatsoever.

The kind or variety of the graticule naturally depends upon the purpose for which it is used in an optical instrument, and the advent of Grainless and Filmless Photography which enables graticules to be produced with image lines opaque, transparent, or semi-transparent, in various colours or tones and possessing different optical properties, has not only considerably increased the purposes for which they can be employed, but also in some instances given rise to new forms of instrument construction. The majority of graticules are required for use with transmitted light, and for most of these it has been customary to use graticules having opaque black lines, the possible advantage in some cases of transparent lines not having received any adequate attention, probably owing to the fact that such graticules were not generally available.

The optical difference between a neutral coloured transparent line and an opaque one is that the former reduces light from the object by a definite percentage, whereas the latter cuts out the whole of the light. There would appear to be a prevailing impression that transparent lines will not stand out sufficiently, or show sufficient contrast against a dark ground, which, however, experiment will show not to be based on fact. Excessive contrast induces eye fatigue and loss of comfort in use, which becomes particularly noticeable and indeed irritating when graticules have opaque patterns in the nature of squared lines or other repeating patterns. Such contrast may hinder the eye in picking up and inspecting critically the object to be viewed. An outstanding merit of transparent lines is that they do not cut off any part of the object viewed, a not unimportant matter where lines are fairly coarse, *i.e.* exceeding ·001 inch, which are frequently required. Other advantages of transparent lines are referred to later on in the notes on graticule design.

For one class of graticules, viz. military binoculars, transparent lined graticules have, however, been in use for some considerable time; for this purpose the German photo-ceramic graticules were in use prior to the war, also etched or directly ruled lines on glass, not filled in. They afford a typical example of the benefit of faint transparent lines, as they do not distract the eye from the object and are little noticed, unless attention is purposely concentrated on them.

Another class of graticules, used typically in sighting instruments for day and night use, are intended for use both with transmitted light and reflected light, appearing black when illuminated in the former way, and white in the latter. They are produced by filling in a diamond-ruled image with white opaque lines, or even more satisfactorily by a modification of the grainless photographic process, which yields white opaque lines. Their opacity renders them black by transmitted light, and for night work the light is introduced through the edges of the disc by a subsidiary lamp, the light so introduced being imprisoned in the glass except where it strikes the image lines, which reflect a portion of it towards the eye lens.

This class of graticules would seem susceptible of development to numerous uses, for example spectroscope eyepieces, as, by illuminating the disc

edge with coloured light, the graticule image may be made to approximate in colour to the part of the spectrum under observation. It is well known that the eye will not sharply focus widely differing colours, or colours and white lines simultaneously, hence the utility of some such device.

Graticules for use by reflecting light only are in general produced by the same processes already referred to. They are usually illuminated either directly or by reflectors prepared with white-diffusing substances.

Whilst in all ordinary cases a graticule is so mounted that the plane of the graticule disc is parallel with the lenses of the optical system with which it is used, an exception occurs in certain military instruments, in which the graticule has to be viewed through the optical system at continuously varying obliquities, whilst the direction of the light

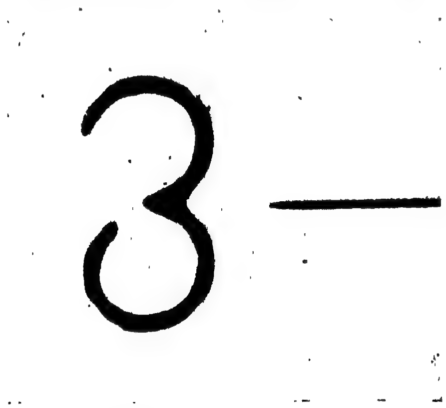

FIG. 1.—Black opaque. Line thickness ·0004″. Magnification 85.

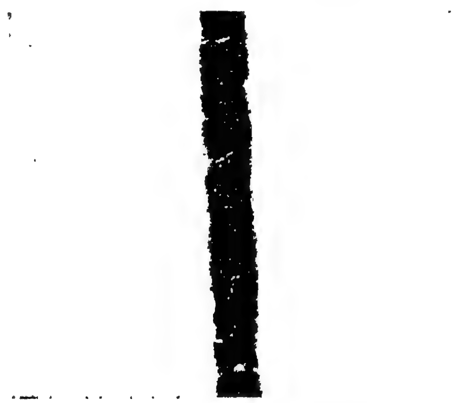

FIG. 2.—Black opaque. Line thickness ·0004″. Magnification 650.

which is reflected from the graticule lines remains more or less constant. Ordinarily the intensity of the light reflected by a line or a surface varies greatly according to the angle at which the light impinges on it, as a consequence of which the image of the graticule would be far less brilliant when viewed at certain degrees of obliquity than at others. To meet this case the "Silverline" process already referred to was devised, in which the image lines have the property of reflecting or diffusing light of approximately equal intensity in all directions, irrespective of the angle at which the light impinges on them.

Another class of graticules are such as have clear lines on a black opaque ground. These are illuminated from behind or by a separate source of artificial light. They are mostly used in the type of instrument in which it is desirable to project graticule lines, etc., in the image plane, but in which it is not convenient to place the graticule in the main optical system, either because that system has no real focal plane, or for other reasons of design. A frequent device is to place the graticule in the focus of a collimating lens and place a semi-transparent reflector in the main optical system at an angle of 45°. Graticules of this description are produced by Grainless Photography, and are similar to the negatives ordinarily employed in that process.

The design of graticules is a matter repaying careful attention. It should not be overlooked that the graticule is often an essential, and frequently a vital part of the optical instrument, that it is under constant scrutiny, and should be so designed as to secure the maximum efficiency and the greatest amount of comfort in use. To ensure this it is absolutely necessary that it should be properly correlated to the conditions under which it is used and to the general optical system of the instrument.

It is desirable to consider—

(1) The nature of the pattern.
(2) The thickness of the lines.
(3) Questions of opacity or transparency.
(4) Questions of differentiation or colour.
(5) Special optical desiderata.
(6) Questions affecting price or difficulties in production.

Regarding the nature of the pattern, an important point is to keep it as simple as possible. Every superfluous line, figure, or other mark should be eliminated, for these only occupy the field otherwise wanted for examination of the object and distract the eye. The fact that additional lines, figures, and so forth do not add commensurately to the cost of graticules produced by photographic processes is a temptation to load them up unnecessarily, but should be resisted, as

practical experience during the War has frequently led to complicated patterns being successively simplified.

With regard to the line thickness of graticules, a number of interesting little points require to be borne in mind and balanced, and in considering these it is convenient to remember that a line 1/1000″ wide, viewed with the unaided eye at normal, *i.e.* 10″ distance, subtends an angle of about 20 seconds. Opaque lines when viewed against a white ground appear rather thinner than they actually are, as the white light encroaches on the two edges of the line, by irradiation of the eye. When the opaque line is too narrow, the line appears faint and indistinct and begins to be uncomfortable. With the unaided eye a line 1/500″ or 1/20 mm. is sufficiently narrow for comfort. For eyepiece graticules the magnification of the eye lens has to be taken into account, and the best rule for comfort is not to have lines narrower than needful. With eyepieces magnifying × 5 to × 8 opaque lines 1/2000″ or 1/80 mm. will be found sufficiently fine. In micrometer scales divided into tenths or twentieths of a millimetre the width of the lines may reasonably be reduced to 1/5000″ or 1/200 mm., and in scales of this description, or scales divided even more finely for microscope stage micrometers of the ordinary description, opaque lines are the most suitable. The illustrations, Figs. 1 to 4, are from photomicrographs of Rheinberg Filmless Graticules taken by Mr. J. E. Barnard, F.Inst.P.

Transparent lines seen against a white ground always appear markedly narrower than opaque ones of similar width, due partly to the greater encroachment on their edges by irradiation. It is rarely necessary or advisable to go below ·001″ in width, the more so as they have the advantage that the object viewed can be seen through them, and centred to the middle of the transparent line with very great accuracy. This feature is also useful because lines of varying thickness can be used on the same graticule disc for differentiation purposes, without sacrificing accuracy of measurements.

Where squared lines or repeating patterns, or markings in the nature of massed patches, are required, transparent lines should always be given preference over opaque ones, unless the latter are indispensable for reasons necessitating *maximum* contrast. The depth of tint of transparent lines should be appropriate to the magnification under which they are to be viewed, as it is a somewhat remarkable fact that it differs with the magnification. The same grey line of ·002″ width may look almost black to the unaided eye; seen with an ocular × 5 it appears grey, with an ocular × 10 a lighter grey, on the microscope stage magnified 100 times it appears a very light grey indeed.

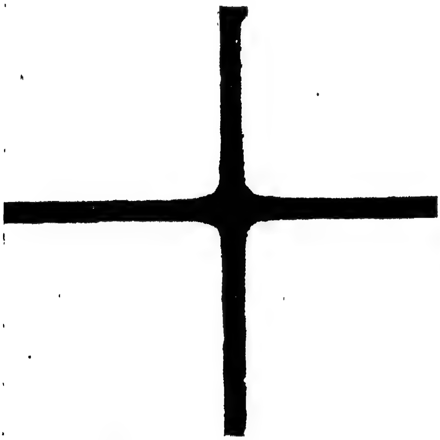

FIG. 3.—Black opaque. Line thickness ·001″. Magnification 85.

FIG. 4.—Black opaque. Line thickness ·001″. Magnification 650.

Differentiation for the sake of clearness and facility in reading or counting is a factor which should receive consideration. For instance, in a graticule for counting purposes, a field consisting of alternate transparent grey and colourless square patches in a chessboard pattern—the so-called Chessboard Micrometers—are more comfortable and easy to work with than graticules simply divided into squared lines. Lines of different thickness on the same graticule are another form of differentiation. Cases occur, however, where it is still more convenient to differentiate by lines of different colour on the same graticule. Such graticules

were patented by Messrs. Aldis Bros., Birmingham, and known by name of composite graticules, because they are usually produced by doing the different colours by Grainless Photography on two separate discs and cementing them together. The colours themselves, in so far as it is possible to produce them, may be selected to obtain contrast in accordance with the purpose for which they are used; for example, an aeroplane telescope graticule for use against the blue sky might have golden amber lines, one principally for use against green foliage would conveniently have lines of a violet tone.

When one scale is measured against another scale (microscope stage micrometers and eyepiece micrometers offer a familiar example) there is an advantage in having the scales differentiated in colour so that they can be distinguished at a glance.

The special optical desiderata which the graticule should possess will depend chiefly upon the methods of illumination under which it is to be used, *i.e.* whether by transmitted or reflected light or edge illumination, whether it is to be viewed normally to its surface or otherwise, whether with colour screens or such-like considerations. These matters have already been referred to.

Lastly, a graticule designer should bear in mind that the cost of production of any pattern frequently depends largely on seemingly quite trivial matters, and should consult with the manufacturers in order to avoid specifications which unduly increase cost without increasing efficiency. For example, specifying a graticule on a disc 10 mm. diameter, when a disc of 15 mm. diameter might be adopted just as well, might entail a difference of 50 per cent in cost of production. Or by requiring the cross-lines in a Filmless Photograph to go right up to the edge of the disc, a large extra cost may be incurred compared with one in which the lines leave off ½ mm. or 1 mm. from the edge of the disc. Very fine lines in immediate contiguity to very coarse ones are inadvisable, as they require different treatment by all photographic processes. In short, the instrument-maker should remember that the graticule, which is at least as important as the other parts of his optical instrument, should not be treated as an independent adjunct, to be fixed up after everything else is settled, but should be carefully considered along with the design of the whole instrument, if he is anxious to obtain maximum efficiency at lowest cost.

Consequent upon the limitation of patterns owing to the restricted methods of production available until recent years, the application of graticules has not been developed in many directions in which they would appear susceptible of extension. During the Great War the tendency manifested itself for the design of new types of optical apparatus which would not have been feasible but for the fact of the facility with which new and unusual types of graticules could be produced, and it seems likely that many types of optical apparatus might be improved, or new types designed, by paying due regard to the possibilities which graticules now afford. It is only needful to bear in mind, for instance, that the steel slits of spectroscopes could be replaced by graticules having a series of perfectly sharp, clean, colourless lines on a black ground of definite widths, and that as the films have less thickness than steel jaws there is less liability to stray reflections or diffraction. Or, again, the fact that completely divided circles can be produced with great accuracy in the form of a small graticule opens up the possibility of designing instruments in which such circles are either placed in, or projected into, the plane of optical instruments to supplant the large and expensive graduated metal arcs and circles with their separate reading-microscopes elsewhere. Such examples show that the possible applications of graticules with a view to improvements or simplification in the design of optical instruments is a subject which will well repay study, and has indeed its own place in the general study of Applied Optics.

HEIGHT, DEFINITION OF. See "Surveying and Surveying Instruments," § (36).

HEIGHT-FINDER, THE PATERSON-WALSH ELECTRICAL

§ (1) THE BENNETT-PLEYDELL PRINCIPLE.—For determining the height of an object, as distinct from its range, the simplest geometrical arrangement is that involving the measurement of the distance between two stations and of two angles. This was suggested in connection with the determination of the height of aircraft by Lieutenant Mansell Pleydell and Dr. G. F. Bennett, and is known as the Bennett-Pleydell principle.

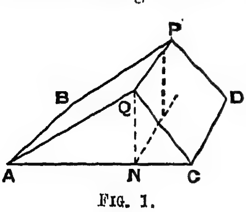

FIG. 1.

In *Fig.* 1, if two planes ABPQ and CDPQ be rotated about their axes AB, CD, until they intersect in PQ, then if AB and CD be parallel to each other, perpendicular to the line AC, and in the same horizontal plane, every point on the line PQ will be at the same height above this plane, this height being given by the formula $h = AC/(\cot A - \cot C)$, where A and C are the angles (both measured in the same sense) which the planes ABPQ and CDPQ make with the horizontal.

For in *Fig.* 1 let AQC be a vertical plane through the base AC, and QN perpendicular on AC. Then

$$QN = h, \text{ also } QAN = A, \ QCN = 180^\circ - C.$$
$$AN = QN \cot QAN = h \cot A.$$
$$CN = QN \cot QCN = -h \cot C.$$
$$\therefore AC = AN + CN = h(\cot A - \cot C).$$

§ (2) THE TELEPHONIC INSTRUMENT.—The height-finders which have been designed on this principle are long-base instruments. The first (telephonic) type consists of two stations, one at each end of a base about a mile long. At each station there is a wooden stand (*Fig.* 2) holding a rectangular sighting frame F,

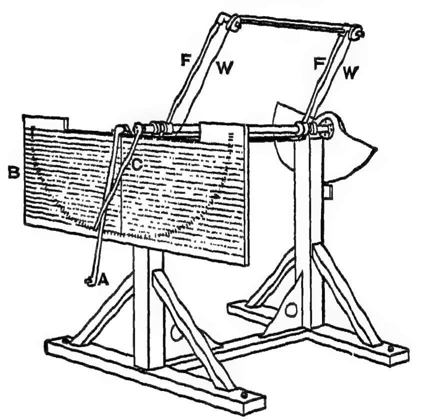

FIG. 2.

capable of rotation about a horizontal axis. At one end of each instrument is a dial and pointer arrangement giving at once the angle between the horizontal plane and the plane of the sighting wire WW attached to the rotating framework F. At the other end of *one* instrument is a "plotting-board" B, rigidly attached to the upright and engraved with a series of equidistant horizontal lines marked in thousands of feet. In addition to these lines there is a semicircular scale of degrees over which a loose arm A may be swung at will. Rigidly attached to the rotating framework F is a second arm C. The inner edge of each of these arms passes

through its own axis of rotation, and the distance between these axes represents the distance between the "home" and "distant" instruments on the same scale as the vertical distance between either axis, and any one of the horizontal lines represents the height marked on that line.

In using the instrument the sighting frames at both stations are set with their axes parallel and at right angles to the base and are turned so that the plane of each wire rectangle passes through the object. The angle of elevation of the "distant" plane is then telephoned to the "home" station, and the arm A is set to this angle on the plotting-board. The arm C automatically gives the same information for the "home" station; the triangle formed by the inner edges of the arms A and B, with the horizontal line passing through their axes, is an inverted scale reproduction of the triangle AQC of *Fig.* 1. Hence the height of the object sighted may be read off from the position of the intersection point of A and B.

§ (3) The Electrical Instrument.—The chief disadvantage of the telephonic instrument is that its readings, being dependent on communication of the angle of elevation at the distant station, are necessarily discontinuous and possess a certain small time lag. To obtain a continuous indication of height the electrical instrument was devised. In this the use of the plotting-board and scale of angles was dispensed with except as incidental to the periodical checking of the electrical adjustments. At each station there is a uniform resistance supported horizontally at a fixed distance below the axis of the sighting frame, and with its centre directly under this axis. Attached rigidly to the axle of this frame, and in continuation of the plane of the sighting wires, is a phosphor-bronze bar which presses against the horizontal resistance. In this way the distance between the *centre* of the resistance and the point of contact of the bar is always proportional to the cotangent of the angle of elevation of the sighting frame (see *Fig.* 3). Thus if it

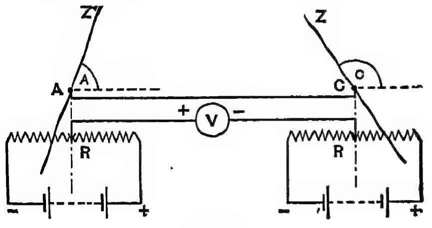

Fig. 3.

be arranged that there is a constant current passing through the resistance, the difference of potential between the bar and the centre of the resistance is also proportional to this quantity

By means of a local battery, voltmeter, and regulating rheostat, the voltage drop across a given length of resistance is maintained at the same constant value at both home and distant stations. The distances between the axes of rotation of the sighting frame and the horizontal tracks of the phosporbronze bars on the resistances are also the same at both stations, so that by connecting line conductors between the stations in such a manner as to put the two voltage differences in series, a milliammeter with a suitable swamping resistance in the circuit gives at once a reading proportional to (cot A − cot C). It follows that, in order to obtain a direct reading of height, the instrument must be provided with a reciprocal scale. For the purpose of increasing the range two scales are provided, one from 1600 to 5000 ft., and the other from 5000 to 20,000 ft. The more open scale is brought into operation by pressing a key switch which normally short-circuits a shunt to the moving coil of the instrument.

§ (4) The Paterson-Walsh Instrument.—The series resistance of the milliammeter is variable, and is so adjusted in relation to (i.) the actual voltages employed at the two stations, (ii.) the sensitivity of the milliammeter, and (iii.) the ratio of the base length to the vertical distance between the axes of the sighting frames and their respective resistances, that a given base length corresponds with a definite series resistance for all instruments. Corresponding values are tabulated in the instrument box, so that any instrument can be used with any length of base by suitably adjusting the series resistance. The electrical circuit used in the Paterson-Walsh design of the instrument is shown diagrammatically in *Fig.* 3. R, R are the uniform resistances, AZ, CZ the sighting planes, and V the milliammeter. In this diagram the local arrangements for maintaining a constant and definite current through the resistances are not shown.

The chief errors to which the instrument is liable are (i.) leakage in the insulation of the main conductors between the stations, and (ii.) change of resistance of these conductors with change of temperature. On this latter account these conductors are required to be as heavy as possible, so that their resistance may be properly swamped by the series resistance of *V*.

§ (5) Other Instruments.—It will be clear that other adaptations of the principle of the electrical solution could readily be devised. One of these avoids the use of a battery at each station. The two portions of the regular resistances are put in series and form one arm of a Wheatstone bridge. By continuously adjusting a local resistance

to keep the bridge in balance, a measurement of the height may be obtained from the value of this resistance in circuit at any time.

The accuracy of all height-finders working on the Bennett-Pleydell principle is necessarily dependent on the parallelism of the axes of the two sighting frames, and it is desirable that the departure from this parallelism should not exceed 6′ of arc. If parallel, the axes may be slewed with respect to the base line by as much as 5° without correction, or by any angle up to 30° if the length of the base line be corrected by the factor cos θ.

§ (6) Correction for Difference of Level.—In all that has been said above it has been assumed that the two stations are on the same level. If their difference of level be d, it may be readily shown that the new formula for h is

$$\frac{\{b-(d/2)(\cot A+\cot C)\}}{(\cot A-\cot C)}.$$

A rigorous practical solution of this expression is not possible, but a very close approximation, in all practical cases, to the correct result is obtained by setting over the sighting frames with respect to their pointers, so that when the latter are reading 90° the frames are not vertical, but are tilted downhill *at both ends* by an angle equal to half the angle of the slope (supposed continuous) between the two stations. In this manner the instrument indicates the values of $b\,(\cot \overline{A-\theta}-\cot \overline{B-\theta})$, where $\tan 2\theta = d/b$, and it may be shown that this formula gives a very close approximation to the accurate expression, heights being indicated as above the *mean level* of the two stations.

§ (7) Use of the Instrument.—The instrument can be used for all angles of elevation greater than 20°, but below this value the line of contact of the phosphor-bronze bar on the even resistance is liable to variation, and a small inaccuracy of sighting produces a considerable error in the indicated height. The error of an instrument such as that described should not exceed 300 ft. at a reading of 12,000.

It will be apparent that if sight of the object be lost at one station an entirely erroneous reading may be given by the indicating instrument if no means is provided for cutting it out of circuit. In the actual design, the circuit connecting the two stations with the indicator is not completed until a small key switch is depressed at each station. These keys are operated by the observers at the sighting frames, so that if the target be lost at either end, the indicator can be at once brought to zero, *i.e.* to infinity height on the reciprocal scale.

IMMERSION REFRACTOMETRY

§ (1) INTRODUCTION. — The ordinary direct methods[1] of measuring the refractive indices of glass specimens cannot be applied when one wishes to determine the refractive properties of a specimen of glass which is unpolished, or is in the form of a lens, or is very small. It is frequently either inadvisable or impossible to grind and polish optically flat surfaces on a specimen, on account of its being a component of some optical system which it is essential to keep intact, or because of its small size. In such cases the usual method adopted for measuring the refractive index for any given wave-length is to immerse the specimen in a transparent liquid having approximately the same index, and to vary the concentration of the liquid until the refractive indices of liquid and specimen for that wave-length are the same. The refractive index of the liquid is then measured by means of one of the ordinary methods.

Four of the more important methods which depend on this principle are as follows :

§ (2) CHRISTIANSEN'S METHOD.—Christiansen[2] described an immersion method of measuring the refractive index of glass in the form of a fine powder. The powder is placed in a hollow glass prism of refracting angle 45° to 60°, which is filled with a mixture of carbon disulphide and benzene. When a homogeneous mixture has been obtained by means of stirring, the prism is placed on the table of a spectrometer, the collimator slit of which is illuminated by a sodium flame. The sodium line is seen sharply defined in the telescope. The powder gradually sinks to the bottom of the prismatic cell and the constitution of the mixture becomes different in different horizontal layers. As a result of this a band of light is seen in the field of view of the telescope. After some minutes, however, the powder collects at the bottom of the cell. One now sees two sharp lines, one due to refraction in the clear liquid and the other due to refraction in the saturated mixture. The refractive index of the powder may then be determined from the results of measurements of the refractive indices of liquid and mixture for two slightly different concentrations of the liquid. Christiansen determined by this method the refractive indices of a specimen of crown glass for the lines C, D, and F. His mean results differed from those obtained by direct measurement by 1 to 5 units in the fourth decimal place.

The above method can only be applied to the case of very finely divided powders, for with coarser powders homogeneous mixtures cannot be satisfactorily obtained. Christiansen measured the refractive properties of coarser powders by a different method, which is easier to apply, but does not yield quite so accurate results. The principle of the method is as follows. If one introduces glass powder into a suitable mixture of carbon disulphide and benzene, one can observe two colours, one of which consists of light which passes through without refraction, while the other is composed of all the other colours. The two colours are therefore complementary, the first being monochromatic and the second heterochromatic. Christiansen in his experiments made use of two sensitive tints corresponding to monochromatic light of wave-lengths 530 and 460 $\mu\mu$; the heterochromatic colours were reddish-violet and dirty yellow respectively. The concentration of the carbon disulphide and benzene mixture is gradually altered until the first sensitive tint is observed. The refractive indices of the liquid and the

[1] See article on "Spectroscopes and Refractometers."

[2] C. Christiansen, *Wied. Ann.*, 1884, xxiii. 298; 1885, xxiv. 439.

glass are then the same for the wave-length 530 $\mu\mu$. The indices of the liquid for the lines C, D, and F are determined in the ordinary way, and the index for the wave-length 530 $\mu\mu$ is obtained by interpolation or with the aid of Cauchy's dispersion formula. The process is then repeated for the second sensitive tint. In this way the refractive indices of the glass for the wave-lengths 530 and 460 $\mu\mu$ are determined. A specimen of flint glass was experimented with, and the values of the indices obtained by this method for the critical wave-lengths differed from those derived by direct measurement by 8 units and 1 unit in the fourth decimal place respectively.

§ (3) Chalmers' Method.—Chalmers [1] employed a method of measuring the refractive indices of a lens, which consisted in immersing the lens in a liquid of approximately the same index and determining its focal length. If μ_1 is the index of the lens and μ_0 that of the liquid, the focal length F is given by

$$F=(\mu_1-\mu_0)(R_1-R_2),$$

where R_1, R_2 are the curvatures of the surfaces, considered positive when convex to the incident light, provided that the thickness of the lens is small in comparison with the radii of curvature. It is then only necessary to determine the values of F, R_1, and R_2 to the degree of accuracy that is required for the value of $\mu_1-\mu_0$. A series of stable transparent liquids of suitable refractive index is used; for example, cedar oil ($\mu_D=1{\cdot}517$ approximately) and oil of cloves ($\mu_D=1{\cdot}530$ approximately) are useful for the measurement of the indices of crown lenses. An average accuracy of about 5 units in the fourth decimal place was obtained with the method.

§ (4) Martin's Method. — The principle of this method [2] is to immerse the specimen in a suitable liquid, such as carbon disulphide or mercury potassium iodide, contained in a prismatic cell resting on the prism table of a spectrometer, and to adjust the concentration of the liquid until the spectrum line, for which the refractive index of the specimen is to be measured, is seen in sharp focus. The angle of minimum deviation for the line in question is then determined and the refractive index calculated in the usual way. The diluent employed is alcohol, and the liquid in the cell is kept homogeneous by mechanical stirring. An average accuracy of about 1·4 in the fourth decimal place was obtained by this method. Measurements were made on the C, D, and F lines of the spectrum, but the author states that when using mercury potassium iodide as the immersion liquid it was not easy to determine the values for the F line.

§ (5) Cheshire's Method. — An accurate method of immersion refractometry has been described by R. W. Cheshire.[3] It is based on the shadow method introduced by Foucault [4] for figuring surfaces. The image of a vertical straight edge, backed by a source of monochromatic light, is projected by a telescope objective into the plane of a second straight edge, which is so arranged as to cover about half the full aperture of the objective of an observing telescope. A rectangular cell containing the glass specimen immersed in a suitable liquid (mercury potassium iodide was employed) is placed near the first objective on the side away from the source of light. The strength of the liquid is varied until, on traversing the second straight edge across the objective of the observing telescope, which is focussed on the glass specimen, the whole field darkens simultaneously and uniformly. This only happens when the refractive indices of the glass and the liquid are the same. The index of the liquid is measured directly, the cell being cemented to the block of a Pulfrich refractometer. An average of 2 units in the fifth decimal place was obtained by this method in measurements on the sodium D line. It was found difficult to obtain accurate values of the indices for the hydrogen C and F lines owing to want of sufficient brightness.

One great disadvantage in most of the methods so far described is the necessity for accurately adjusting the strength of the liquid so as to obtain equality of index for any given standard wave-length. On approaching the balance point it is frequently found that, after adding a drop of the concentrated liquid or of the diluting medium, in order, as the case may be, to increase or decrease the density of the mixture, the point of equality has been overreached. Even when one goes to the trouble of preparing for each wave-length two mixtures, one slightly denser and the other slightly less dense than the mixture of required refractive index, a considerable time is spent before the correct amounts of these mixtures have been added. Then again, even if the correct density of the immersion liquid has been attained, it may alter appreciably, due to evaporation at the surface, during the time occupied in making the necessary measurements of the refractive index. Such difficulties are overcome in the two following methods, descriptions of which have recently been published.

[1] S. D. Chalmers, *Proc. Opt. Convention*, 1905, p. 198.

[2] L. C. Martin, *Opt. Soc. Trans.*, 1916, xvii. 76.

[3] R. W. Cheshire, *Phil. Mag.*, 1916, xxxii. 409.

[4] L. Foucault, *Ann. de l'Observatoire de Paris*, 1859, v. 197; *Recueil des travaux scientif.*, Paris, 1878, 232; see article on "Objectives, The Testing of Compound."

§ (6) Fabry's Method.—This method[1] depends on the measurement of small differences of refractive index by comparison with the index of a reference prism. The immersion liquid is contained in a cell with approximately parallel sides, and the reference prism and the specimen whose index is required are simultaneously placed in the liquid. A certain number of standard reference prisms is required (Fabry uses five), and in each case that one is chosen whose index is nearest to that of the specimen under examination. The index of the liquid is then determined by means of the deviation which the prism produces relatively to the ray which traverses the cell without passing through the prism. Fabry employs carbon disulphide as the immersion liquid. The cell is placed between a collimator and a telescope mounted on a divided circle, which reads to about one second. The faces of the cell are set normal to the collimator beam, and the reference prism, whose refracting angle is 90°, is placed in the cell with its faces equally inclined to the incident beam. The observing telescope is provided with an objective of 40 cm. focal length and an adjustable eyepiece with millimetre graduations. The collimator slit is illuminated by means of a source of light giving a line spectrum. Now if A be the angle and n the refractive index (corresponding to the wave-length of one of the lines) of the reference prism, and N the index of the liquid, the angle of deviation D due to the prism is given by

$$D = 2(n - N)\tan A/2, \quad . \quad . \quad (1)$$

if the difference between n and N is small.

Thus, if A=90°,

$$N = n - D/2, \quad . \quad . \quad . \quad (2)$$

an equation which gives N in terms of the known refractive index n and the deviation D, which is measured on the circle. If D is greater than 1° it is advisable to use a more accurate formula, such as

$$N = n - \tfrac{1}{2}\sin D + \frac{1}{8n}\sin^2 D + \frac{1}{4n^2}\sin^3 D + \frac{15}{128n^3}\sin^4 D + \ldots, \quad (3)$$

of which the third term is very nearly quite negligible. It gives correct values, where A=90°, up to values of D of about 15°.

The method of obtaining the refractive indices of a specimen in the form of a lens is as follows: The strength of the liquid is roughly adjusted so that its index is very nearly equal to that of the lens for a given radiation. The position of the telescope draw-tube, for which the line in question is sharply focussed, is determined when the reference prism alone is immersed in the liquid. The lens is then immersed in the path of the beam of light, and the position of the draw-tube is altered by an amount x so as to bring the line into sharp focus again. At the same time the deviation D is measured. The composition of the liquid is then slightly altered and new values of x and D are measured. Having obtained two or three pairs of values, including positive and negative values of x, a curve is drawn with x and D as co-ordinates. From this curve, which is practically a straight line, the value of D which corresponds to $x=0$—that is, to equality of index of lens and liquid—can be deduced. The index of the lens can then be obtained from the formula (3). Fabry finds that the error of focussing the telescope is of the order of ± 1 mm. and theoretically deduces the fact that, in order to obtain for refractive indices an accuracy of one in the fifth decimal place, the difference in thickness of the centre and of the edge of the effective portion of the lens must at least reach the value 6000λ. Thus a difference in thickness of 4 mm. is sufficient to ensure this accuracy throughout the spectrum.

The method as applied to a specimen in the form of a prism is somewhat similar. The prism is immersed in such a way that its edge is perpendicular to the edge of the reference prism. A wire is stretched across the collimator slit, its image appearing as a black point. The vertical deviation d of this image is measured by means of a micrometer eyepiece, the motion of which is parallel to the length of the slit, and at the same time the horizontal deviation D caused by the reference prism is determined. The simultaneous measurements of D and d are made for two or three different strengths of the immersion liquid, and a curve is drawn through the points corresponding to the values obtained. From this curve, which is practically a straight line, the value of D which corresponds to $d=0$ may be obtained, and then the index of the specimen can be deduced, as in the former case, from formula (3). Fabry found that the method gave results correct to 1 or 2 units in the fifth decimal place in the case of a specimen of quartz, the angle between adjacent faces of which was 120°. He does not indicate for what wave-length the measurement was made.

The method can also be applied to the case of irregular fragments with curved faces (such as rods of glass or beads of borax fused to platinum wire) and transparent substances in the form of powders with coarse grains.

The method is in many respects a great improvement on those that have already been described, but it is doubtful whether the degree of accuracy claimed, namely one unit in the fifth decimal place of refractive index, will be attained in general practice.

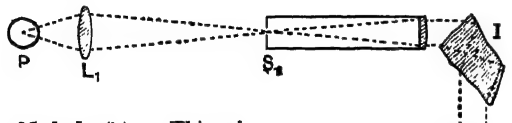
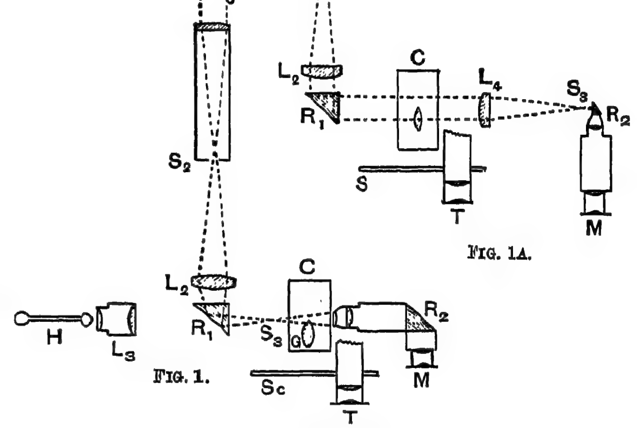
§ (7) ANDERSON'S METHOD.—In this case[1] the use of auxiliary prisms of known refractive index is not required. The salient point of the method consists in the substitution of a variation of wave-length for a variation of the strength of the immersion liquid. The apparatus required consists of a rectangular glass cell for holding the immersion liquid,[2] a Hilger constant deviation spectrometer used as a monochromatic illuminator, a Pulfrich refractometer for measuring the index of the liquid, and suitable observing apparatus for determining the wave-lengths for which the indices of the liquid and the specimen are equal. A number of alternative methods are used for finding the balance points; they are as follows:

Method (i.).—This is illustrated in plan in *Fig.* 1. The light from a "Pointolite" tungsten arc P is focussed on the first slit S_1 of the monochromatic illuminator I by means of a lens L_1. An image of a vertical spider-line stretched across the second slit S_2 of the illuminator is formed at S_3 by the lens L_2, a reflecting prism R_1 being used to deflect the beam of light through a right angle. C represents the cell containing the liquid in which the specimen of glass G is immersed. The mechanical stirrer used for mixing up the liquid in the cell is not shown. Optical contact is made between the base plate of the cell and the block of the Pulfrich refractometer by means of a drop of α-monobromonaphthalene, or, in the case of extra dense flints, mercury barium iodide. T represents the observing telescope, Sc the vertical scale, and L_3 the condensing lens of the refractometer. H is the hydrogen vacuum tube which is used as the source of light for the measurement of the refractive index of the liquid. The telescope T during the experiment is below the horizontal plane containing the axis of the optical system for measuring the balance point of refractive index. A low-power microscope M is focussed on S_3 through the liquid. A 3-inch objective is used in the microscope in order to get sufficient working distance between S_3 and the microscope for the introduction of the cell. For convenience of observation a reflecting prism R_2 is employed to deflect the beam of light in the microscope through a right angle. In this way the eye-pieces of the refractometer telescope and the microscope are brought close together. The prism R_1 is mounted on a small table attached to the refractometer and is rotated out of the position shown in the diagram when the wave-length has been adjusted for equality of index of liquid and glass, in order that the refractometer measurement may be made.

The method of measuring the refractive index of the glass specimen G for, say, the hydrogen C line is as follows: The concentration of the liquid is first of all roughly adjusted until its refractive index for C is nearly equal to that of the specimen. This can be rapidly done, before the cell is placed in position on the refractometer block, by altering the strength of the liquid until the image of an object (preferably illuminated by red light) seen through the specimen and the liquid very nearly coincides with the image seen through the liquid alone. When the cell is in position, the specimen is mounted in such a way that it intercepts part of the beam of light which passes through the liquid. In general, therefore, two images of the spider-line will be seen in the microscope; the one which is formed by the light which traverses the specimen and the liquid will be fairly well defined only if the specimen is regular in shape (such as a lens or prism). The drum of the monochromatic illuminator is now rotated until the two images are brought into coin-





FIGS. 1 and 1A.

[1] J. S. Anderson, *Opt. Soc. Trans.*, 1920, xxi. 105.
[2] Mercury potassium iodide is used.

cidence and the scale reading *s* is noted. The prism R_1 is then swung out of position and the scale reading *r* on the micrometer drum of the Pulfrich refractometer, corresponding to the refractive index of the liquid *for the C line,* is determined. The reading *s* can be made from a position in the neighbourhood of T and M by placing a reflecting prism and lens combination above the drum of the monochromatic illuminator, the scale being illuminated by a flash-lamp bulb.

The concentration of the liquid is next altered slightly by introducing a drop of liquid of somewhat higher or lower refractive index, as the case may be, and the observer waits until the mixture is made homogeneous by stirring. Two images of the spider-line will again be seen, and their separation will depend on the effective angle of the edge of the specimen used and on the difference of index of the liquid caused by the addition of the drop. In order to get as great a separation as possible it is therefore advisable to adopt such an orientation of the specimen as to present a maximum effective angle in the path of the beam. The wave-length of the light is now altered until the scale readings *s* and *r* are determined, the latter corresponding to the refractive index of the new mixture *for the C line.* The process is repeated for two or three different concentrations of the liquid, its refractive index being varied by small steps.

The pairs of values of *s* and *r* thus obtained are now plotted and a curve is drawn through the points. From this curve the value of *r*, which corresponds to the scale reading *s* for the wave-length of the hydrogen C line, is determined; this value of *r* then gives the angular reading on the refractometer which would have been obtained if a mixture with the same refractive index as the specimen for the C line had been made up. The reason for plotting values of *s* and *r*, and not the values of the wave-lengths and the refractive indices, is that the curve thus obtained *is a straight line,* provided that the scale of the monochromatic illuminator is an evenly divided one. On this account only a few sets of readings are necessary for each determination of refractive index.

A similar process to the above is applied in the case of the other wave-lengths employed, namely those corresponding to the sodium D_1 and hydrogen F lines. In the case of the former the refractometer settings are made for the sodium D_2 line, and a correction has to be made in order to obtain the index for the D_1 line.

Method (ii.).—The second method that was adopted for determining the balance points is similar to the one just described, but is somewhat more sensitive. The optical system employed is shown in *Fig.* 1A. The image S_3 of the vertical spider-line stretched across the second slit S_2 of the monochromatic illuminator is formed by two lenses L_2 and L_4, one on either side of the cell C, the beam of light which passes through the liquid being rendered parallel by the lens L_2. One advantage of using this system rather than the one shown in *Fig.* 1 is that a higher power microscope may be employed, since its working distance is not limited by the interposition of the cell between S_3 and the microscope objective. A small right-angle prism R is attached to the objective of the microscope M so as to bring the eyepiece of the latter into close proximity to that of the refractometer telescope T.

Both of these methods (but especially the latter) are very convenient for observing the balance point, particularly when the specimen under examination is in the form of a lens or prism. Attention may again be directed to the fact that, in order to obtain the greatest accuracy with any given specimen, the greatest effective angle of the specimen should be utilised, so as to give a maximum deflection of the image formed by the light which passes through the glass and the liquid. Thus, for example, in the case of a flat lens the specimen should be mounted edgewise in the beam of light, for with such an orientation it is practically equivalent to a thin prism of large angle.

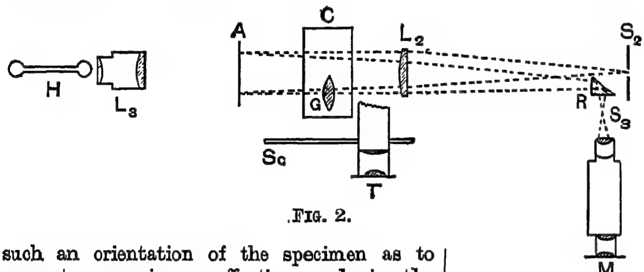


FIG. 2.

A modification of method (ii.), whereby the beam of light is made to pass twice through the specimen, and thus give double the deviation, is shown in *Fig.* 2. The second slit S_2 of the monochromatic illuminator is placed at the focus of the lens L_2, so that a parallel beam of light is caused to pass through the cell C. This beam is reflected back by a plane mirror A, slightly inclined to the beam, and after again traversing the cell is brought to a focus at S_3, a small right-angle prism R being inserted so as to deflect the light through 90°. The spider-line image formed at S_3 is

then observed by means of a microscope M. The mirror A may be mounted on a table which can be swung out of position when the refractometer measurements are being made, or it may be fixed in such a way that the beam of light from the hydrogen tube H passes underneath it. By placing the mirror at a small angle to the beam, the reflected light is brought to a focus at the side of the slit S_2, thus involving less loss of light than if a half-silvered mirror were used instead of the prism R, and, further, the images formed by light reflected from the walls of the cell do not disturb the main image which is to be observed.

Method (iii.).—Another method, which is convenient to employ in the case of lenses and prisms, the edges of which form fairly large effective angles, is illustrated in *Fig.* 3. A intersect corresponds then to the wave-length for which the refractive indices of the liquid and the specimen are equal. This method is a very pleasant one to work with, but it does not give such accurate results as the previous ones, unless the angle of the specimen is fairly large. With specimens of small angle it is sometimes rather difficult to determine the point C with accuracy, as the region round C is filled with systems of fringes.

Method (iv.).—Another method of observing the balance point is similar to the one employed by R. W. Cheshire, and is especially convenient in the case where the specimen to be examined is in the form of an irregular fragment. The general arrangement of apparatus is the same as that shown in *Fig.* 1A, except that, instead of using a fine vertical spider-line across the second slit of the monochromatic illuminator,

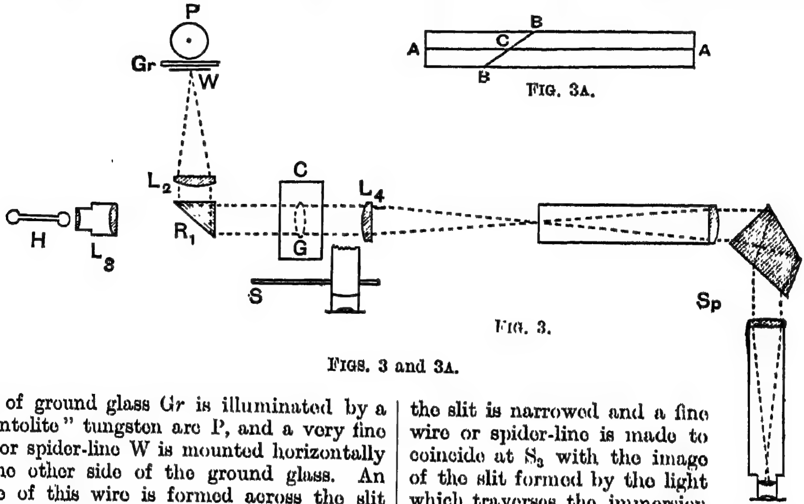

FIG. 3A.

FIG. 3.

FIGS. 3 and 3A.

piece of ground glass *Gr* is illuminated by a "Pointolite" tungsten arc P, and a very fine wire or spider-line W is mounted horizontally on the other side of the ground glass. An image of this wire is formed across the slit of a spectrometer *Sp* by means of two lenses L_2 and L_4, the wire being at the focus of the former. The cell C is mounted in the path of the parallel beam of light between L_2 and L_4, the general arrangement of apparatus being much the same as in the previous method. The specimen is mounted in such a way that its edge intercepts the upper half of the beam of light which passes through the liquid in the cell. Before the specimen is immersed in the liquid one sees in the spectrometer a spectrum traversed horizontally by a fine dark line AA (*Fig.* 3A), corresponding to the point on the slit where the image of the wire W falls. If, now, the specimen is placed in position, another dark line BB will be observed. This line, which is straight if the specimen is a prism and approximately straight if it is a lens, makes an angle with the line AA depending on the effective angle of the specimen. The point C where these two lines the slit is narrowed and a fine wire or spider-line is made to coincide at S_3 with the image of the slit formed by the light which traverses the immersion liquid alone. No observing microscope is required; on placing one's eye behind the wire at S_3 no light reaches it unless the refractive indices of the liquid and the specimen are different. The method of observation is, therefore, to alter the wave-length of the light until the specimen suddenly disappears in the field of view. This modification of the shadow method does not, of course, give such accurate results as Cheshire's method, but it has the advantage of greater compactness and, in combination with the rest of the process, of greater available intensity.

Method (v.).—One of the most accurate methods of observing the balance point is to make use of an interferometer system.[1] For the sake of simplicity this may be built up

[1] The problem has recently been dealt with by C. Barus, *The Interferometry of Reversed and Non-reversed Spectra*, Part II., Carnegie Institution of Washington Publication, 1917, ccxlix. 95.

on the plan of the Rayleigh interference refractometer.[1] Preliminary experiments carried out some years ago with a Michelson interferometer system showed that very accurate determinations of the equality of refractive index could be obtained. The method, however, necessitates the employment of an optically accurate, parallel-sided cell, and the system must be mounted in such a way that it is free from vibration. For most purposes, therefore, the increased sensitivity does not compensate for the more rigorous conditions required. The method would, however, be extremely useful for detecting and measuring small variations of refractive index in specimens of irregular shape.

In experiments with prisms having angles of about 12·5° the results obtained by using method (ii.) were found to give for the C, D_1, and F lines a mean error of about 5 units in the fifth decimal place, though this error may be somewhat reduced by modifications of the optical systems employed.

In conclusion, it is interesting to note that the principle of immersion refractometry is used in mineralogy for determining the refractive indices of mineral fragments.[2] J. S. A.

INFRA-RED TRANSMISSION AND REFRACTION DATA ON STANDARD LENS AND PRISM MATERIAL[3]

§ (1) Introduction.[4]—This paper gives exact data on the spectral transparency and, in particular, the refractivity of materials which are useful for prisms and lenses for spectroradiometers.

The data on refractive indices were taken from smooth curves drawn through values which were collected from various sources and reduced to a common temperature.

It is important, especially in work of the highest precision (such as, for example, the determination of the constant of spectral radiation), to use the most precise instruments and optical data available. It is therefore relevant to discuss very briefly some recent designs of optical instruments suitable for spectroradiometry.

The pioneering investigation of the infra-red refractive indices of a substance dates back to 1886 when Langley determined the dispersion of rock salt to about 5μ. In these determinations a spectrometer having an image-forming mirror of long focal length was used. In subsequent determinations of the refractive indices of rock salt and of fluorite, the image-forming mirror of the spectrometer used by Langley had a focal length of 4 to 4·7 metres. The apparatus was in a large enclosure which could be maintained at a constant temperature. Langley (19) was therefore justified in calling attention to the very high precision attainable, "owing, if to no other reason, to the far greater size of the apparatus employed, where size is a most important element of accuracy." Other experimenters (20, 23, 24), using his methods but having spectrometer mirrors of only about one-twelfth the focal length, have attempted to produce similar data which, unfortunately, have been given the widest recognition in tables of physical constants. These published results, especially the older ones, have been very confusing to the writer who, for some years, has been confronted with the task of obtaining reliable refractive indices.

The recent measurements on rock salt (26) and on fluorite (28) by Paschen, when corrected for temperature (33, 34), are in agreement with Langley's (19) measurements. The numerical values, given in the present paper, have been adopted after a careful study of all the data available.

§ (2) The Spectroradiometer. — For measuring thermal radiation intensities in the ultra-violet part of the spectrum one may use a spectrometer having achromatic lenses of quartz-fluorite. However, the scarcity of clear fluorite for large-sized lenses makes such apparatus very expensive.

Pflüger (1) used simple lenses of fluorite 4 cm. in diameter (32 cm. focal length) and a fluorite prism. An inexpensive spectroradiometer of high light-gathering power was made by Coblentz (2) by using simple plano-convex lenses (6 cm. in diameter and 20 cm. focal length) and a prism of quartz. Pfund (5) has described similar apparatus in which the radiometer is kept in focus automatically in different parts of the spectrum.

The apparatus may be designed also as an illuminator for separating the visible from the ultra-violet of, for example, the sun or a quartz mercury vapour lamp (4).

For spectroradiometric measurements in the visible spectrum and the infra-red to about

[3] With special reference to Infra-red Spectroradiometry.

[4] References are given in a classified bibliography at the end of this paper.

$0{\cdot}8\mu$ we can use a spectrometer with visually achromatised lenses of glass. Here, also, it is desirable to use apparatus having a high light-gathering power, such as one obtains with lenses 6 cm. in diameter and 20 cm. focal length (2, 3, 4).

A common property of all metals is a low reflectivity in the ultra-violet and in the violet-blue part of the visible spectrum (15, 16, 17). Furthermore, the spectral reflectivity in the short wave-length is greatly reduced on tarnishing of the metal. Hence concave mirrors of metals have never been used extensively for spectroradiometric measurements in the visible and in the ultra-violet spectrum.

Because of the lack of achromatism (and the opacity of the material) lenses of glass, quartz, fluorite, etc., achromatised for the visible spectrum, have not been used extensively in infra-red spectroradiometric work. Lehmann (46) has described an infra-red spectrograph achromatised for $\lambda = 0{\cdot}589\mu$ and $\lambda = 1{\cdot}529\mu$.

A concave mirror is achromatic (also astigmatic) and hence spectrometers with collimating and image-forming mirrors, instead of lenses, have been used almost exclusively for infra-red spectral radiation intensity measurements. In the infra-red spectrum beyond 2μ most of the metals have a very high reflecting power (90 to 98 per cent), and concave metal mirrors, or metal-on-glass mirrors are, therefore, especially useful for infra-red investigations.

Recent designs of spectrometers having collimating and image-forming mirrors are described in papers by Coblentz (6) and by Gorton (9). Vacuum spectrometers have been described and used by Trowbridge (7) and by McCauley (8).

In order to obtain the spectral energy distribution of an incandescent substance it is necessary to correct the observations for absorption of radiation by the mirrors and by the prism. The proper formula for eliminating the absorption in a wedge is given by Paschen (29), and by Coblentz (39), who gives also the numerical factors for eliminating the absorption in a wedge of quartz.

It is beyond the scope of this paper to discuss the construction and operation of the instruments (bolometers, thermopiles, etc.) used for measuring the thermal radiation intensities. References are given in the appended Bibliography (10) on "Radiometers."

§ (3) Spectrometer Calibration.—In most spectroradiometric work it is necessary to know the wave-lengths at which the thermal radiation intensities are measured. In the visible spectrum it is an easy matter to note the spectrometer settings for the emission lines of some source (*e.g.* the mercury arc or helium gas in a Plücker tube), the wave-lengths of whose emission lines are known. Similarly in the ultra-violet the emission lines of mercury, cadmium, zinc, etc., may be noted with a fluorescent canary glass screen, or radiometrically with a thermopile (1) or bolometer.

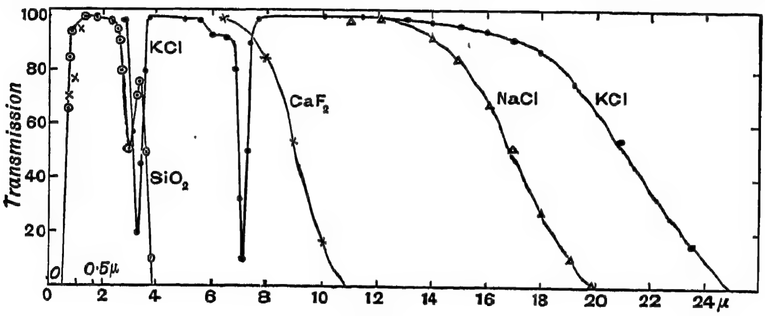

Fig. 1.

The spectrometer circle may be calibrated for wave-lengths in the infra-red spectrum to 1μ by noting the emission lines (12) of sodium and potassium in a carbon arc; also the emission lines of a quartz mercury vapour lamp and helium in a vacuum tube.

Beyond 2μ, where the emission lines are usually weak (except the strong emission band of carbon dioxide at $4{\cdot}4\mu$ in the bunsen flame) one can calibrate the prism by noting sharp absorption bands (13, 14) such as, for example, the bands of sylvite, KCl, illustrated in *Fig.* 1.

For work requiring great accuracy the proper method of calibration is by calculating the minimum deviation settings for different wave-lengths, using the refractive indices and the angle of the prism. For this purpose the yellow sodium lines, or, better, the yellow helium line, $\lambda = 0{\cdot}5875\mu$, is used as a reference point on the spectrometer circle. The minimum deviation settings for the various infra-red wave-lengths are computed from the corresponding refractive indices, and referred

to the yellow helium line as a basis. After this the bolometer or thermopile is adjusted upon the yellow helium line, then on rotating the spectrometer through a certain angle, say 2°, the corresponding wave-length is, say, 6μ, while a rotation of 4° places the bolometer at about $8{\cdot}7\mu$ in the spectrum of a 60° fluorite prism ((6), p. 49).

Elimination of Scattered Radiation in Spectral Energy Measurements.—In the design of optical instruments there are opportunities for great improvement in this respect. Take, for example, the image-forming telescope of a spectrometer. The telescope tube should be large and suitably diaphragmed so that when the violet end of the spectrum is incident upon the radiometer receiver the infra-red end of the spectrum cannot be reflected from the side of the tube and impinge upon the receiver. Furthermore, the bevelled edges of the exit slits of the spectrometer should face outwards (18) instead of facing the image-forming lens, as obtains in commercial instruments.

By using suitably constructed optical instruments the scattered radiation is practically eliminated. What little remains may be obviated by using, before the entrance slit of the spectrometer, a shutter (22, 5, 18), which is opaque to the region of the spectrum under investigation, but which transmits the scattered radiations. In this manner the scattered radiations are incident upon the radiometer all the time and, hence, do not affect the energy measurements. Using a spectrometer which is provided with slits and diaphragms, as just mentioned, it has been found (4) that the scattered radiation was immeasurable in comparison with the intensities under investigation.

§ (4) Optical Constants of Glass.—In the ultra-violet end of the spectrum ordinary crown glass is transparent to about $0{\cdot}3\mu$, while the flint-silicate glasses absorb strongly throughout the blue and violet end of the spectrum.

In the infra-red spectrum all glasses (38, 40) begin to absorb at about 2μ, and for a thickness of 1 cm. they are practically opaque to radiations of wave-length greater than 3μ. Glasses containing traces of iron impurities have an absorption band at 1μ.

The refractive indices of various glasses have been determined by Rubens (20). He determined the refractive indices also of water, xylol, benzol, etc. However, in view of the fact that the refractive indices depend upon the composition of the glass, no refraction data are given in this paper. Practically no infra-red work is being done with glass prisms.

§ (5) Optical Constants of Carbon Disulphide.—Carbon disulphide is quite transparent in the infra-red. In the region to 3μ Rubens (20) found an absorption of only 5 to 7 per cent for a 1 cm. thickness. Beyond 4μ there are a number of very large absorption bands (36).

As illustrated in *Fig.* 3, carbon disulphide has a very much larger dispersion than quartz, etc., in the region of 0·5 to 2μ, and hence is especially adapted for certain fields of spectro-radiometry.

The infra-red refractive indices of carbon disulphide were determined by Rubens (20). Those in the visible and in the ultra-violet were determined by Flatow (32). Rubens's values of the infra-red refractive indices are given in Table I.

Table I

$1{\cdot}998\mu$	1·5872	·2006317

§ (6) Optical Constants of Quartz.—Quartz is one of the most useful materials for prisms. It is extremely transparent to ultra-violet radiations. Pflüger (41) found a transmission of 94 per cent at $0{\cdot}222\mu$ and 67 per cent at $0{\cdot}186\mu$, for a sample of crystalline quartz 1 cm. in thickness. Some samples of amorphous quartz have been found to be more opaque than crystalline quartz; but this may be the result of contamination in melting.

The infra-red transmission of quartz has been determined by various observers. A characteristic absorption band occurs at about $2{\cdot}95\mu$. A sample 1 cm. in thickness is practically opaque (38) to radiations of wave-length greater than 4μ (see *Fig.* 1).

The absorption, reflection, and dispersion constants of quartz are given in a paper by Coblentz (39), who determined the transmission of samples 3 cm. in thickness. The paper gives also factors for eliminating the absorption in a quartz prism.

In the short wave-lengths the refractive indices of quartz have been determined by

Martens (31). In the infra-red there are important determinations by Rubens (21, 23), Carvallo (35), and Paschen (27). Carvallo's data extend to 2·2μ, and in the region of 1·45 to 1·8μ they are slightly lower (by several units in the 5th decimal place) than three determinations made by Paschen. In this region of the spectrum the data must therefore be considered uncertain with the doubt in favour of Carvallo's data. This uncertainty affects Warburg's (43) determination of the spectral radiation constant by perhaps 0·2 to 0·4 per cent.

The refractive indices (ordinary ray) of quartz at 18° C. are given in Table II. They are taken from a graph of sufficient size to permit reading the data to 1 or 2 units in the fifth decimal place. In many cases the values agree exactly with Carvallo's measurements. Paschen's data may be recognised by the fact that his wave-lengths are given to the fifth decimal place.

§ (7) Optical Constants of Fluorite.—Fluorite is very transparent to radiations of wave-lengths extending from 0·2μ to 10μ (see *Fig.* 1). Pflüger (41) found a transmission of 86 per cent at 0 23μ and 70 per cent at 0·186μ, for a sample 1 cm. in thickness. Lyman (42) examined fluorites from various sources, and of various colours, and found that they are opaque to radiation of wave-lengths less than about 0·12μ. Coblentz (38) examined green fluorites with a view of determining their suitability for prisms. He found numerous sharp absorption bands, in the infra-red, which would render such material unsuitable for prisms.

The refractive indices of fluorite have been determined by various observers (21, 23), and repeatedly by Paschen (23, 24, 25, 28). Applying temperature coefficients of refraction (33, 34), it is found that Paschen's determinations, especially the latest ones (28), which were obtained with an improved spectrometer, coincide with the dispersion curve of fluorite determined, to 3·5μ, by Langley (19). Beyond 4μ the dispersion of fluorite is much larger than at 1·5 to 2μ, and there is better agreement among the various determinations of the refractive indices. Furthermore, slight deviations have less effect upon spectral radiation measurements.

In Table III. the refractive indices of fluorite to 3·5μ are taken from the smooth curve published by Langley (19). In many cases Paschen's original wave-lengths are retained. As already mentioned, the corresponding refractive indices, when corrected for temperature of the prism, fall exactly upon Langley's curve of refractive indices.

Beyond 3·5μ the refractive indices are taken from the smooth curve (extended from 3μ) through the various determinations of Paschen

(25) and Rubens (20). All these data are reduced to 20° C.

Langley's data are referred to the "A line," $\lambda = 0·7604\mu$. The most convenient reference point for adjusting a spectroradiometer in the spectrum is the yellow helium line, $\lambda = 0·58758\mu$. Until recently, when Paschen (28) determined

the refractive index of this line, there has been some uncertainty in infra-red spectral radiation measurements (44) requiring the highest accuracy. An error of 5″ (or $n = 3 \times 10^{-5}$) in the determination of this refractive index affects the constant of spectral radiation by 0·3 per cent.

The dispersion curve of fluorite is illustrated in *Figs.* 2 and 3 (from Rubens).

In the infra-red the variation of the refractive

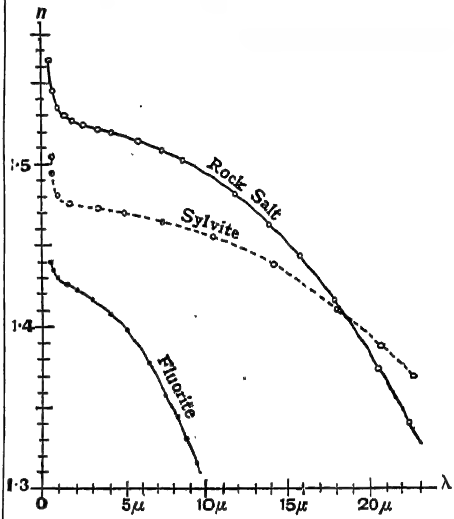

FIG. 2.

index of fluorite (34) with temperature decreases slowly with wave-lengths. At 1μ the coefficient of variation amounts to about $\Delta n = 0{\cdot}000012$ and at 6·5μ it amounts to about $\Delta n = 0{\cdot}000009$ for 1° rise in temperature.

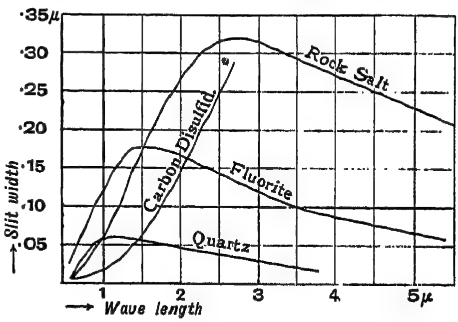

FIG. 3.

§ (8) OPTICAL CONSTANTS OF ROCK SALT.—Rock salt is uniformly transparent from 0·2μ in the extreme ultra-violet (41) to 12μ in the infra-red (23) (see *Fig.* 1). In the region of 15μ the absorption increases rapidly. A plate of rock salt 1 cm. in thickness is completely opaque (22) to radiation of wave-lengths greater than 20μ. The refractive indices of

rock salt have been determined in the short wave-lengths by Martens (30, 31), and in the infra-red by Langley (19), by Rubens (21, 22), and by Paschen (26). In the region of 1 to 3μ there is considerable disagreement among the older determinations. However, the recent work of Paschen (26) is in excellent agreement with Langley's measurements, which are, without doubt, very accurately determined.

The infra-red refractive indices of rock salt, at 20°, are given in Table IV. The first part of the table, to 5μ, consists principally of Langley's (and Paschen's corrected for temperature) measurements as read from the smooth curve ((19), p. 235, Plate XXIX.). Beyond 5μ, to 16μ, the refractive indices are principally Paschen's measurements corrected for temperature (34); also some of Rubens's measurements and several interpolated values.

The temperature coefficient of refraction of rock salt (19, 33, 34) decreases slowly with wave-length; amounting to about $\Delta n = 0{\cdot}000038$ at 1μ and $\Delta n = 0{\cdot}000025$ at 9μ for 1° rise in temperature.

The general outline of the dispersion curve of rock salt is illustrated in *Fig.* 2 (from Rubens).

§ (9) Optical Constants of Sylvite.—Of all the substances which are otherwise suitable for prisms, sylvite, KCl, is transparent throughout the greatest part of the infra-red spectrum. A plate 1 cm. in thickness transmits (22) radiations to 24μ (see *Fig.* 1). In the region of 5μ to 10μ the dispersion is small. Furthermore, there are sharp absorption (11, 13) bands at $3{\cdot}18\mu$ and $7{\cdot}08\mu$. Hence sylvite is the most useful for investigations in the region of the spectrum extending from 10 to 20μ.

In the short wave-lengths the refractive indices of sylvite have been determined by Martens (31). In the infra-red we have various determinations by Rubens (22) (with Nichols and with Trowbridge), by Trowbridge (45), and by Paschen (26).

The infra-red refractive indices of sylvite are given in Table V. They are read from a smooth curve (practically Paschen's curve) drawn through the various determinations, all of which are in close agreement, except at 9 to 11μ, where the older determinations do not agree very well with Paschen's data.

The temperature coefficient of refraction of sylvite observed by Liebreich (34) decreases from

$$\Delta n = 0{\cdot}0000364 \text{ at } \lambda = 0{\cdot}589\mu \text{ to}$$

$$\Delta n = 0{\cdot}000031 \text{ at } \lambda = 8{\cdot}85\mu.$$

§ (10) Summary: Comparison of Dispersive Materials.—In *Fig.* 3 is given the width that a radiometer receiver, of 4′ of arc, subtends in wave-lengths, in different parts of

17·680	1·41403	·1504586
18·10	1·4108	1494655
19·00	1·4031	·1470886
20·00	1·3939	·1442316
20·60	1·3882	·1424520
22·5μ	1·3692	·1364669

From these curves it is evident that, in the region of 0·5 to 1·5μ, a carbon disulphide prism is the most useful for producing a large dispersion.

The next best prism material is quartz, which is the most useful in the region of the spectrum extending from the visible to 2·8μ in the infra-red. Beyond this point a quartz prism is too opaque for practical work.

From the standpoint of dispersion and transparency, a fluorite prism is the most useful in the region of 2μ to 9μ. However, the material is difficult to obtain, and the next best substance is rock salt, which permits measurements to 14μ when using a 60° prism, and to 16μ when using a 30° prism. By enclosing the spectrometer (14) and by keeping the prism covered when not in use, the faces of a rock-salt prism are easily protected from moisture.

There are few but sylvite prisms in existence, and their usefulness is confined to that part of the spectrum extending from 10 to 20μ.

INTERFEROMETERS: TECHNICAL APPLICATIONS

I. INTERFERENCE FRINGES

§ (1) INTRODUCTORY.—In utilising interference methods in Optical Test work we are always concerned with nearly parallel plates, or with arrangements which are optically equivalent to them. The character of the interference fringes obtainable from such plates depends on the method of illumination and the method of observation. They can conveniently be divided into three classes.

CLASS I.—If a plate is illuminated by a broad source of light[1] and is viewed by the naked eye from a convenient distance, the rays which reach the eye from different points of the plate are reflected from the surfaces of the latter at different angles. The path difference between the rays reflected from the two surfaces at any point $=2\mu t \cos r$, where r is the angle of incidence on the *back* surface, μ the refractive index, and t the thickness of the plate. For a complete treatment of the fringes produced under such circumstances the reader should consult Mann's *Manual of Advanced Optics* or Michelson (*Phil. Mag.*, 1898). For our present purpose it is sufficient to note that the fringes will be the loci of points for which $2\mu t \cos r$ is constant, and therefore indicate variations of μ, t, or r jointly or separately. If t is very small, *i.e.* for extremely thin films, the variation of phase due to the variation of r at different points of the film may be negligible, so that if the optical thickness μt is uniform the film will appear uniformly dark or bright all over. If either μ or t vary, fringes will be seen which are the loci of equal optical thickness.

If the thickness is appreciable, however, the variation of phase due to the varying angle of incidence becomes of importance, and for any but quite thin plates the fringes are practically loci of points from which the light reaching the eye meets the plate at equal angles of incidence. With a plane parallel plate they are circles concentric with the normal from the eye to the plate and are located at infinity. If the surfaces are not parallel, the fringes are still circles or arcs of circles, but their centres are displaced from the normal. If the surfaces are irregular, or if the material of the film is not perfectly homogeneous, so that from one or both of these causes there are local variations of μt, there will be local distortion of the circular fringes at these points. Such irregularities will only be noticeable, however, near the centre of the system where the fringes are not too close together. With any but the thinnest films the fringes become so closely packed, as the incidence angle increases, that they are only visible in the neighbourhood of normal incidence.

To summarise, therefore, fringes of Class I. are formed in such circumstances that the light corresponding to each point in the fringe system reaches the eye from separate points (or relatively small regions) of the film, and is reflected from the latter at varying

[1] Except where otherwise specified, the light is assumed to be monochromatic.

angles. Except for extremely thin films, the fringes are mainly loci of equal incidence angles, being very slightly affected in shape and position by variations in film thickness.

CLASS II.—Instead of viewing the fringe system at infinity with the naked eye, as supposed in the preceding discussion, we may employ a telescope of large aperture focussed for infinity, so that for all parts of the field of view light from the whole surface of the film is received by the telescope. The fringes are then purely loci of equal inclination, and are unaffected in shape or position by variations in the optical thickness of the film. Thus if the telescope is directed normally to the film, circular fringes concentric with the axis will be seen in the focal plane of the eyepiece. Since, at any point in this plane, light from the whole of the film is focussed, the phase at any such point depends on the *mean* film thickness and the angle of incidence of the beam. Any variations in film thickness contribute their effect equally to all points in the fringe system, which therefore indicates the inclination of the rays only, and tells us nothing about the flatness, homogeneity, or parallelism of the film.

If, however, μt varies much, the *distinctness* of the fringes will be impaired; for we can regard the resultant illumination at the focal plane of the telescope in such a case as due to the superposition of a number of exactly similar fringe systems, of which some differ in phase from others. The result of this is to diminish the contrast between the bright and dark parts of the field.

Thus, to summarise, fringes of Class II. are formed when light corresponding to each point of the fringe system comes from the whole of the film (or from the same part of it), but meets it at varying angles of incidence. They are purely fringes of equal inclination. If they are crisp and distinct we deduce that the film is of fairly uniform optical thickness over the region utilised; but no clue whatever is given to the character or position of any variations which may actually be present.

CLASS III.—If we employ a point source at infinity, such, for example, as a small illuminated pinhole at the focus of a collimating lens, all rays strike the film at the same angle of incidence. There are consequently no variations of phase from one part of the film to another except such as may be due to variations of μt. To observe a fringe system under such circumstances it is necessary to employ a telescope with the eyepiece removed. The object-glass collects the parallel beam after it leaves the film and produces an image of the pinhole in its focal plane. If the eye is placed at this image, the whole surface of the film (if the object-glass is large enough) is seen illuminated and traversed by fringes which are true contours of the optical thickness, μt.

These fringes are not located at a definite distance from the eye, as are those of Classes I. and II. They are visible at all distances, and so appear to coincide with any surface on which the eye is focussed.[1]

If the film is thick the fringes will be most distinct at perpendicular incidence. It is not practicable to use a theoretical point source: considerations of brightness require that the hole shall have an appreciable area, and its image in the focal plane of the telescope lens may be regarded as a small portion of the Class II. fringe system produced by a broad source. If this portion is in the centre, where the phase varies slowly with the angle of incidence, there will be no phase difference between the light from one part of the pinhole and another; but if it is at an outer part of the system where the Class II. fringes are closely packed, the small cone of rays which reach the eye from any point of the film comprises an appreciable range of phase retardation, and the contour fringes are rendered indistinct.

II. TECHNICAL APPLICATIONS

§ (2) TEST PLATES.[2]—The simplest application of interference fringes is the testing of optical surfaces by means of test plates. The surface under test is placed in contact with another surface which it ought to fit perfectly. This may either be plane, for prism surfaces, etc., or may be curved, for lens surfaces. A separate test plate is of course necessary for every curvature. The surface and test plate are worked together to squeeze out the air between them and obtain a very thin film. This is viewed by the light from a window or bright wall. Fringes of Class I. are obtained, hence the necessity to work the film down as thin as possible in order that the fringes should truly represent film contour rather than variation of incidence angle. With white light the fringes are coloured owing to the variation of retardation with wave-length. If the surfaces are very close and quite parallel, the film will appear of a uniform colour, which will vary with the obliquity from which it is examined. Variations of thickness insufficient to produce a complete fringe will cause a variation of tint; and if the general tint is yellow or bluish green, the two regions of the spectrum where tint varies most rapidly with wave-length, the test is very sensitive. It is usually possible to secure a sensitive tint by working the film and choosing a suitable obliquity.

§ (3) CONSTANCY OF OPTICAL THICKNESS OF

[1] Guild, "Location of Interference Fringes," *Phys. Soc. Proc.*, 1920, xxxii. 32.

[2] See also "Optical Parts, Working of," § (4).

Flat Discs.—This is a most important test. For many purposes, for instance in making echelon gratings, Lummer Gehrke plates, etc., it is essential to have plates of which the variations of optical thickness from one part to another are reduced to a very small amount indeed.

The best known arrangement for testing such plates is shown in *Fig.* 1 (*a*). Light from a broad source S is thrown normally on the plate AB by a glass plate MM′. The fringes are observed by an eye at E. The fringes will be of Class I. and will be concentric circles located at infinity if the glass is nearly parallel. As we have seen, the form of these fringes does not at once tell us much about the variations of optical thickness. To determine this, the plate is moved parallel to itself. If the optical thickness is uniform, the fringes will not move; but if it varies, a fringe will pass across any point, E′ say, on the fixed support, for every half wave-length by which the optical thickness varies. By moving the plate in such a way that no fringes pass E′, it is possible to trace out contour lines of equal optical path.

If desired, a *small* telescope with cross-lines in the eye-piece may be used at E.

This method is tedious and troublesome, since each contour line has to be traced separately by indirect means. By a simple modification of the arrangement the plate can be examined by fringes of Class III., and the fringe system itself is then the contour map. A lens LL′, *Fig.* 1 (*b*), is interposed between MM′ and AB, and a point source (an illuminated pinhole) is placed at the focus of LL′. A parallel beam of rays meets the plate AB. It is reflected back through LL′ and refocussed in the neighbourhood of S. Some light is reflected at the surfaces of MM′ to form two images of the source at *e* and *e*′. MM′ should be thick so as to separate *e* and *e*′ as widely as possible. An eye placed at *e* or *e*′ sees the plate AB traversed by interference fringes which are the required contours of equal optical thickness.

For the reasons given earlier, the fringes will only be distinct with thick plates provided the incidence is normal. The table on which AB rests should be provided with levelling screws. The normal adjustment is then easily made, because the retardation is a maximum in this position, and on altering the tilt the fringes will move towards a certain configuration and then retreat from it as the perpendicular position is passed.

Care must of course be taken to ensure that the light is properly collimated. This is done by adjusting so that the reflected image,

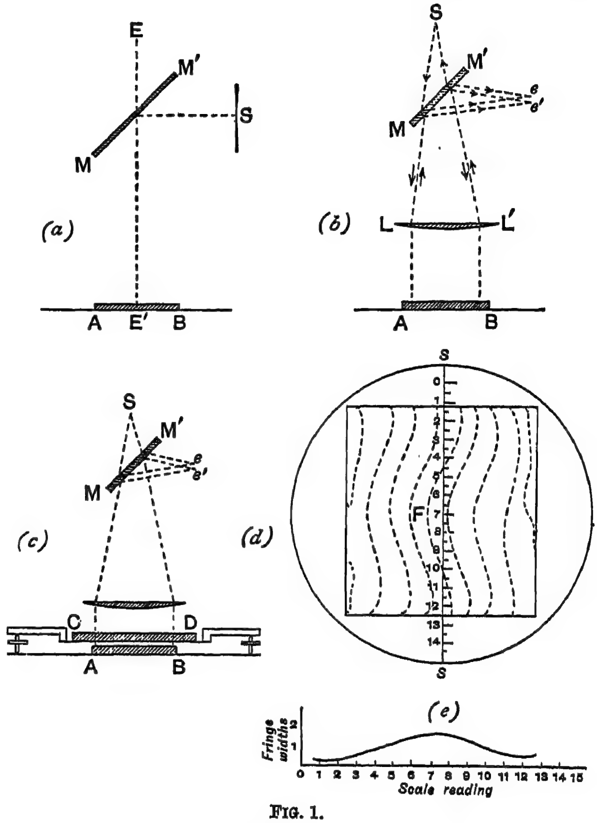

Fig. 1.

when formed just beside S, is in sharp focus.

When a suitable source of monochromatic light is used [1] plates of over an inch thick may be examined in this way.

§ (4) Contour Maps of Flat Surfaces.—The same apparatus affords a very convenient means of determining the contour maps of surfaces which are intended to be flat. The customary method of working the surface into close contact with a test plate and examining the fringes with a broad source of light is unsatisfactory on various grounds. In the first place, troubles sometimes arise, due

[1] Guild, *Phys. Soc. Proc.*, 1920, xxxii. 341.

to the surfaces not being perfectly dry, in which case local patches of perfect blackness, due to absence of air film, may be formed. Further, it is possible, when two nearly flat surfaces are wrung together in this way, to squeeze out slight convexities and make the surface under test appear better than it really is. Lastly, in spite of the greatest care to exclude dust particles, it frequently happens that the surfaces get scratched in the process.

It is on every ground more satisfactory to test the surfaces without putting them in contact at all. If the upper surface of the slab AB, *Fig.* 1 (*c*), is the surface to be tested, the test plate is mounted above it, with its standard face downward, supported on a suitable carrier with three adjustment screws. It is clear that in general there will be four reflected beams, each of which will give rise to images of S in the neighbourhood of *e* and *e′*. If any two of the four surfaces are parallel the corresponding images will coincide. It is desirable that the test plate CD should be somewhat prismatic, so that the image from its upper surface may be out of the way. By means of the levelling screws the test plate is adjusted so that those images which are respectively due to the upper surface of AB and the lower surface of CD coincide. If the eye is then placed at *e* or *e′* fringes are seen which are the loci of equal thickness of the air film. By carefully adjusting the test plate while watching the fringes, the latter can be broadened out until, if the film is perfectly parallel, a uniform illumination is obtained. If the surfaces are not perfectly flat there will be a position in which a minimum number of fringes appear, which form a contour map of the joint defects of the surfaces at all points. This is the best adjustment in order to see at a glance the general character of the contour; but to make quantitative measurements it is better to proceed indirectly and use a slightly wedge-shaped film such that the fringes are about a centimetre or so apart. A diametral scale, *ss*, divided to ½ centimetres, should be drawn in ink on the surface of the test plate, and also a line on the surface under test passing approximately through the centre, which should be marked by means of a dot. The lower block is then moved on the table until this line coincides with the line on the test plate as seen by the eye at *e*. The position of the central dot on the scale is noted. The fringes are then adjusted until they run as nearly parallel to the scale as possible and are about a centimetre or so wide. The appearance of the field of view might then be something like *Fig.* 1 (*d*). The most convenient fringe, say F, may be taken as the datum of film thickness, and the thickness at different distances along the scale *ss* may be specified by the distance of the scale from this datum fringe, as measured in fringe widths. For instance, with a configuration as drawn (if the thickness of the film is increasing from left to right) the excess of thickness above the datum is ·4 at 3 on the scale, 1·05 at 4·5, 1·6 at 6, 1·7 at 7, 1 at 10, ·6 at 12, and so on. If these are plotted to a suitable scale, a contour line of the variations of film thickness along the line *ss* is obtained (*Fig.* 1 (*e*)), the unit corresponding to one interference fringe, that is, to a difference in thickness of one ½ wavelength.

The surface under test is then rotated until another line, making, say, 30° with the first, coincides with the scale on the test plate, and the contour along this line is determined in the same way. This is done for a number of radial lines and also for two non-radial lines intersecting the others as shown in *Fig.* 2 (*a*).

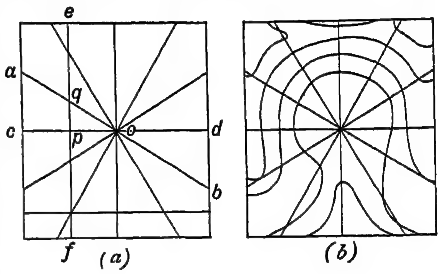

FIG. 2.

The non-radial contours give relations between second points on each of the radial contours, which enable us to alter the position and inclination of the base lines of the latter so as to make the contours mutually consistent. Thus we may take the contour along *ab* as first obtained: the base line for any other contour, such as *cd*, must be altered so that the ordinates corresponding to the common point O are equal, and also so that the ordinate at *p* differs from the ordinate of the *ab* contour at *q* by the amount indicated by the non-radial contour along *ef*. If now an outline of the surface is drawn on paper, and along each radial line we mark off the distances from O at which the ordinates of the revised contours have particular values (differing, say, by $\frac{1}{10}$th fringe), we obtain a contour map of the surface, such as *Fig.* 2 (*b*). It will be observed that in the whole process we are only concerned with the properties of the test plate along one line *ss* (*Fig.* 1 (*d*)), and the contour of the plate along this line is easily determined. If two other fairly good surfaces are available, by testing one line of each of these against the test plate and against each other, their contours and that of the test plate can be deduced. The method is thus absolute and no surface has to be taken for granted.

§ (5) TESTING BY TRANSMITTED LIGHT.—*F. Twyman* [1] has evolved an elegant method of testing prisms, lenses, and even complete optical instruments by interference. The instrument employed is the well-known Michelson interferometer.[2] The general principles of this instrument are described in all text-books. It is only necessary to remind readers that the instrument is optically equivalent to two approximately parallel planes separated by an air film of a thickness which can be varied from zero to any desired value by moving one of the mirrors. This being so, we can obtain with the instrument fringes of any of the three classes previously described. The most suitable type to employ depends on the purpose in view.

If a broad source is employed, and the fringes are viewed by the naked eye, fringes of Class I. will be obtained. If a telescope is employed the fringes will be of Class II. These are the arrangements most commonly described in text-books and employed in the physical laboratory; but they are quite unsuitable for optical testing. For this purpose fringes of Class III. are required, and the arrangement of the interferometer to give these is shown in *Fig.* 3 (*a*). Light from a suitable source S is focussed by means of a condensing lens on a small "pinhole" P which is at the focus of a lens L_1. We have thus the equivalent of a very small source at infinity. That portion of the parallel beam which is reflected by the half-silvered surface of the oblique plate m strikes the mirror M_1 normally, and returns along its own path until it again meets the oblique plate. Here a portion is reflected back through L_1 and refocussed at P, and a portion transmitted. The latter is focussed in an image of P at P′ by a lens L_2. Similarly a portion of the beam, which is in the first instance transmitted by m, forms, after reflection by M_2 and partial reflection at m, a second image of P in the neighbourhood of P′. If the image of M_2 by reflection in m is very nearly parallel to M_1 the two images at P′ will coincide. An eye placed at P′ will then see interference fringes of Class III., which are the contour lines of the thickness of the "air film" to which the instrument is equivalent. If M_2 is carefully adjusted while examining the fringes, they can be broadened out until the air film is parallel, when, if the surfaces are perfectly flat, the film will appear of uniform brightness. If the surfaces are not perfectly flat (or, rather, if their irregularities are not exactly similar and similarly situated) the film can never be cleared of fringes over its whole area, and the fringe system, when broadened out as much as possible, forms a contour map of the irregularities.

It is clear, of course, that whether the fringes have been broadened out or not, they give precisely the same information regarding the irregularities of the film; but they are

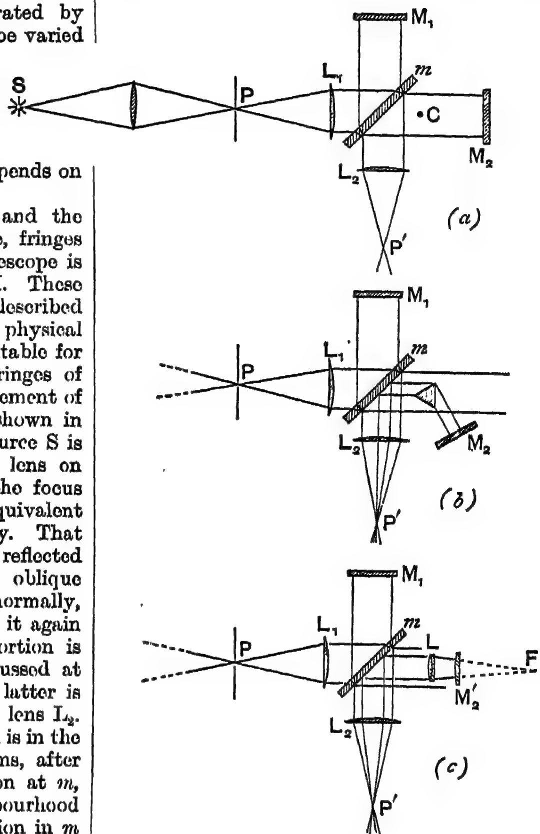

FIG. 3.

equivalent to the contour map of a country based on a datum plane inclined to the horizontal. If the inclination were considerable such a map would consist of closely packed, nearly straight lines parallel to the horizon, hills and valleys appearing simply as slight bends in the contours. Such a map would give all the information as to the nature of the country that could be deduced from an ordinary one; but it is much less easy to interpret its general appearance. Similarly, whatever the adjustment of the mirrors, the fringe system gives full information as to their departures from exact similarity of surface; but it is usually convenient to

[1] F. Twyman, *Phil. Mag.*, Jan. 1918, p. 49; *Photographic Journal*, Nov. 1918, p. 230; and *Astrophys. Journ.*, 1918, xlviii. 256.

[2] See also "Wave-lengths, Measurement of," § (3).

have the fringes as broad as possible in order to render them easily interpretable. Sometimes, however, an adjustment departing slightly from parallelism is helpful in deciding between two possible interpretations.

In the interferometer, as used for optical testing, the mirror M_1 is mounted on a carriage which rests in a geometrical slide. By pulling one or other of two strings the mirror can be moved nearer to or farther from the oblique plate without its inclination to the direction of the light being seriously altered. The mirror M_2 is arranged on a carriage which can rotate about a point C. Each mirror is provided with delicate adjustment screws for final adjustment of the parallelism of the equivalent film. The mirrors are worked to such accuracy that when used alone, as in *Fig.* 3 (*a*), a field free from fringes can be obtained.

The method of testing an optical piece, such as a slab or a prism, *or any optical instrument of which the focal length is infinite*, consists in placing it in the beam mM_2, and adjusting M_2 to be perpendicular to the transmitted rays so that they are returned through the instrument and finally focussed at P′. The eye at P′ then sees the aperture of the instrument traversed by a fringe system which is the contour map of the wave front, originally plane, after passing twice through the instrument. The general method will be fully understood from its application to a spectroscope prism. The prism is placed in the position indicated in *Fig.* 3 (*b*). That portion of the beam which is transmitted by the prism is deviated in the direction shown. M_2 is adjusted so as to reflect this beam back through the prism, after which it is partially reflected by m and focussed at P′. The eye at P′ then sees the effective aperture of the prism traversed by fringes which, when broadened as much as possible, tell us how a plane wave-front has been affected by the double passage through the prism.

These defects of the wave-front may either be due to imperfect planeness of the surfaces of the prism or to imperfect homogeneity of the glass, or to both causes. But to whatever cause they may be due, they can be corrected by local polishing of the surfaces. For instance, if the fringes show that the optical path through any part of the prism is longer than at others, by polishing a little hollow in the corresponding part of the surface the wave can be flattened out. In this way, by local polishing at the points indicated by the contour fringes, the prism can be made to transmit a perfectly plane wave-front. But it should be noted that the correction only holds when the light traverses the prism in the same way. The interference tests should always be made, therefore, with the light passing through the prism in the direction which it will pass in use. Thus for a spectroscope prism the prism should be adjusted for minimum deviation.

In applying the interferometer to instruments of the lens type which have not infinite focal length, the arrangement employed is that of *Fig.* 3 (*c*).

The lens L is mounted in a suitable chuck, with its axis parallel to the incident beam. It causes the beam to converge towards its focus at F. A convex mirror M_2' is placed in the position shown, and adjusted so that its centre of curvature coincides with F. The converging rays then meet the surface of M_2' normally, and, after repassing through L, form a parallel beam once more, and are focussed at P′ by L_2 as usual. If the lens were free from spherical aberration, so that rays from all zones converged to one focus, it would be possible to adjust M_2' so that the aperture of the lens as seen by the eye at P′ would be free from fringes. In the presence of aberration, however, the different zones have different foci, and in whatever position M_2' may be there will be circular fringes in some zone, indicating the amount of the aberration. In the event of the lens being astigmatic, the fringes will be elliptical.

This method has been extended by Twyman to quite complicated cases, such as photographic lenses at oblique incidence, microscope objectives, etc. As applied to lenses, however, the interference method must be regarded as still in the course of development; much has yet to be done in designing the best mechanical means of realising the necessary conditions of adjustment in order that the resulting fringe system will give the information which it is desired to obtain. There is, however, little doubt that the use of interferometer methods for the examination of almost every kind of special instrument will ultimately be widely adopted.

In employing the interferometer for such purposes it is necessary, as with the arrangements of *Fig.* 1 ((*b*) and (*c*)), to obtain exact collimation and normal incidence of the beam on the equivalent film.[1]

Joly Photometer. See "Photometry and Illumination," § (29).

K

K Series: a group of spectrum lines in the characteristic X-rays emitted by an element. See "Radiology," § (17).

KINEMATOGRAPH

§ (1) Introduction.—Although the name kinematograph has been selected for the title of this section as being more in accordance with the Greek derivation, other terms such as cinematograph, or more briefly cinema, the first syllables of which are pronounced softly, have received greater public recognition. Over sixty designations have been introduced from time to time, but, with the exception of a few proprietary names, practically all have now lapsed in favour of those mentioned above.

The history[1] of the highly perfect apparatus of the present day is a record of comparatively slow and intermittent progress during half a century, culminating in the introduction of the continuous photographic film by Friese Greene in England and its perfection by Edison in America, and, in consequence, a rapid development of the apparatus as a means of public entertainment and, to a more limited extent, of education.

§ (2) General Description.—The primary function of the kinematograph is to reproduce pictorially upon a screen the movements of objects. This is done by presenting to the eye in regular order a series of pictures each of which represents a consecutive stage in the motion, the speed of presentation being such that the eye appreciates the series as a continuous picture in which the objects may appear in motion. By means of a special camera[2] a series of instantaneous photographs of the moving object is taken, with exposures of about $\frac{1}{100}$ second, upon a sensitised transparent celluloid film which is advanced stage by stage in the focal plane of the objective at intervals of about $\frac{1}{16}$ to $\frac{1}{20}$ second. During the stationary periods the film is exposed and during the transitions the light is occulted by the shutter. Thus the series of photographs does not comprise the complete movement of the object. Short alternate stages are unrepresented.

When the images are projected upon the screen by means of the kinematograph projector, a true representation of the original movement is obtained when the speed of the movement of the operation and the ratio of the bright and dark intervals are the same as those pertaining during the taking of the series of photographs with the camera, but in actual practice there are small departures from true reproduction arising from differences in the velocity ratios.

Although the image projected upon the screen may appear to be in continuous motion, the action is actually discontinuous. A stationary image representing one stage remains on the screen for a period of about $\frac{1}{20}$ second. This is followed by a dark interval lasting about $\frac{1}{80}$ second. Although the original

[1] *Living Pictures*, Hopwood and Foster, 1915.

[2] "Motion Picture Cameras," C. L. Gregory, *Trans. Soc. Motion Picture Engineers*, April 1917.

stages of the movements corresponding with these brief dark intervals are not reproduced upon the screen, the mind of the observer fails to detect their absence, and the interrupted series of images when combined by the retino-cerebral apparatus is accepted as being equivalent to the original continuous appearance.

To obtain this stroboscopic effect it is essential that the dark intervals should be so small that the impression on the mind of one stage has not become unduly weak before the succeeding impression has been formed. That the effect is entirely due to a physiological process of fusion of the successive images has been contested [1] on the experimental grounds that under certain conditions an impression of movement is obtained even when the dark intervals are also distinctly appreciated by the mind.

If the visual sensation ceased immediately the direct excitation had ceased, that is, if the phenomenon of persistence of vision did not exist, one image sensation could not extend over the dark interval and overlap, as it were, the succeeding image. Under these circumstances the complete synthesis of a series of images separated by brief dark intervals would hardly be possible, and kinematography would be impracticable.

§ (3) The Eye and Vision — Flicker.— The functions of the eye as the organ of sight are discussed in the article on "The Eye and Vision" (*q.v.*).

In its dark adapted state, as under the conditions of a modern picture house, the retina can be subjected to a range of intensity of from one to about a thousand without producing a glare effect. But in practice, under these conditions, a sudden change of intensity from one to more than a hundred or two should be avoided to ensure entire absence of visual discomfort. If the eye were repeatedly turned from the illuminated screen to very dark surroundings, the contrast might easily be such as to cause discomfort in the course of time, and therefore a certain amount of general illumination, which also facilitates the entrance of the spectators, is customary, the contrast being kept, however, within the above-mentioned limits. As the illumination of the picture on the screen varies from about 1 to 1·5 foot-candles in the case of the quarter lights to about 5 or 6 foot-candles over the brightest parts, a general illumination of 0·07 foot-candle is permissible. Much, however, depends upon the circumstances, and general illumination of twice this amount has been advocated.[2]

Reference has already been made to the persistence of vision upon which kinematography essentially depends. The first definite measurements of the time of persistence are those recorded by M. D'Arcy,[3] who measured the time of whirling necessary to produce the appearance of a continuous circle of light when a live coal was whirled at a distance of 165 feet from the observer.

When the retina is excited by a single low-intensity impulse of very short duration, the resulting pulse of sensation takes an appreciable time to grow and a similar time to wane, the duration of the sensation being longer than that of the stimulation. According to McDougall, a stimulus of greater intensity produces a series of partially overlapping pulses of rapidly diminishing maximum intensities.[4] Charpentier's bands, which may be observed when a suitable radial slot is rapidly rotated, are attributable to pulses of this kind. The initial pulses of greatest maximum intensity wax and wane rapidly. Succeeding pulses do so more slowly, and within the fraction of a second the intensity of the pulses becomes too small to be appreciated. Recurrent images and other phenomena of vision [5] that involve periods much greater than those of the kinematograph need not be considered here.

Flicker, the elimination of which is a problem of such great importance in the intermittent type of kinematograph, is dependent upon the duration of the individual impulses that fall upon the retina. During the period of transference of the consecutive pictures it is necessary to interrupt the projection of the image upon the screen. This is done almost universally by means of a rotating shutter having a blank sector which intersects the beam of light between the objective and the screen during the period of the movement. Thus the illumination of the screen is intermittent and the retina is subjected to a rapid series of impulses which, under certain conditions, produce a disturbing appearance of flicker, that may even prove injurious to the eyesight if long continued.

Flicker can be eliminated by increasing the frequency of the interruptions or by reducing the illumination. It is also dependent to some extent upon the relative durations of the consecutive black and white periods,[6] the maximum effect being obtained when the white interval equals the black. Thus suppose the disc is half black and half white and the speed such that flicker is pronounced. If then the white sector is increased at the expense of the black, the flicker will diminish and be entirely absent when the disc is all white,

since there are then no interruptions of the light. Similarly, if the black is extended at the expense of the white, the flicker will progressively be diminished and again vanish when the disc is all black. In the kinematograph the black sector which cuts off the light during the transference of the picture often covers about 90° of arc, that is, 25 per cent of the light is cut off on this account. The remaining 75 per cent of the light would be available for the illumination of the screen if the speed was sufficiently high to eliminate flicker. As sixteen pictures are projected per second, the shutter makes 16 revolutions per second, which in practice is nearly three times too slow so far as the elimination of flicker is concerned. It is necessary, therefore, to increase the number of interruptions per second by the introduction

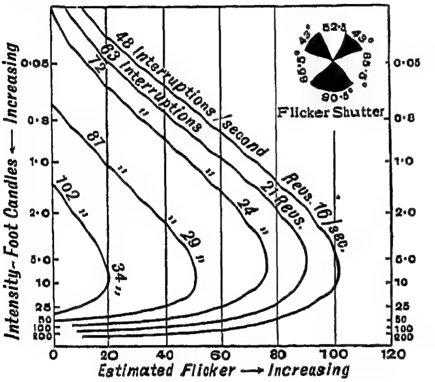

FIG. 1.

of one or more, usually two, additional dark sectors, the arcs of which are generally made less than that of the main occulting sector, in order to conserve the illumination.

Results of flicker tests of a three-bladed shutter supplied with one well-known type of machine are indicated in *Fig.* 1. In the tests the film itself was removed and the fluctuations of the light in the aperture were measured photometrically. Abscissae represent the estimated strength of flicker and ordinates the intensity of illumination in foot-candles. Upon each curve is indicated the corresponding number of interruptions per second, that is, three times the number of revolutions per second of the particular shutter. Thus, for example, in the case of the curve corresponding with a speed of 29 revolutions per second, the interruptions of the light were 87 per second. When the intensity of the illumination was reduced to 0·7 foot-candle the flicker disappeared. As the intensity was increased flicker reappeared and became more and more pronounced until it reached a maximum value at an intensity of 10 foot-candles. A further increase of the intensity produced an appearance of glare and caused the flicker to disappear very rapidly. Glare effects of this order need not be considered as they do not occur in the case of the kinematograph.

The curves indicate that with an intensity of illumination of 2 foot-candles about 36 revolutions per second would be required to eliminate flicker. In practice, however, this condition is fortunately attained at a much

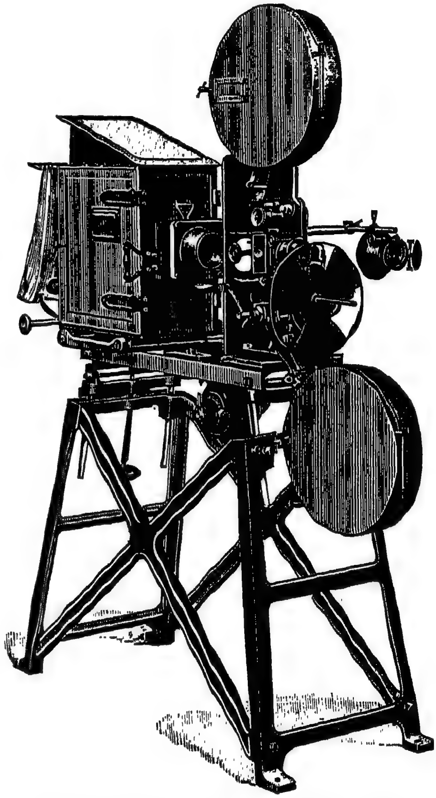

FIG. 2.—The "Indomitable" Projector Outfit.

lower shutter speed of 16 revolutions per second, equivalent to 48 interruptions in the case of the three-bladed shutter. This is largely due to the fact that with the film in position not only is the illumination reduced by at least 25 per cent in the case of the lightest portions, but also there is no longer a rapid change from uniform light to darkness, since the light is broken up by the various tones of the picture, thus further reducing the general illumination and contrast with the dark intervals.

§ (4) THE APPARATUS.—A kinematograph projector equipment, of which the Indomitable outfit (*Fig.* 2) of Messrs. Kershaw & Sons is a

typical example, comprises the lamp, lamp-house and condenser, the machine or projector, including the projector lens, and the stand. The primary function of the machine is to draw the film from the upper reel box; to bring each consecutive picture of the film very exactly into position before the gate aperture through which the light passes; to keep the picture stationary in this position for a period of about $\frac{1}{20}$th second; to remove the picture and bring the succeeding one into position in the brief interval of about $\frac{1}{80}$th second; to wind the film upon the lower reel after it has passed through the gate before the aperture; to interrupt the image falling upon the screen, particularly during the transference period; and to mask the picture, that is, to adjust the film so that the individual pictures lie within the boundaries of the aperture and thus lie correctly on the screen.

FIG. 3.

In order that the film may be fed through the machine regularly, the sides are perforated in the manner indicated in *Fig.* 3, the perforations in question being now standardised.[1] Similarly, the sprocket wheels or drums have their teeth, which engage the film perforations, also pitched exactly according to a standard. Upon the regularity and accuracy of the perforations and the teeth depends to a large extent the steadiness of the picture upon the screen.

In the diagram, *Fig.* 4, the film A is drawn from the upper reel box B by means of the uniformly driven upper feed sprocket C, the teeth of which engage the film perforations. A roller D holds the film in engagement with C, from whence it passes through the gate E in front of the aperture F through which the light from the condenser passes. Friction strips, which press upon the sides of the film and not upon the part occupied by the pictures, offer a certain amount of resistance

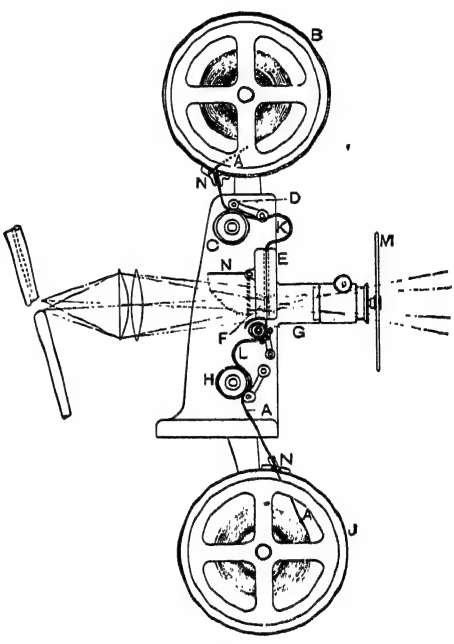

FIG. 4.

to the passage of the film as it is pulled through the gate by means of the intermittent sprocket G. From G the film passes over the continuously driven lower feed sprocket H into the lower reel box J, the spindle of which is frictionally driven in order that the rate of winding may be constant notwithstanding variation of the reel diameter. As the feed sprockets C and H rotate uniformly while G rotates intermittently, it is essential to provide loops at K and L the lengths of which must not be less than one picture, as otherwise the film would be broken. If the loops, on the other hand, are too long an objectionable whipping noise may result.

[1] *Report and Recommendations of the Standards Sub-Committee, Incorporated Association of Kinematograph Manufacturers, Ltd.*

In certain machines in which masking is performed by a displacement of the intermittent sprocket, the lower loop must be sufficiently long to permit of masking to the extent of at least one complete picture.

§ (5) The Intermittent Feed Mechanism.—Of the elements above described the most interesting and indeed the most important is the intermittent feed mechanism, because upon the accuracy with which it places each picture in front of the gate aperture depends the steadiness of the picture upon the screen. Assuming that a variation in the position on the screen of consecutive pictures of $\frac{1}{4}$ inch is permissible, and that the distance of the objective from the screen is 100 feet and from the film 5 inches, then the pictures must be centred with an accuracy of $\frac{1}{1000}$ inch.

Innumerable devices have been proposed for the intermittent movement of the film, but in the great majority of projectors the Maltese cross arrangement, or the Geneva cross, as it is sometimes called, represented in *Fig.* 5, is employed. Upon the axis E of the gate sprocket which feeds the film there is mounted the cross H, having four radial slots and four concave sides which suggest the name accorded to this mechanism. On a parallel axis F there is mounted a disc and driving pin A, the disc being cut away as indicated at K (*Fig.* 6) in order to clear the extreme points of the cross. The drive is applied to this driving disc, which rotates uniformly in one direction only.

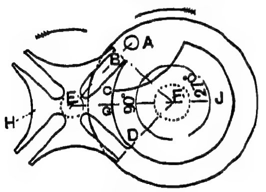

Fig. 5.

In the relative positions indicated in *Fig.* 5, the driving pin A is approaching the slot B tangentially, and the Maltese cross, the gate sprocket associated with it, and the film are at rest. Rotation of the cross is prevented in one direction by the locking action of the disc portion GD on one side of the line joining the centres EF and in the other direction by the portion CG. As the pin approaches the slot this locking portion decreases, but the drag on the film tends to hold the cross against the other locking portion.

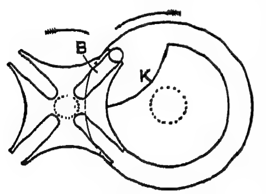

Fig. 6.

In the position *Fig.* 6, the pin has just entered the slot B and is driving the cross in the direction of the arrow, and with it the film. The recessed portion K of the disc is necessary to clear the points of the cross as indicated in *Fig.* 7.

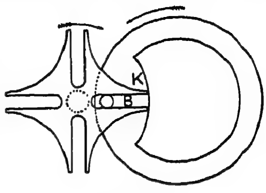

Fig. 7.

In *Fig.* 8 the driving pin A has just left the slot B of the cross, which with the film has therefore just come to rest, and the cross is locked to the maximum extent by the disc. As the cross has four symmetrical slots it makes a quarter revolution for one revolution of the driving disc.

Further, as the angle BFD (*Fig.* 6) is 90°, the cross during one rotation of the driving disc is being driven for one-quarter of the period and is at rest during the remaining three-quarters. The gear is said to be three to one, since the picture on the film rests before the gate aperture during three-quarters of the period and is transported during the remaining fourth.

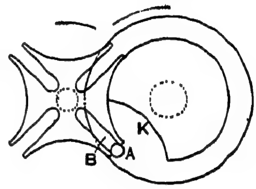

Fig. 8.

Owing to the occultation of the light during this period only three-quarters of the total light reaches the screen, and in practice considerably less, owing to the additional width of the black sector required to cover nearly the width of the objective and to the flicker sectors previously referred to. As illumination is of great importance the width of the occulting sector is reduced by the adoption of a four-to-one, or even a five-to-one gear, as indicated in *Fig.* 9. The driving pin engages the cross during 60°, or $\frac{1}{6}$th of its rotation, and leaves it at rest during the $\frac{5}{6}$ths of the total period. The occulting sector can thus be reduced from about 90° to about 60°, with a corresponding increase of illumination. But

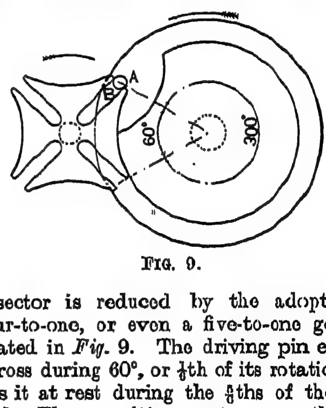

Fig. 9.

it will be observed that the pin A, instead of gently entering the slot B tangentially, forcibly strikes the driving face, and as the film has to be started from rest, moved, and brought to rest again in $\frac{1}{6}$th instead of $\frac{1}{4}$th of the period, the strain on the film, and particularly the wear of the perforation, is much greater. Notwithstanding these disadvantages four- and five-to-one arrangements are frequently adopted.

A greater strain is thrown on the film at the moment of starting than of stopping, as the film has to be drawn through the gate against the resistance of the friction side blocks. An excentric arrangement [1] of the slots as indicated in *Fig.* 10 has the advantage

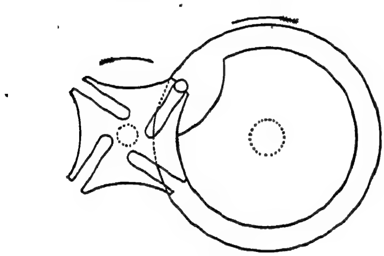

FIG. 10.

that, although the action may still be, say, five to one, the film is started more slowly, the movement being decelerated correspondingly more rapidly; but, as already stated, rapid starting is more serious as regards wear than rapid stopping. For the excentric arrangement the further advantage is claimed that a portion of the occulting sector on the leading side can be cut out with a consequent increase of the light, since a greater part of the initial movement of the picture is too slow to be recognised as a ghost image by the eye; but it should be remembered that it may be necessary to extend the following side, which under ordinary circumstances is often reduced in practice below the theoretical amount.

Claw-feed mechanisms of many kinds have been introduced, but although they are frequently adopted in camera, perforating, and printing mechanisms, they are but rarely used in the projector. Whereas in the projector the picture rests for $\frac{1}{20}$ second and moves during $\frac{1}{80}$ second, these periods are more or less reversed in the case of the camera, as the time of exposure during which the film is at rest is less than $\frac{1}{100}$ second.

For printing machines the claw arrangement [2] has the advantage that the teeth engage simultaneously the perforations of the positive and the superposed negative and drive both together with great precision. A considerable wear of the film perforations is attributable to the teeth of the claws, but as the film is only subjected once in the camera to the claw action, this disadvantage is not of great importance. The teeth of the claw are caused to move in a more or less D-shaped path, the straight side of the D being parallel to the film. The vertical motions are controlled by a main cam and the horizontal movements by a subsidiary cam.

One of the earliest devices, known as the Dog or Beater, is now only found in machines of the cheapest kind. While simplicity of construction is its chief characteristic, its destructive action on the film is considerable. The device was originally suggested by the appearance of a lathe dog, from which the name is derived. At each revolution of the dog the pin strikes the film and beats it downwards, thus drawing the picture through the gate. The throw of the dog is such that the film is displaced to the extent of one picture at each revolution. A cam is usually provided to press the gate open against the resistance of a spring immediately before the striking pin comes into action in order to reduce the strain on the film. A reciprocating arm is sometimes used instead of the rotating dog, not only as a feed device but, in some cases, as a means of masking. Particulars of numerous other devices will be found in works devoted to kinematograph details.[3]

§ (6) THE SHUTTER.—With very few exceptions, the shutter M (*Fig.* 4), placed immediately outside the objective, has the form of a rotating disc which intersects the beam of light. It is driven in direct association with the driving disc of the Maltese cross, one revolution of which corresponds with the interval between the pictures. Thus, when properly set, the dark sector of the shutter occults the light while the picture is being transferred. The angular width of the occulting sector should theoretically be such that it just covers the whole beam before the picture commences to move, and does not uncover any portion of it before the picture has come to rest. To satisfy this condition would involve the loss of a great part of the light, especially as flicker sectors are also required. If the transfer takes place during $\frac{1}{5}$th of the period—that is, during 72° of rotation—the angular width of the sector is generally between 90° and 95°, which usually means that some light passes at the commencement and end of the transfer, when, however, the motion of the image is comparatively slow. That some latitude is permissible is suggested by the fact that in some houses where the film is run at an unusually high speed,[4] or where the illumination is low, due to fog or smoke, for example, a special single-bladed shutter, or sometimes no shutter, is used.

[4] F. H. Richardson, "The Various Effects of Overspeeding Projection," *Trans. Soc. Motion Picture Engineers*, No. 10, p. 61.

Several typical shutters in common use are illustrated in *Fig.* 11.

Innumerable devices have been introduced with the object of improving the illumination, but the result must necessarily be a compromise between light and definition, as practically all involve the projection of diffuse or irregular light upon the screen. Thus the blank sectors may be pierced with holes, have gauze-covered portions, be of semi-transparent, variegated, or coloured material, or be provided with a small-diameter, light-diffusing lens.

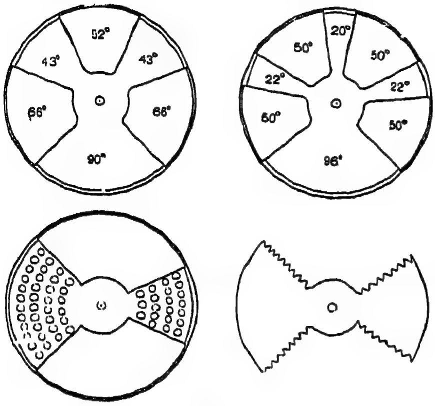

FIG. 11.

§ (7) THE GATE.—An important element is the gate (*Fig.* 12) through which the film is drawn downwards intermittently by the intermittent sprocket. The film passes through the space B between the aperture plate A and the gate E, which is so hinged at C that it can be quickly opened by pressing the spring catch D to facilitate the stringing of the film.

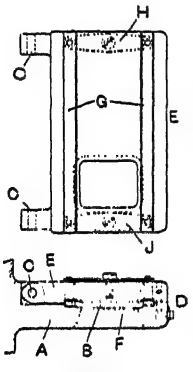

FIG. 12.

Usually, but not in all cases, the aperture plate faces the lantern and the gate the objective. When the gate is on the objective side it is often necessary to swing the objective holder upwards before the gate can be opened to the full extent. When the gate faces the lantern, the disposition of the guide rollers is usually such that if the film breaks it accumulates between the machine and the lantern and increases the danger of fire. Inside the aperture face there are provided two side strips, against which the film is pressed by two corresponding hard steel strips or shoes G, carried springily upon the gate. As it is the pressure of these shoes that determines the drag on the film, it is essential that not only should the tension be capable of adjustment, but that the tensions on the two sides of the film should be equal. This result is usually attained by making the top tension spring H act equally upon the upper ends of the two shoes and the lower spring J upon the lower ends. In some cases one spring is arranged to act equally on all four ends.

Small differences in the width of the film necessitate some side guidance, as the width of the slot in the aperture plate must be sufficiently great to accommodate films of extreme width. The flange of the top guide roller may be made to serve as a side guide, as the use of springs, especially in the side wall of the aperture plate, is not free from objection on account of their tendency to become clogged with the collodion torn from the surface, particularly of new films. For the same reason the use of velvet strips has been practically abandoned.

To facilitate the cleansing of the guides the gate should be capable of being opened widely and the shoes themselves should be removable. In many machines the lower guide roller which holds the film against the intermittent sprocket is carried upon the gate, and is capable of being so adjusted that it does not bear too hard upon the film. Underneath the sprocket there is mounted a stripper plate which separates the film from the under side of the sprocket. When this plate is not fitted there is danger of the film being wound round the sprocket.

§ (8) MASKING.—Masking the film is necessary from time to time, in order to set the individual pictures exactly before the aperture and therefore correctly upon the screen.

In re-joining a film the pieces may be displaced by a fraction of a picture, and when this portion passes through the machine the correct location of the image upon the screen is affected. The earlier method of masking, which has only recently been generally discarded, consisted in displacing, relatively to the film, the optical axis containing the source, the centre of the aperture, and the optical centre of the objective, by the amount required to replace the image centrally upon the screen. The model illustrated in *Fig.* 2 is of this type. The aperture and objective are usually moved together, and then the light source is readjusted until the best condition of uniform illumination is again attained.

As the frequent readjustment of the source is not without objection, the greater proportion of modern machines have the optical axis fixed, masking or framing being effected by pulling the film through the gate until the picture is again central, without, however, altering the relative positions of the Maltese

cross and the driving disc with which the shutter is associated; that is, the operation of masking must not affect the timing of the carry-over gear and shutter. The intermittent sprocket, Maltese cross, and driving disc are moved up or down as one unit carrying with it the film relatively to the gate. It is then necessary to make the top and bottom loops sufficiently large to permit of this adjustment. The drive may be communicated to the adjustable element through the intermediary of a coupling so disposed that no rotation of the coupling shaft and no rotation of the shutter shaft is involved in the masking operation. If these conditions are fulfilled, the timing is not affected, the occultation of the light corresponding with the transfer of the film by the rotation of the intermittent sprocket.

This system of masking is embodied in the Power's Cameragraph. The apparatus, as is customary, can be placed in an inclined position, which is necessary when the projection booth is situated at a high level relatively to the screen. Means are provided on the stand for angling the whole machine together with the lamp as one unit to suit the conditions of the installation.

An interesting device is used in the Cameragraph for automatically re-setting the lower loop, which in practice may quite easily be lost if the film perforations, for instance, are badly worn, necessitating ordinarily an interruption of the projection. The strip of film forming the lower loop is passed under a roller. When for any reason the loop is lost, the film in becoming taut raises the roller and partially rotates a cylinder on the surface of which is cut a spiral slot. An arm, a pin on which engages the slot, is thus swung sideways and declutches the lower feed sprocket, the rotation of which momentarily ceases. During this interval the loop increases, the roller under the action of a spring falls with the loop, the clutch is brought into normal action, and the sprocket recommences to feed the film.

In the masking devices previously described the intermittent sprocket in its lowest position is a considerable distance from the gate, and the length of the film loop between the gate and the intermittent sprocket is of variable amount. Although additional complexity is involved, this disadvantage may be successfully avoided by mechanism such as is used, for example, in the Simplex machine. The gate sprocket is mounted close to the gate with its axis in a fixed position. Masking is effected by the rotation of the whole intermittent mechanism about the axis of the sprocket, the maximum rotation required being a quarter revolution, which corresponds with a film displacement of one picture. Since the pinion of the driving disc must necessarily be in gear either directly or indirectly with the driving wheel, having its axis concentric with the intermittent sprocket about the axis of which the masking rotation takes place, it will be evident that in the masking operation the driving disc will be rotated relatively to the Maltese cross. To preserve the timing, the shutter must therefore be automatically rotated by an equivalent amount in the appropriate direction.

For a displacement of one picture—that is, a quarter revolution of the intermittent sprocket—it is necessary to correct automatically the displacement of the shutter by one revolution. This is done in one particular example by communicating the drive to the shutter axis through spiral gears, the pinion gear on the shutter axis having a length of one spiral. When the gate sprocket mechanism is rotated the spiral driving element is displaced longitudinally upon a squared shaft by a corresponding amount, and in its longitudinal movement it rotates the shutter quite independently of its ordinary rotational movement. The arrangement has the advantage that, by providing an additional hand control of the longitudinal movement, the timing can be adjusted while the machine is running.

In view of the precision with which the intermittent sprocket must locate the film, the introduction of elements between this sprocket and the Maltese cross is objectionable owing to the possibility of backlash introduced by slackness or wear of the parts. It has been proposed, for example, to rotate the sprocket independently of the Maltese cross through the intermediary of a differential, one element of which is controllable by hand. In another arrangement the sprocket is mounted upon a spiral sleeve on the Maltese cross spindle to which it is keyed. By a longitudinal displacement of the sleeve the sprocket can be rotated relatively to the cross, and, as in the previous example, the timing of the shutter is not affected, since no relative movement of the cross and driving disc is involved. Devices of these kinds, which involve the use of additional parts, particularly between the sprocket and the cross, are unlikely to prove satisfactory on account of the objectionable backlash that may be introduced.

An essential and important feature is the take-up mechanism of the lower spool-box which rolls up the film after its passage from the lower feed sprocket at a constant rate of about 1 foot per second. As the diameter of the roll increases the speed of rotation necessarily decreases and the tension on the film varies. In a few cases the drive is applied through the intermediary of a variable speed gear, but in the great majority of machines a simple slipping clutch is employed, the pressure being adjustable by means of a spring. As the diameter of the roll grows larger the slipping increases, but although the maximum force that can be applied to the film is limited, the force is not automatically kept constant. For reels having 1000 feet of film the slipping-clutch, when properly set, suffices, but for longer reels of 2000 feet a variable speed drive becomes desirable. Satisfactory results have been attained by causing the increasing weight of the roll to increase the frictional resistance to rotation, whereby the uniformity of the tension on the film is maintained.

So long as inflammable celluloid film is used, there must always be a certain amount of fire risk, notwithstanding the stringent legal regulations that are commonly imposed. For the prevention of panic among the spectators, who may be alarmed by the fiery glow projected

upon the screen when the film in the aperture space is ignited, it is essential that the projection should be interrupted immediately by closing the window shutter of the booth and by closing the lamp shutter or dowser. These operations are generally done by hand. Upon the machine itself, however, there must be provided a fire shutter N (*Fig.* 4), which covers the gate aperture when the machine is at rest, as shown dotted in the illustration.

When the machine is in operation the film is subjected to the concentrated heat for brief intervals of only $\frac{1}{16}$th second, during which time it does not reach the temperature of ignition. But if the machine is stopped and the film is at rest for a second or even less, it will become ignited unless the shutter falls immediately the motion ceases. The shutter is often operated by means of a governor directly associated with the driving mechanism, and in other cases by simple friction discs separated by a thin viscous layer of oil.

If the film breaks while the machine continues in motion the fire shutter will not fall. In such a case the lamp dowser must be closed by hand.

To provide automatic protection capable of dealing with every contingency involves mechanical and electrical complications that may prove a greater danger than security. Reliance is usually placed upon the fire shutter at the gate and the alertness of the operator. Ignited film in the machine itself, being in contact with cold metal, burns comparatively slowly and may easily be extinguished if dealt with promptly.

It is most important that the large masses of film in the roll boxes should not become ignited. Provided the lids are closed as they ought to be, this can be effectively prevented by passing the film into the boxes between metal plates N (*Fig.* 4), having a surface length of several inches. The cold metal extinguishes any flaming film that may be drawn between them.

§ (9) The Objective.—As the individual pictures on the film are only 1 inch wide and $\frac{3}{4}$ inch high, whereas the image projected on the screen may be 20 ft. wide, it will be evident that so great a magnification necessitates a quality of definition of a very high order over as large a central area as possible, since the action of a picture play cannot be confined to the centre of the screen. Illumination being of the greatest importance, a large aperture is desirable as in the case of portrait lenses, in which the conditions to be satisfied are very similar. There may be a considerable loss of light, however, in the passage through the lens system, not only at each transmission, but also owing to the actual cutting off in the combination when the front and back elements are widely separated as in the case of the early Petzval objectives. Compactness of design is therefore of importance.

An objective equivalent focal length of 4 inches is a common one, and since the picture is 1 inch wide the angular field is about 15°, and for longer focus objectives still less. This small angular field makes it possible to obtain a quality of general definition on the screen that would be unattainable if the width of field common in the case of a portrait objective was required.

Computation is also facilitated by the fact that complete freedom from distortion is not of greatest importance. With very few exceptions, the centre of the projected beam does not fall normally upon the screen, owing to the elevated position of the kinematograph booth and to the vertical arrangement of the screen. For these reasons the magnification at the bottom of the screen is usually greater than at the top by an appreciable amount considerably in excess of the distortion error attributable to a good objective.

The principal aberrations that have to be reduced to a minimum in the computation of objectives are discussed in the undernoted works.[1] They are as follows:

(i.) Chromatic aberrations.
(ii.) Axial spherical aberration.
(iii.) Coma.
(iv.) Astigmatism and curvature of the field.
(v.) Distortion.

Freedom from chromatic aberrations ensures the absence of coloured margins in the projection of black and white details and a true representation of coloured images. Crispness of central definition is associated with freedom from axial spherical aberration, and fulfilment of the sine condition. Coma or spherical aberration for extra axial points and astigmatism result in fuzziness and elongation of details which increase with the distance from the centre.

When there is curvature of the field the image cannot be sharply focussed at the centre and sides of the screen simultaneously, owing to the image surface being curved. When astigmatism is present there are really two image surfaces whose vertexes coincide on the axis where the astigmatic aberration is zero. Distortion, already referred to as being of secondary importance in view of the greater error due to the angle of projection, results from a change of magnification from the centre radially over the surface of the screen.

Most kinematograph objectives are based upon the type of portrait objective invented by Professor Petzval of Vienna in 1840. This type is remarkable for its freedom from aberration over a central area corresponding with an angular field of about 8°, that is, 4° on either side of the axis. Beyond this width non-fulfilment of Abbe's sine condition becomes increasingly marked.

[1] Steinheil and Voit, *Handbook of Applied Optics*, edited by J. W. French, vols. i. and ii., 1918; A. S. Cory, "Optical Requirements of Motion Picture Projection Objectives," *Trans. Soc. Mot. Pict. Engrs.*, April 1918; C. Lindsay Johnson, *Photographic Optics*.

The Petzval system comprises an outer cemented doublet nearest the screen and an inner non-cemented doublet nearest the film. It has the additional advantage that the latter is not so liable to be affected by the heat of the concentrated light as would be the case if the elements were balsamed. In 1866 J. H. Dallmeyer considerably improved the uncemented element of the Petzval system.

By a judicious selection of types of glass introduced within comparatively recent times it is now possible to obtain numerous excellent anastigmatic combinations of British, German, and French make that, in addition to crispness of definition over a large area, provide a field that is flat over nearly the whole angular width common to kinematograph projection.

§ (10) Illumination. — When it is considered that the whole light available for distribution over the surface of the screen, which may be 20 feet long and 15 feet high, has to be emitted by the crater of the arc having an effective surface of less than 0·2 sq. in., it will be understood that a very intense source is essential. For smaller projection lengths special incandescent tungsten lamps [1] having a condensed area of filament are extensively employed in America. With these lamps there are used rear reflectors and special corrugated condensers [2] which, being placed near the lamp, intercept a large cone of rays. But for screens of 20 feet width a more powerful source, such as the carbon arc, is still employed.

In comparison with the incandescent lamp the carbon arc [3] is more inconvenient to use, less constant, and less hygienic. If the carbons are solid the arc wanders and the illumination for this reason varies greatly, but usually the upper carbon has a soft core which, by burning away more quickly, centres the arc and prevents wandering. When using alternating current both carbons are usually cored. Arc controllers designed to avoid hand control, and magnetic devices for steadying the arc, are available and are sometimes installed.

When using cored carbons an illumination of about 120 candle-power per sq. mm. of crater is obtainable. An effective crater area of 100 sq. mm. or 0·16 sq. in., which is common, thus emits 12,000 c.p. If the arc was an unobstructed point source radiating in all directions, the nearer the condenser lens was placed to it the greater would be the cone of light intercepted, and the greater the light available. Much of the light, however, is obstructed by the lower negative carbon of direct-current arcs and by the upper crater edge of the positive carbon, and further, on account of the intense heat, it is not practicable to bring a condenser lens closer than 3½ in. to 4 in.

A 4½-in. diameter condenser lens, which is a usual size, set 3·6 in. from the arc intercepts a cone of light whose base covers 1 sq. ft. and whose length is 1 foot. Such a condenser thus intercepts 12,000 lumens if the candle-power is 12,000. At each transmission surface at least 4 per cent of the incident light is lost, in accordance with the Young-Fresnel law. There is also some absorption of light by the glass. In the case of the objective this is almost negligible, as the glass employed is of good optical quality and the thicknesses are small. Glass of a much inferior character is too frequently employed for the condenser lenses and the loss is then quite important. It is very questionable economy to use condenser lenses made of a type of window glass, as is so frequently the case.

The losses of light in its passage from the first condenser surface facing the arc to the screen are as indicated in *Fig.* 13. At the surfaces A, B, C, and D at least 4 per cent of the light incident at each of the respective surfaces is lost. An absorption of 5 per cent per cm. thickness of glass has been assumed, but this amount is often exceeded. In the first lens the loss is 17 per cent and in the double lens condenser 33 per cent. The loss in a triple condenser is still greater.

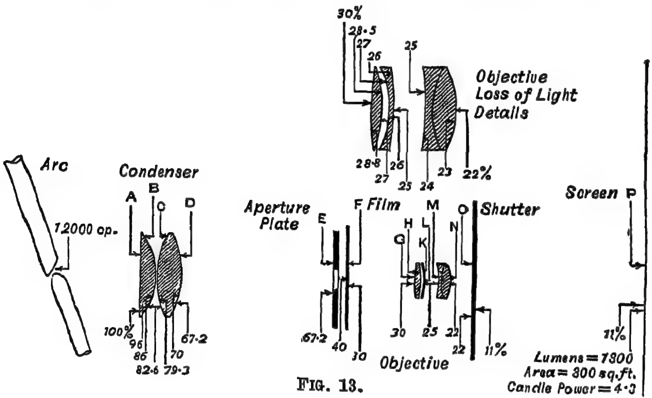

Fig. 13.

[3] W. C. Kunzmann, "Carbon Arc for Motion Picture Projection," *Trans. Soc. Mot. Pict. Engrs.*, Nov. 1918, p. 20.

It has been assumed that the whole circular area of the condenser lens contributes light. Actually, however, only a rectangular area corresponding with the rectangular form of the film aperture is utilised. About 40 per cent of the circular beam is cut off by the rectangular aperture at E. Thus about 40 per cent of the original light reaches the film F. Only an approximate estimate of the loss at the film is possible, as the density varies greatly. Photometric measurements show that 25 per cent of the light may be lost in transmission through even the least dense parts.

The objective, whose surfaces are lettered G to N, usually has two uncemented lenses which involve a drop from 30 per cent to 25 per cent, and one cemented doublet which involves a further drop to 22 per cent.

In the usual flicker shutter O there is a very large loss of light, amounting in one commonly used type to nearly 50 per cent. Of the total light incident upon the first surface A of the condenser, namely 12,000 lumens, only 11 per cent passes the shutter, that is 1300 lumens. Neglecting the loss through absorption by the atmosphere, which may be considerable, this quantity of light is available for distribution over the screen P, having an area cf, say, 300 sq. ft. Thus, assuming the whole film is of the lightest shade, the intensity of the light on the screen would be 4·3 foot-candles. The actual intensity reflected to the observer's eye is considerably less, and depends not only upon the nature of the screen but also upon the obliquity of the observer's line of sight.

§ (11) The Screen.—A perfect reflector if used as a screen would reflect a high proportion of the light, but only in a definite direction determined by the angle of incidence. A matt surface, on the other hand, diffuses the light over a wide angle, within which the picture is visible, but the light reflected in any one direction is correspondingly less. Thus, although the albedo value, that is, the ratio of the reflected light to the incident light, for a polished glass sheet silvered on the back may be 90 per cent, such a screen would be quite unsuitable as compared with a matt surface of fine white plaster which, when clean, has an albedo value of about 80 per cent but spreads the reflected light over a wide angle.

White cloth well stretched reflects from 70 to 75 per cent of the light. Cartridge paper has even a higher albedo value, but such hygroscopic materials readily deteriorate. The choice of a screen surface [1] depends also upon the maximum obliquity from which it must be viewed.

[1] Jones and Fillius, "Reflection Characteristics of Projection Screens," *Trans. Soc. Mot. Pict. Engrs.*, Oct. 1920, p. 59.

Glass screens [2] ground on the face and silvered on the back confine the greater part of the light to an angle of about 30° and may have a good reflecting value of over 80 per cent when clean, but moisture on the ground surface has a serious effect upon the spreading power of the parts affected. Screens coated with silver, aluminium, or other metallic paints are often used. Special claims are sometimes made for yellow-tinted surfaces that reflect a greater proportion of yellow light.[3] Whatever the type of screen employed, it is essential that its surface should be kept clean and dry, as otherwise the reflecting power may be much reduced.

§ (12) Special Forms of Machine.—It is not possible within the limits of this brief account to deal with the more special applications of the kinematograph.

For the projection of synthetically coloured pictures Friese Green in 1899 proposed the use of a red, green, and blue rotating shutter in front of the objective. In the original kinemacolour method successive exposures of the film in the camera are made through three and sometimes two filters consecutively, and each set of three or two consecutive pictures is projected simultaneously, and in other arrangements alternately, upon the screen through corresponding filters. Numerous other arrangements have been proposed for the synthetic production of natural colours,[4] but, in view of the expense and complications involved, simple hand-tinted films [5] are more frequently used whenever coloured pictures are desired.

The kinematograph is of great scientific value for the analysis of very quick motions,[6] the pictures being taken at a rapid rate in the camera and projected upon the screen at the rate of about sixteen per second.

Many inventors have attempted to devise a satisfactory dissolving view machine, the advantages of which need no description, but no real practical success can be recorded. The intermittent machine, notwithstanding its inherent difficulties, still remains unsurpassed for the projection of pictures under picture-house conditions. Most of the continuous devices hitherto proposed have involved a large number of lenses, prisms, or mirrors difficult to adjust or maintain in adjustment individually with the accuracy essential for the projection of a picture at a

distance of a hundred feet, which is quite a common practice.

Many attempts have also been made to project stereoscopic images [1] upon the screen, but with little real practical success. The use of coloured spectacles to view suitably coloured pictures is unlikely to become popular. An impression of depth can also be obtained from the parallax appearance resulting from a translation of the camera during the exposure of the film.

To a very considerable extent the use of the kinematograph in schools, and the more general introduction of portable kinematographs [2] for home and commercial purposes, is dependent upon the development of a durable non-inflammable or slow-burning film. If slow-burning non-standard film is used, the choice of subjects is at the present time greatly restricted.

König-Martens Spectrophotometer. See "Spectrophotometry," § (12).

— L —

L Series: a group of spectrum lines in the characteristic X-rays emitted by an element. See "Radiology," § (17).

Lambert: a unit of brightness used in America. It is equal to the brightness of a perfectly diffusing surface of unity reflection ratio, illuminated to the extent of one phot (*q.v.*). It therefore equals $1/\pi$ candles per square centimetre. See "Photometry and Illumination," § (2).

Lamp Rotator: a device for obtaining a measurement of mean horizontal candle-power of a lamp by a single photometric reading. See "Photometry and Illumination," § (38).

Landolt and Lippich's Polarimeter: an instrument for measuring the position of the plane of polarisation, depending on the use of a very intense light source and a pair of wide-angled Nicol prisms, the field being not uniformly dark but crossed only by a narrow black band. See "Polarimetry," § (9).

Lantern Projection of Images on a Screen. See "Projection Apparatus," § (14).

Latitude, definition of. See "Surveying and Surveying Instruments," § (4).

Determination of, for survey purposes. See *ibid.* § (24).

Laurent Polarimeter. See "Polarimetry," § (5).

Lead, Use of, in Glass Manufacture. See "Glass," § (8).

Leading Marks for Fixing Position. See "Navigation and Navigational Instruments," § (2).

Length, Focal, determination of, for simple spherical lens. See "Lenses, The Testing of Simple."

Lens, aspherical: a type of spectacle lens designed to correct the aberration introduced when the eye looks towards the edge of the lens instead of to the centre. See "Ophthalmic Optical Apparatus," § (8) (ii.).

Bifocal: a type of spectacle lens having two different powers or foci set in the same eye-wire or spectacle frame; the upper focus is used for distance and the lower for reading or close work. See *ibid.* § (8) (i.).

Cataract: a type of spectacle lens for aphakic patients, designed to reduce the weight and aberration of the suitable lens of an ordinary type. See *ibid.* § (8) (iii.).

LENS SYSTEMS, ABERRATIONS OF

§ (1) Introduction.—The Gaussian theory of a system of coaxial lenses is given in the article on "Lenses, Simple Theory of," while in the articles on the Lenses for Telescopes,[3] Photographic Lenses,[4] and Microscopes [5] reference is made to the various aberrations to which any such system is subject.

In the following sections the theory is given of the five first-order aberrations, generally known by the name of Von Seidel, viz. Distortion, Curvature, Astigmatism, Coma, and Spherical Aberration. A more complete treatment will be found in the article on Systems of Lenses.

§ (2) Hamilton's Characteristic Function.—Light is propagated by transverse waves which spread outwards from any luminous source; in an isotropic medium—one, that is, which has identical properties in all directions—the wave velocity is the same in all directions, and the waves emanating from any point source spread outwards in sphere. Consider now the disturbance leaving the source at any given instant; at any future instant, supposing no reflection or refraction to have occurred, its effect will be spread over a sphere having the source as centre, and the

[3] See "Telescopes," § (3).

[4] See "Photographic Lenses," § (8).

[5] See "Microscope, The Optical Theory of," §§ (5), etc.

time taken to reach any point on this sphere will be the same, and will be given by dividing the radius of the sphere by the velocity of the light. This sphere constitutes the wave front for that disturbance. The effect of reflections or refractions, such as take place at the surfaces of a series of lenses, is to modify the form of the wave surface, but it always retains this fundamental property; it is the assemblage of points at which the disturbance emanating from the source at any given instant has arrived at the instant considered, and its form is given by the fact that the time taken to travel from the source to all points on the surface is the same. Moreover, it can be shown (i.) that the light which reaches any point is travelling at right angles to the wave surface through that point, and (ii.) that the ray or path by which the light has travelled is such that the time of transit from the source to the point is the least possible.

Now if x, y, z be the co-ordinates of any point on the wave front we may write its equation as $f(xyz)=c$, and since the time of transit from the origin to any point on the wave is constant we may express the time as a function of the variables which is constant when the point xyz is on the wave front. This will be satisfied if the time is expressed as a function of $f(xyz)$. Thus, if V denote the time we may put

$$V=\phi\{f(xyz)\}.$$

Again the direction cosines of the direction of propagation, which, as we have seen, is normal to the wave front, are proportional to df/dx, df/dy, and df/dz respectively. But

$$\frac{dV}{dx}=\frac{dV}{df}\frac{df}{dx}, \text{ etc.}$$

Thus the wave travels in a direction whose direction cosines, given say by L, M, N, are proportional to dV/dx, dV/dy, and dV/dz, when V represents the time taken to travel from the source—the origin—to the point x, y, z.

From this it follows that if V be regarded as a function of the co-ordinates of two points, one in the object, the other in the image, space—V being the time of transit between the points—the differential coefficients of V with regard to the co-ordinates of the points give the initial and final directions of the ray passing through the points. Thus a knowledge of V, which is the characteristic function of Hamilton, enables all the properties of the lens system to be deduced.

§ (3) Hamilton's Function for a Series of Coaxial Lenses.—The problem is simplified in the case of a system of lenses by the facts (i.) that the system is symmetrical about the axis of the lenses, and (ii.) that the objects and images considered are assumed to lie either in planes perpendicular to this axis or on surfaces of revolution about the axis.

Let X, Y, Z be the co-ordinates of a point P (*Fig.* 1) in the object space, consider a fixed

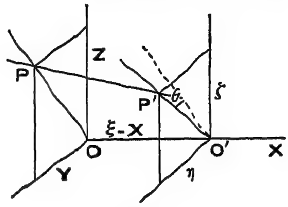

Fig. 1.

plane—the plane of a stop in the lens system—in the image space, and let the ray considered meet this in P′ whose co-ordinates are ξ, η, ζ.

Let planes through P and P′, normal to the axis, meet it in O, O′ respectively. Then it is clear from the symmetry about the axis that for any pair of points P, P′ in these planes V will be the same, so long as the distances OP, O′P′ and the angle between OP and O′P′ are fixed; thus, denoting this angle by θ, V may be treated as a function of the distance between the planes considered, the radii OP and O′P′ and the angle θ. But

$$OP=(Y^2+Z^2)^{\frac{1}{2}},$$

$$O'P'=(\eta^2+\zeta^2)^{\frac{1}{2}},$$

$$\cos\theta=\frac{Y\eta+Z\zeta}{OP.\,O'P'},$$

and $$OO'=\xi-X.$$

Thus we may treat V as a function of Y^2+Z^2, $\eta^2+\zeta^2$, $Y\eta+Z\zeta$, and $\xi-X$; this latter quantity is constant if the images are plane. Again in lens problems the quantities Y, Z, η, ζ are small compared with the focal lengths and other constants of the lens and with the distances of the object and image from the unit planes of the lens.

Thus we may expand V in powers of Y^2+Z^2, $Y\eta+Z\zeta$, and $\eta^2+\zeta^2$, and if we retain only the fourth powers of the small quantities we obtain the expression

$$\left.\begin{aligned}V=v_0&-\tfrac{1}{2}v_1(Y^2+Z^2)+v_2(Y\eta+Z\zeta)\\&-\tfrac{1}{2}v_3(\eta^2+\zeta^2)-\tfrac{1}{8}[v_4(Y^2+Z^2)^2\\&-4v_5(Y^2+Z^2)(Y\eta+Z\zeta)+4v_6(Y\eta+Z\zeta)^2\\&+2(v_6+v_7)(Y^2+Z^2)(\eta^2+\zeta^2)-4v_8(Y\eta+Z\zeta)(\eta^2+\zeta^2)\\&+v_9(\eta^2+\zeta^2)^2]+\ \ldots\ \text{terms involving higher}\\&\text{powers of the variables,}\end{aligned}\right\}\quad(1)$$

where the v's are quantities which depend only on the properties of the lenses through which the light has passed and on the positions of the object and stop planes, the values, that is, of X and ξ.

Also we have for the direction cosines of the emergent ray

$$M=\frac{dV}{d\eta},\quad N=\frac{dV}{d\zeta},\quad L=(1-M^2-N^2)^{\frac{1}{2}}.$$

Thus

$$\left.\begin{aligned}M=Y\{v_2+\tfrac{1}{2}v_5(Y^2+Z^2)-v_6(Y\eta+Z\zeta)\\+\tfrac{1}{2}v_8(\eta^2+\zeta^2)+\ .\ .\ .\ \}\\-\eta\{v_3+\tfrac{1}{2}(v_6+v_7)(Y^2+Z^2)-v_8(Y\eta+Z\zeta)\\+\tfrac{1}{2}v_9(\eta^2+\zeta^2)+\ .\ .\ .\ \}\end{aligned}\right\}, \quad (2)$$

with a similar expression for N, but with Z and ζ before the two brackets in place of Y and η. Also

$$L=1+\tfrac{1}{2}v_2^2(Y^2+Z^2)-v_1v_2(Y\eta+Z\zeta)+\tfrac{1}{2}v_3(\eta^2+\zeta^2)+\ .\ .\ . \quad (3)$$

§ (4) Position of the Image.—Now let the image plane be at a distance X′ from the stop plane, and let Y′, Z′ be the co-ordinates of the point in which the ray L, M, N meets the image plane. Then

$$\left.\begin{aligned}Y'&=\eta+\frac{M}{L}X'\\Z'&=\zeta+\frac{N}{L}X'\end{aligned}\right\}.\quad .\ .\ .\ (4)$$

Therefore

$$\left.\begin{aligned}Y'=\eta+MX'\{1-\tfrac{1}{2}v_2(Y^2+Z^2)\\+v_2v_3(Y\eta+Z\zeta)-\tfrac{1}{2}v_3(\eta^2+\zeta^2)\}\\=X'Y\{v_2+\tfrac{1}{2}(v_5-v_2^3)(Y^2+Z^2)\\-(v_6-v_2^2v_3)(Y\eta+Z\zeta)\\+\tfrac{1}{2}(v_8-v_2v_3^2)(\eta^2+\zeta)^2\}\\+X'\eta\{(1/X')-v_3\\-\tfrac{1}{2}(v_6-v_2^2v_3+v_7)(Y^2+Z^2)\\+(v_8-v_2v_3^2)(Y\eta+Z\zeta)\\-\tfrac{1}{2}(v_9-v_3^3)(\eta^2+\zeta^2)\}\end{aligned}\right\},\quad (5)$$

with a similar equation for Z′.

Now the condition that the plane for which the intersections have been found is the correct image plane, is that, for terms of the lowest order, Y′ and Z′ shall be proportional to Y and Z respectively, for the image must be similar to the object. Thus we must have $X'=1/v_3$. Hence the traces of the ray intersections with the image plane are found by substituting this value of X′ in the above expressions.

We can simplify these expressions by supposing that the axis of y passes through the source of the light so that $Z=0$. If this be done, we find the values

$$\left.\begin{aligned}2v_3Y'=2v_2Y+(v_5-v_2^3)Y^3\\-\{3(v_6-v_2^2v_3)+v_7\}Y^2\eta\\+(v_8-v_2v_3^2)Y(3\eta^2+\zeta^2)\\-(v_9-v_3^3)\eta(\eta^2+\zeta^2)\\2v_3Z'=-\{(v_6-v_2^2v_3)+v_7\}Y^2\zeta\\+2(v_8-v_2v_3^2)Y\eta\zeta\\-(v_9-v_3^2)\zeta(\eta^2+\zeta^2)\end{aligned}\right\}.\quad (6)$$

§ (5) The Aberrations.—These expressions agree with those employed in discussing the aberrations separately in § (8) of the article on Photographic Lenses if we put

$$v_2Y=v_3y,$$
$$Y'=y+\delta y,$$
$$Z'=0+\delta z,$$

so that y, 0 are the co-ordinates of the image when there is no aberration, and δy, δz the aberrations in the radial and transverse directions respectively.

(i.) *Distortion.*—The first term in the expression for the aberrations is given by

$$\delta y=\frac{v_5-v_2^3}{2v_3}Y^3,\quad .\ .\ .\ .\ (7)$$

and this gives the distortion [1] in the form

$$\delta y=a_1y^3,$$

where $$a_1=\frac{(v_5-v_2^3)}{2v_2^3}v_3^2\,;$$

the image is displaced by this amount in the radial direction and the aberration is wholly radial.

(ii.) *Curvature and Astigmatism.*—We have next the terms in $Y^2\eta$ and $Y^2\zeta$ given by

$$\left.\begin{aligned}2\delta y&=-\frac{1}{v_3}\{3(v_6-v_2^2v_3)+v_7\}Y^2\eta\\ \text{and}\quad 2\delta z&=-\frac{1}{v_3}\{(v_6-v_2^2v_3)+v_7\}Y^2\zeta\end{aligned}\right\},\ .\ (8)$$

or, as we may write them,[2] remembering that

$$Y^2=\frac{v_3^2}{v_2^2}y^2,$$

$$\frac{2\delta y}{y^2}=\eta(3e+e'),$$

and $$\frac{2\delta z}{y^2}=\zeta(e+e'),$$

where $$e=\frac{v_3}{v_2^2}(v_6-v_2^2v_3),$$

$$e'=\frac{v_3}{v_2^2}v_7.$$

To examine the nature of this aberration more closely consider the intersection of the rays with a sphere given by the equation

$$X'=\frac{1}{v_3}+\tfrac{1}{2}\left(\frac{Y'^2+Z'^2}{R}\right),$$

where R is the radius of the sphere.

Additional terms are thereby introduced into the right of equation (5), which are given by

$$\frac{1}{2R}\left(\frac{v_2}{v_3}\right)^2(Yv_2-\eta v_3)(Y^2+Z^2),$$

or, putting $Z=0$, the further terms in $2v_3Y'$ are

$$\frac{1}{R}\frac{v_2^3}{v_3}Y^3-\frac{1}{R}v_2^2Y^2\eta,$$

and in $2v_3Z'$

$$-\frac{1}{R}v_2^2Y^2\zeta.$$

[1] See "Photographic Lenses," § (8) (ii.) (*a*).
[2] See *ibid.* § (8) (ii.) (*c*).

The additional term in Y^3 means that the ray through the centre of the stop for which $\eta=\zeta=0$ strikes the sphere in a point at a different distance from the axis from that in which it meets the plane.

The complete coefficients of the terms in $Y^2\eta$ and $Y^2\zeta$ become

$$-\left\{3(v_6-v_2{}^2v_3)+v_7+\frac{1}{R}v_2{}^2\right\}$$

and $$-\left\{(v_6-v_2{}^2v_3)+v_7+\frac{1}{R}v_2{}^2\right\}.$$

Thus the spreading of the light which these terms imply disappears if surfaces of curvature

$$-\frac{1}{v_2{}^2}\{3(v_6-v_2{}^2v_3)+v_7\}$$

and $$-\frac{1}{v_2{}^2}\{(v_6-v_2{}^2v_3)+v_7\}$$

be considered as the image surfaces instead of the plane given by $X'=1/v_3$. In other words, the defects are due to the fact that pencils for which η is appreciable and ζ small come to a focus on a spherical surface having the former curvature, those for which η is small and ζ appreciable focus on a surface having the latter curvature. Thus the images are curved. Clearly, also, if e is finite the two spheres are distinct, no point image is formed; the aberration to which this gives rise is known as astigmatism. These curvatures may be written $-(3e+e')/v_3$ and $(e+e')/v_3$, and should be compared with the corresponding expressions given in the articles on "Optical Calculations," § (17), and "Eyepieces," § (4).

(iii.) *Coma.*—The next two terms[1] in the expressions for δy and δz are

$$\left.\begin{aligned}2v_3\delta y&=(v_8-v_2v_3{}^2)(3\eta^2+\zeta^2)Y\\ 2v_3\delta z&=2(v_8-v_2v_3{}^2)\eta\zeta Y\end{aligned}\right\}, \quad (9)$$

and these may be written

$$\frac{\delta y}{cy}=2(\eta^2+\zeta^2)+(\eta^2-\zeta^2)$$

$$=r^2(2+\cos 2\theta)$$

and $$\frac{\delta z}{cy}=2\eta\zeta=r^2\sin 2\theta;$$

if $$\eta=r\cos\theta,\ \zeta=r\sin\theta,$$

$$\therefore(\delta y-2cyr^2)^2+(\delta z)^2=c^2y^2r^4.$$

Thus the rays from a zone of the stop for which r^2 is equal to a constant pass through a circle in the image plane, the co-ordinates of whose centre are given by $2cyr^2$, 0, and whose radius is cyr^2.

It will be noticed that $\delta z=0$, *i.e.* the rays meet the image plane in the axial plane $z=0$, both when $\eta=0$ and when $\zeta=0$. In the first case

$$\frac{\delta y}{cy}=\zeta^2=r^2$$

and in the second

$$\frac{\delta y}{cy}=3\eta^2=3r^2.$$

Thus, in the second case the displacement of the image from its ideal position is three times as great as in the first.

Again the rays from opposite ends of any diameter of the annulus of the stop, *i.e.* from points whose co-ordinates are respectively η, ζ, and $-\eta$, $-\zeta$, meet the image plane in the same point. The complete circle in the image plane is formed by rays from half the annulus of the stop, thus when the complete annulus is considered the image circle is formed twice over.

(iv.) *Spherical Aberration.*—Spherical aberration[2] is independent of Y; it exists when Y is zero, or the light comes from a point on the axis of the system. In the expressions for $2v_3Y'$ and $2v_3Z'$ we have the terms

$$-(v_9-v_3{}^3)\eta(\eta^2+\zeta^2)$$

and $$-(v_9-v_3{}^3)\zeta(\eta^2+\zeta^2),$$

or, as we may write them,

$$\frac{\delta y}{\eta}=\frac{dz}{\zeta}=v_1r^2. \quad . \quad . \quad . \quad (10)$$

These do not vanish with Y, and indicate that a ray from an axial point passing through a point $\eta\zeta$ of the stop is not brought to a focus at the same point as a central ray for which X' is $1/v_3$, but at a point for which X' has the value given by

$$\frac{1}{v_3}+\tfrac{1}{2}S(\eta^2+\zeta^2),$$

where S is a quantity depending on the spherical aberration.

We find on making this assumption an additional term in the expression for $2v_3Y'$,

$$\tfrac{1}{2}S(v_2Y-v_3\eta)(\eta^2+\zeta^2),$$

and in that for $2v_3Z'$,

$$-\tfrac{1}{2}Sv_3\zeta(\eta^2+\zeta^2).$$

The terms in $(\eta^2+\zeta^2)$ then disappear from our expressions for δy and δz if

$$\tfrac{1}{2}Sv_3+(v_9-v_3{}^3)=0,$$

i.e. if $$S=\frac{2(v_9-v_3{}^3)}{v_3},$$

which indicates different focussing planes for light from an axial source passing through

[1] See "Photographic Lenses," § (8) (ii.) (*c*).

[2] See "Photographic Lenses," § (8) (ii.) (*b*).

distinct zones of the slot. The axial displacement δx of the focus is given by

$$\delta x = \mathrm{R}r^2,$$

where, as before, r is the radius of the zone.

In applying this analysis of the aberration to any actual system it must be borne in mind that, in order to obtain a satisfactory correlation between theory and the appearance of the image, the intensity distribution derivable from theory must be considered in conjunction with the geometrical trace, and, further, that the theory must be modified to allow for the effects of diffraction whenever very small dimensions are in question. The appearances due to aberration are modified from those derivable from the foregoing theory of small aberrations.

LENSES, concave, the testing of. See "Lenses, The Testing of Simple," § (3).

LENSES, THE TESTING OF SIMPLE.

THE chief characteristics to be examined in the testing of a simple spherical lens are, firstly, the focal length, and secondly, the centering error, that is to say, any want of coincidence of the optical centre with the geometrical centre of the lens. In the case of a cylindrical lens attention must also be paid to the orientation of the axis of the cylinder.

The theory on which the tests are based is dealt with elsewhere.[1]

These tests are most easily carried out on an optical bench such as is illustrated in *Figs.* 1, 2, and 3. A standard at one end of the

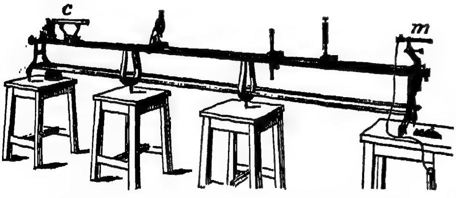

FIG. 1.—Optical Bench for testing the Lenses in Oculists' Trial Cases.

bench holds a collimator c (*Fig.* 1) with illuminated vertical and horizontal cross-wires at its focus. At the other end, facing towards the collimator, is a microscope m which can be moved parallel to itself in a vertical or horizontal direction, while at its focus is a graticule M (*Fig.* 2) engraved with vertical

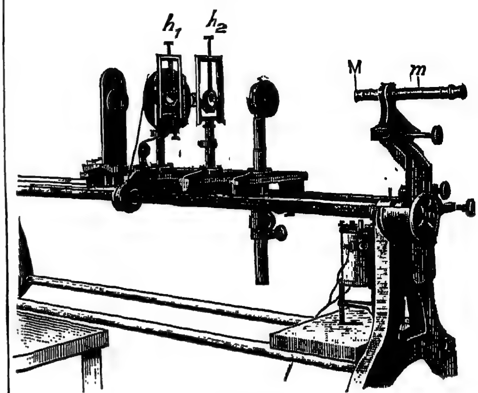

FIG. 2.

and horizontal cross-lines cutting symmetrically across a series of concentric circles of radii 1, 2, 3 . . . mm. An endless steel tape t (*Fig.* 3), attached to a lens-holder h_1, and passing over a pulley at each end of the bench, enables the observer to adjust the holder to

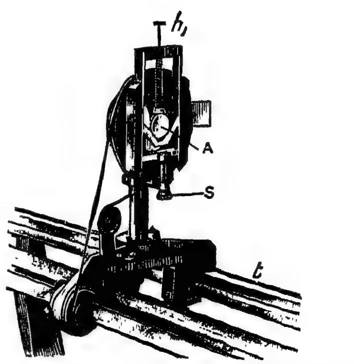

FIG. 3.—Travelling Carriage with Rotating Head on Trial Case Lens Testing Bench.

any position along the bench. The portion of the holder which grips the lens can be rotated about a horizontal axis in line with the axis of the collimator. The lens A, which is held in position by an adjustable screw s, can thus be rotated in its own plane, the amount of rotation being indicated on a circular scale. A second standard h_2 for holding an auxiliary lens can be placed on the bench at any point and its position read by means of a pointer working over a scale on the bench.

(i.) *Convex Lenses.*—The lens under test is placed in the holder h_1 and brought close

[1] See "Lenses, Theory of Simple."

up to the microscope, the position of which is adjusted to bring one edge of the lens into the field of view. The screw holding the lens is adjusted so that on rotation the edge of the lens remains in a fixed position relative to the microscope cross-lines; the geometrical centre of the lens is then on the axis of the bench. Next, the holder is racked along the bench until the lens focusses the collimator cross-wires on the graticule of the microscope. If the lens is rotated, any separation of the optical centre from the geometrical centre will cause a corresponding rotation of the central point of the image in a circle of radius equal to the centering error in the lens, and by adjusting the microscope to make this circle of rotation concentric with the circles engraved on the graticule, whose radii are known, the centering error can be estimated to 0·1 mm. If, as in cases considered later, an auxiliary lens is used between the test lens and the microscope, the magnification it produces must be taken into account when estimating the centering error by this method.

When the lens A focusses the parallel rays from the collimator on to the graticule M (*Fig.* 4), the distance AM represents the focal length of the lens, neglecting the thickness of the latter. The position of A can be read on the tape, and the corresponding reading for M may be found by taking the tape reading when the lens is separated from the graticule by a small gauge of known length; the difference between these readings for A and M will give the distance of the focus from the back surface of the lens, that is, the back focal length. If the lens is thin, this will not differ from the true focal length by more than the probable experimental error. All plano-convex or plano-concave lenses should be tested with their curved surface towards the microscope, for then the second nodal point coincides with this surface and the focal length will be equivalent to the back focal length.

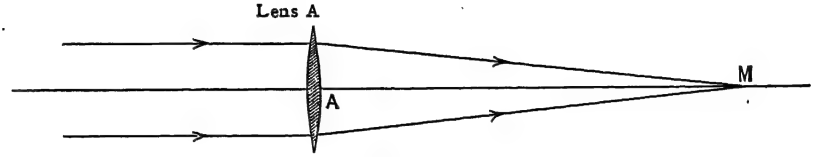

Fig. 4.

For biconvex lenses of equal radii and of considerable thickness a length[1] $2t/\mu$ must be added to the back focal length to give the true focal length, t being the central thickness and μ the refractive index of the lens. In obtaining this expression the square of the thickness has been omitted. For glass of refractive index 3/2 the correction comes to $t/3$.

(ii.) *Use of Auxiliary Lens.*—This method of measuring focal lengths is obviously applicable only to positive lenses whose focal length does not exceed the available length of the bench; with lenses of longer focus and with negative lenses a positive auxiliary lens must be used. The arrangement is indicated in *Figs.* 5 and 6. An equiconvex lens B of suitable focal length is mounted on the bench and its position noted when it brings parallel rays to a focus at the graticule M (*Fig.* 5). If F_1 and F_2 represent the foci of lens B, F_2 will in this case coincide with M. Let the distance B_2F_2, determined as described before, be p. The test lens is then introduced between lens B and the collimator (*Figs.* 6A, 6B), and the position of each lens is read when together they bring the rays to a focus at M. Let the distances AM and B_2M be now q and r respectively. The formation of the image is shown for a positive lens in *Fig.* 6A and for a negative lens in *Fig.* 6B. In *Fig.* 6A parallel rays passing through A converge towards O; O may therefore be taken as a virtual object the image of which is produced by the lens B at M. If B is equiconvex and of thickness t, assuming a refractive index of 3/2, its first and second nodal points lie within the lens at a distance[1] $t/3$ from B_1 and B_2 respectively; hence the focal length of B is $p+t/3$, while the distances of the object O from the first nodal point, and of the image M from the second nodal point, are respectively $B_2O+2t/3$ and $B_2M+t/3$.

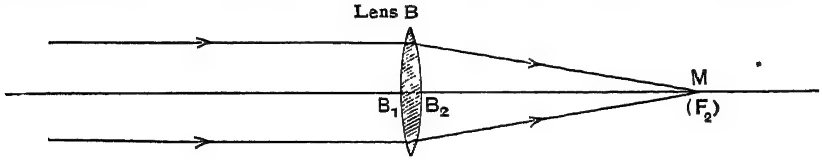

Fig. 5.

[1] See "Lenses, Theory of Simple."

Therefore, using the ordinary formula $f(u-v)=uv$, we find

$$\left(p+\frac{t}{3}\right)\left(B_2O+\frac{2t}{3}-B_2M-\frac{t}{3}\right)=\left(B_2O+\frac{2t}{3}\right)\left(B_2M+\frac{t}{3}\right)$$

or

$$\left(p+\frac{t}{3}\right)\left(f-q+\frac{t}{3}\right)=\left(f-q+\frac{t}{3}+r+\frac{t}{3}\right)\left(r+\frac{t}{3}\right),$$

giving

$$\left(f-q+\frac{t}{3}\right)(p-r)=\left(r+\frac{t}{3}\right)^2.$$

focal length of the auxiliary lens and depends only upon the amount of shift of this lens between the two positions, a measurement much less susceptible of error. The second formula is also independent of the thickness of the auxiliary lens; if necessary, the formula may be modified to take account of the thickness of lens A.

(iii.) *Concave Lenses.*—A third method is applicable for negative lenses only; the arrangement adopted is indicated in *Fig.* 8. The lens B is placed in any convenient position so that lens A may first be adjusted to produce in conjunction with B an image of the colli-

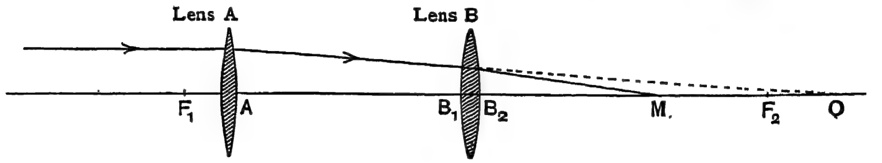

FIG. 6A.

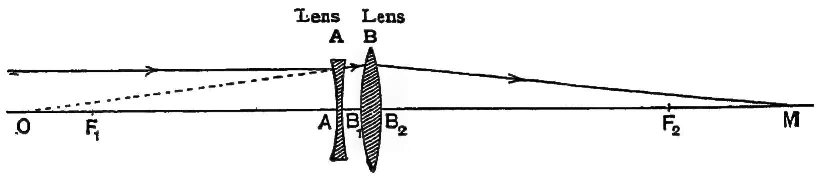

FIG 6B.

Hence the focal length of lens A

$$=f=q-\frac{t}{3}+\frac{\left(r+\frac{t}{3}\right)^2}{p-r}.$$

A similar formula is obtained in the case of a negative lens, illustrated by *Fig.* 6B.

Another arrangement is sometimes preferable. In this lens A is placed between the

mator cross-wires at M, and afterwards may be placed at the conjugate point to M with respect to the lens B; in *Fig.* 8, A_1 and A_2 represent these two positions. The position A_2 is determined by dusting a little lycopodium powder on to the back surface of A, and adjusting A until an image of the powder is focussed by lens B at M. The distance moved by lens A between the two positions is equivalent

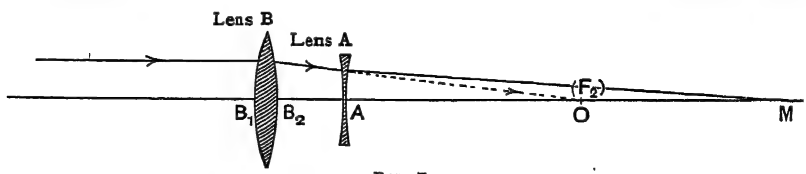

FIG. 7.

auxiliary lens and the microscope (*Fig.* 7). Using the same notation as before, the same formula may be applied, this time connecting the distances of O and M from the lens A. Neglecting the thickness of A, we have

$$f(AM-AO)=AM \cdot AO$$

or
$$f=\frac{q(p+q-r)}{r-p}=\frac{q^2}{r-p}-q.$$

It will be noted that with both arrangements the focal length f is independent of the actual

to the back focal length; the correction to be applied to obtain the true focal length is very small unless the central thickness of the lens is large.

The accuracy obtainable by these methods is not very great, in the case of long focus lenses especially, but the limits of error are small compared with those which are permissible in a simple lens used for a spectacle lens, and it is for lenses of this class that the tests are generally used. More accurate methods of focal length measurement, which

may also be applied to simple lenses, will be found under the article "Objectives, The Testing of Compound."

(iv.) *Optical Standards Committee*.—In 1908 the Optical Standards Committee of the Optical Society laid down certain limits for the error permissible in the manufacture of spectacle lenses;[1] these have obtained recognition generally, and are the limits allowed in the testing of trial case lenses at the National Physical Laboratory.

As the thickness of a negative lens may be kept small, no matter what the power may be, the latter can be found with considerable precision by measurement of the surface curvatures, taking a standard value of 1·52 for the refractive index of the glass. In the case of positive lenses the power is less independent of the thickness, especially with strong lenses; it is the recognised custom, therefore, to make the standard power and thickness of a positive lens such that it will exactly neutralise a standard negative lens of equal power. This method of neutralisation gives a simple means of checking one lens against another, and with experience an accuracy of at least $\frac{1}{8}$ D may be obtained.

According to the rules adopted by the Committee, the true power of a negative lens must not differ from the nominal value marked on it by more than ±2 per cent, or by more than ±0·01 D if this is greater than 2 per cent. For positive lenses of powers less than 10 D the limits are the same; for equiconvex lenses between 10 D and 12 D inclusive the limits of error are +3 per cent and −1 per cent, and for lenses between 13 D and 20 D inclusive the limits are +2½ per cent and −1 per cent.

The standard thickness of all negative lenses is 1 mm. at the centre. The standard thickness of a positive lens of any definite power is the minimum thickness possible for a lens of that power with a diameter of 3·8 cm. (1½ in.) and an edge thickness of 0·5 mm., the refractive index being 1·50.[2] This varies from 4·3 mm. for a 10 D lens to 7·8 mm. D for a 20 D lens.

The limits of error allowable in the centering of a spherical lens are as follows:

1 mm. for lenses between 20 D and 1 D.
2 mm. for lenses between 0·87 D and 0·37 D.
3 mm. for a lens of 0·25 D.
5 mm. for a lens of 0·12 D.

The maximum permissible error in the marking of the cylindrical axis of a lens is 2°; on a 3·8 cm. (1½ in.) lens this is equivalent to a displacement of each of the marks by 0·6 mm.

A. B. D.

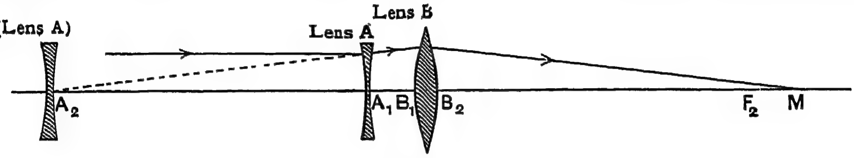

FIG. 8.

[1] Report of Optical Standards Committee on Standardisation of Trial Cases, 1908.

[2] An increase of 1 mm. in the thickness of a lens produces a change of power of −0·06 D in a lens of power 20 D, and −0·02 D in a lens of 10 D.

LENSES, THEORY OF SIMPLE

§ (1) GAUSS THEORY OF LENSES.—The simple theory of lenses developed below is due to Gauss. It is assumed that the rays of light considered are nowhere inclined at more than a small angle to the axis of the lens; that to any point in the object space there corresponds a point-image in the image space, and that the image of a small line in the object space intersecting the axis at right angles is itself a small line at right angles to the axis in the image space.

We assume further, in obtaining the formulae, that light is travelling from left to right and that lines drawn in this direction are positive; the radius of any spherical surface on which the light falls is thus positive when the surface is convex to the light.

§ (2) LENS FORMULAE.—Consider a ray PQ (*Fig.* 1) converging to a point Q on the axis AO

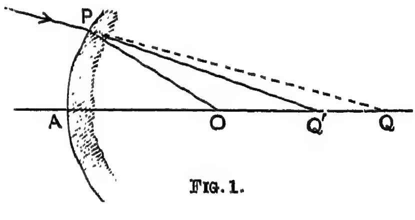

FIG. 1.

of spherical surface AP; it is refracted at the surface and the refracted ray cuts the axis at Q′, and if $AQ=u$, $AQ'=v'$, $AO=r$, and the refractive index be μ, we have

$$\frac{\mu}{v'}-\frac{1}{u}=\frac{\mu-1}{r}.$$

For $$\mu=\frac{\sin OPQ}{\sin OPQ'}=\frac{\sin OPQ}{\sin POQ}\cdot\frac{\sin POQ'}{\sin OPQ'}$$

$$=\frac{OQ}{PQ}\times\frac{PQ'}{OQ'}=\frac{OQ}{AQ}\times\frac{AQ'}{OQ'},$$

when P is very near to A.

Hence $\mu u(v'-r)=v'(u-r)$

and $$\frac{\mu}{v'}-\frac{1}{u}=\frac{\mu-1}{r}. \quad . \quad . \quad . \quad (1)$$

Consider now the case of light traversing a biconvex lens ACB′ (*Fig.* 2); the ray PQ′ strikes

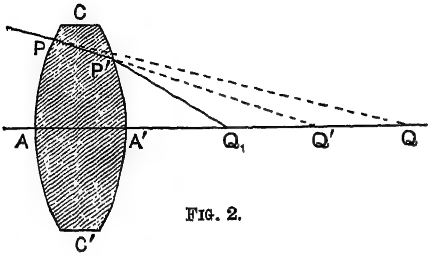

FIG. 2.

the concave surface at P′ and is again refracted, cutting the axis at Q_1. Let $A'Q_1=v_1$, the radius of the second surface be s and the thickness AA′ be t. We assume the medium on both sides of the lens to be the same.[1] Since the surface is concave to the light s is negative. Also $A'Q'=v'-t$, and we have, the refractive index from glass to air being $1/\mu$,

$$\frac{1/\mu}{v}-\frac{1}{v'-t}=-\frac{(1/\mu)-1}{s}=\frac{\mu-1}{\mu s},$$

or $$\frac{1}{v}-\frac{\mu}{v'-t}=\frac{\mu-1}{s}. \quad . \quad . \quad (2)$$

On substituting in (2) the value of v' derived from (1) and reducing we arrive at an equation which may be written either as

$$v=\frac{\gamma u+\delta}{\alpha u+\beta}, \quad . \quad . \quad . \quad (3)$$

or $$u=\frac{\delta-\beta v}{\alpha v-\gamma}, \quad . \quad . \quad . \quad (4)$$

where

$$\left.\begin{aligned}\alpha&=(\mu-1)\left(\frac{1}{r}+\frac{1}{s}\right)-\frac{(\mu-1)^2}{rs}\frac{t}{\mu}\\&=(\mu-1)\left(\frac{1}{r}+\frac{1}{s}\right)\left\{1-\frac{\mu-1}{r+s}\frac{t}{\mu}\right\},\\\beta&=1-\frac{\mu-1}{s}\frac{t}{\mu},\\\gamma&=1-\frac{\mu-1}{r}\frac{t}{\mu},\\\delta&=-\frac{t}{\mu}.\end{aligned}\right\} \quad . \quad (5)$$

By substituting the values of α, β, γ, δ, found above, we can also prove that

$$\alpha\delta-\beta\gamma=-1. \quad . \quad . \quad . \quad (6)$$

§ (3) PRINCIPAL FOCI.—If in the above formulae we make $u=\infty$ so that the incident pencil consists of parallel rays, we find

$$v=\frac{\gamma}{\alpha}=A'F' \text{ (say).}$$

F′ (*Fig.* 5) is then the point known as the second principal focus.

While if we make $v=\infty$ so that the emergent pencil is parallel, then

$$u=-\frac{\beta}{\alpha}=AF \text{ (say),}$$

and F is the first principal focus.

If Q and Q′ are any pair of conjugate points, then

$$\begin{aligned}FQ.F'Q'&=(AQ-AF)(A'Q'-A'F')\\&=\left(u+\frac{\beta}{\alpha}\right)\left(v-\frac{\gamma}{\alpha}\right),\end{aligned}$$

and this, on substituting for u and v, leads to

$$FQ.F'Q'=\frac{\alpha\delta-\beta\gamma}{\alpha^2}=-\frac{1}{\alpha^2}. \quad . \quad . \quad (7)$$

§ (4) MAGNIFICATION CAUSED BY REFRACTION.—We can find an expression for the magnification caused by refraction thus. Consider the rays converging to a small object QM (*Fig.* 3) at right angles to the axis of a single refracting surface AP with its centre at

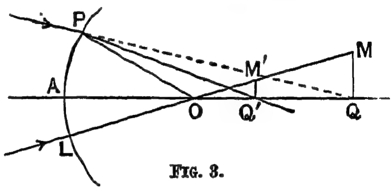

FIG. 3.

O. An image M′Q′ is formed at Q′ and with the previous notation

$$\frac{\mu}{v'}-\frac{1}{\mu}=\frac{\mu-1}{r}.$$

An incident ray such as LOM, which passes through the centre O and also through a point M of the object, passes on without deviation. Thus M′, the image of M, lies on this ray; it will therefore be the point where a line Q′M′ drawn through Q′ at right angles to the axis cuts LOM. Thus Q′M′ is the image of QM, and the magnification m_1 due to the one refraction is measured by the ratio of Q′M′ to QM. Hence

$$m_1=\frac{Q'M'}{QM}=\frac{v'-r}{u-r}.$$

But we have already seen, § (2), that $\mu u(v'-r)=v'(u-r)$. Thus

$$m_1=\frac{1}{\mu}\frac{v'}{u}. \quad . \quad . \quad . \quad (8)$$

Proceeding now to the case of the lens (*Fig.* 4), the image Q′M′ formed by the first refraction is again magnified[2] at the second

[1] For the more complicated case of a series of lenses see "Optical Calculations."

[2] In the figure as drawn the image is diminished, not magnified; the magnification is less than unity.

surface, and clearly we have similarly for this magnification m_2 the value $m_2=\mu v/(v'-t)$.

The resultant magnification m is the product of the two quantities m_1 and m_2. For

$$m=\frac{Q_1M_1}{QM}=\frac{Q'M'}{QM}\times\frac{Q_1M_1}{Q'M'}=m_1\times m_2.$$

Thus $$m=\frac{v'}{u}\times\frac{v}{v'-t}=\frac{v}{u}\cdot\frac{v'}{v'-t}.$$

On substituting in this the value of v' found

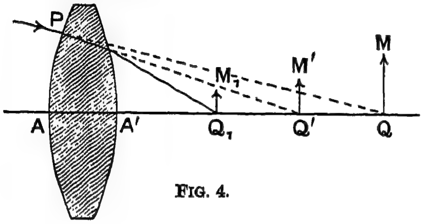

FIG. 4.

from equation (1) and using (3) and (4), we obtain

$$m=\frac{1}{\beta+\alpha u}=\gamma-\alpha v. \quad . \quad . \quad (9)$$

§ (5) PRINCIPAL POINTS OR POINTS OF UNIT MAGNIFICATION.—If, in the expressions for the magnification, we put m equal to unity so that the magnification is unity, the image and object are of the same size, and we find

$$\beta+\alpha u=1,$$

or $$u=\frac{1-\beta}{\alpha}, \quad . \quad . \quad . \quad (10)$$

and $$\gamma-\alpha v=1,$$

or $$v=\frac{\gamma-1}{\alpha}. \quad . \quad . \quad . \quad (11)$$

The two points thus defined are points of unit magnification; they are conjugate points

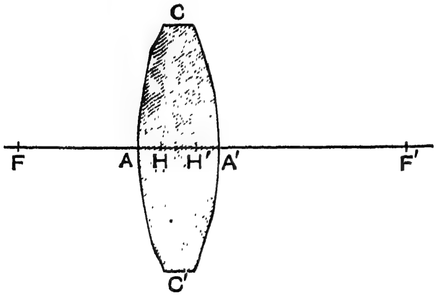

FIG. 5.

on the axis; we denote them by H and H′ respectively (*Fig.* 5). They are known as the unit or principal points of the lens, and an image of a small object at right angles to the axis at one principal point will be formed at the other, and will be equal in size to the object.

The first principal focus is, we have seen, given by the equation

$$AF=-\frac{\beta}{\alpha},$$

and the first principal point H by

$$AH=\frac{1-\beta}{\alpha}.$$

Thus $$HF=AF-AH=-\frac{1}{\alpha}, \quad . \quad . \quad (12)$$

which gives the distance between the first principal focus and the first unit or principal point.

Again, $$A'F'=\frac{\gamma}{\alpha},$$

and $$A'H'=\frac{\gamma-1}{\alpha}.$$

Thus $$H'F'=A'F'-A'H'=\frac{1}{\alpha}, \quad . \quad . \quad (13)$$

or the distances between the principal foci and the corresponding principal points are the same.

§ (6) LENS FORMULA WHEN THE DISTANCES ARE MEASURED FROM THE PRINCIPAL POINTS.—Let u_1 v_1 be the distances of the object and its image from the first and second principal points respectively, then

$$u=u_1+\frac{1-\beta}{\alpha},$$

$$v=v_1+\frac{\gamma-1}{\alpha}.$$

On substituting these values in the equation

$$v=\frac{\gamma u+\delta}{\alpha u+\beta},$$

we obtain

$$\frac{1}{v_1}-\frac{1}{u_1}=\alpha. \quad . \quad . \quad . \quad (14)$$

If we put $v=\infty$ so that the emergent pencil is parallel, we have

$$u_1=-\frac{1}{\alpha};$$

while if $u=\infty$ so that the incident pencil is parallel, we obtain

$$v_1=\frac{1}{\alpha}.$$

Thus as before

$$HF=-\frac{1}{\alpha}$$

and $$H'F'=\frac{1}{\alpha}.$$

The distance H′F′ or $1/\alpha$ measures the focal length of the lens.

§ (7) Nodal Points.—We can obtain expressions for the magnification in terms of the distances u_1 and v_1 from the principal points thus,

$$m=\frac{1}{\beta+\alpha u}=\frac{1}{\beta+\alpha u_1+(1-\beta)}$$

$$=\frac{1}{1+\alpha u_1}, \quad . \quad . \quad . \quad (15)$$

Or in terms of v_1

$$m=\gamma-\alpha\left(v_1+\frac{\gamma-1}{\alpha}\right)=1-\alpha v_1. \quad . \quad (16)$$

But $$\alpha=\frac{1}{v_1}-\frac{1}{u_1}.$$

Thus $$1-\alpha v_1=-\frac{v_1}{u_1}.$$

Hence $$m=-\frac{v_1}{u_1}.$$

Thus in *Fig.* 6

$$\frac{M'Q'}{MQ}=m=\frac{H'Q'}{HQ},$$

and the triangles MHQ and M'H'Q' are similar, so that MH is parallel to H'M' or a ray incident through the first principal

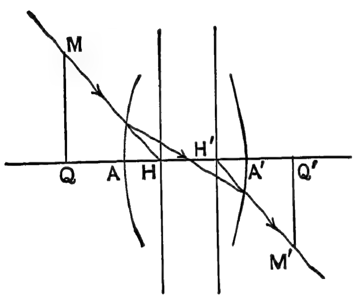

Fig. 6.

point emerges, parallel to its original direction, through the second. We have thus another property of the unit or principal points which are in consequence known as nodal points.

The coincidence of the principal and nodal points is a consequence of the assumption that the first and third media are the same. In general, points having the property of nodal points can be found, but they do not coincide with the principal points.

§ (8) Applications to Biconvex Lenses.—The values of the constants α, β, γ, δ in terms of the form and refractive index of the lens are given in equations (5).

Making use of these equations we obtain the following results for the positions of the principal foci and unit points neglecting powers of t above the first. We have

$$AF=-\frac{\beta}{\alpha}=-\frac{rs}{(\mu-1)(r+s)}\left\{1-\frac{\mu-1}{\mu}\cdot\frac{t}{r+s}\cdot\frac{r}{s}\right\}, \quad (17)$$

$$A'F'=\frac{\gamma}{\alpha}=\frac{rs}{(\mu-1)(r+s)}\left\{1-\frac{\mu-1}{\mu}\cdot\frac{t}{r+s}\cdot\frac{s}{r}\right\}, \quad (18)$$

$$AH=\frac{1-\beta}{\alpha}=\frac{r}{r+s}\cdot\frac{t}{\mu}, \quad . \quad . \quad (19)$$

$$A'H'=\frac{\gamma-1}{\alpha}=-\frac{s}{r+s}\,\frac{t}{\mu}, \quad . \quad . \quad (20)$$

while for the focal length $H'F'=f$, we have

$$f=H'F'=\frac{1}{\alpha}$$

$$=\frac{1}{\mu-1}\cdot\frac{rs}{r+s}\left\{1+\frac{\mu-1}{\mu}\cdot\frac{t}{r+s}\right\}. \quad (21)$$

If we put $t=0$ in these expressions we recover the ordinary formulae for a thin lens.

We may write the expression for the focal length as

$$f=\frac{1}{\mu-1}\cdot\frac{rs}{r+s}+\frac{rs}{(r+s)^2}\,\frac{t}{\mu}$$

$$=f_1+\frac{rs}{(r+s)^2}\,\frac{t}{\mu}, \quad . \quad . \quad . \quad . \quad (22)$$

where f_1 is the focal length of the lens treated as thin. In the case of an equiconvex lens of glass for which $r=s$, $\mu=3/2$ the value of the correcting term is $t/6$, while in the same case the principal points are within the lens and at a distance of $t/3$ from the vertices. If one surface, say the second, be flat, then s is infinite, the correction to the focal length is zero. The value of AH is also zero, so the first focal point is on the curved surface of the lens, while for A'H' we have the value $-t/\mu$ or, taking as before $\mu=3/2$, $A'H'=-2t/3$, the secondary principal point is within the lens at a distance of 2/3 of the thickness from the flat side.

§ (9) Biconcave Lenses.—The above formulae have been developed for the case of a biconvex lens in air. Any other lens can be treated similarly, having due regard to the signs of r and s.

Thus for a biconcave lens r is negative and s positive; we have therefore to change the signs of both r and s in the above formulae, and find

$$AF=\frac{rs}{(\mu-1)(r+s)}\left\{1+\frac{\mu-1}{\mu}\cdot\frac{t}{r+s}\cdot\frac{r}{s}\right\}, \quad (23)$$

$$A'F'=-\frac{rs}{(\mu-1)(r+s)}\left\{1+\frac{\mu-1}{\mu}\cdot\frac{t}{r+s}\cdot\frac{s}{r}\right\}, \quad (24)$$

$$AH=\frac{r}{r+s}\,\frac{t}{\mu}, \quad . \quad . \quad . \quad . \quad (25)$$

$$A'H'=-\frac{s}{r+s}\,\frac{t}{\mu}, \quad . \quad . \quad . \quad (26)$$

$$f=-\frac{1}{\mu-1}\,\frac{rs}{r+s}\left\{1-\frac{\mu-1}{\mu}\,\frac{t}{r+s}\right\}. \quad (27)$$

§ (10) General Cases.—Cases in which more than one lens occurs are dealt with by algebraical methods in the article on "Optical Calculations," to which the reader is referred. The practical application of the formulae to find the focal length and other properties of lenses is treated of in the articles "Lenses, Testing of Simple," and "Objectives, Testing of Compound," to which reference should be made. Microscope lenses are dealt with in the article "Microscope, Optics of the."

§ (11) Aberrations.—No lens behaves even for rays which diverge from a point on its axis in exactly the manner described, and when the object point is not on the axis the divergences from the above theory are more marked still.

The position[1] of the image point corresponding to a given object point can be expressed in terms of the distance of the object from the lens, of a series of ascending powers of the angle between the axis of the lens and the central ray of the pencil which forms the image, and of the curvatures, thickness, and refractive index of the lens. In the above discussion terms involving the third and higher powers of the angle of incidence have been neglected, symmetry ensures that no terms involving even powers of the angle occur. If, however, the higher powers be included the theory developed needs considerable corrections.[2] These faults in the geometrical theory of strict linear correspondence between the object and image space are known as aberrations.

If we limit ourselves to third powers of the obliquity of the central ray, the aberrations, as von Seidel[3] showed, are five in number, viz.:

(i.) *Spherical Aberration.*—Rays diverging from an object point on the axis, which reach the image from different zones of the lens, strike the axis at different points; the distance between the point of intersection of the paraxial ray and that of a ray from any given zone of the lens measures the spherical aberration of that zone.

(ii.) *Coma.*—The magnification produced by the different zones of the lens is not a constant; hence the rays diverging from a point not on the axis of the lens are not brought to coincidence at one point in the image space; the intersection points of the rays from any given zone are distributed in a circle. The position of the centre and the diameter of this circle depends on the obliquity of the central ray of the pencil falling on the zone in question; hence the intersections of the rays from the object point and a plane through the image point are distributed over a fan-shaped area whose position and dimensions depend on the obliquity. This defect is known as Coma.

[1] See "Optical Calculations"; also "Telescope," §§ (1)-(3).
[2] See "Telescope," § (3).
[3] See "Lens Systems, Aberrations of."

(iii.) *Astigmatism.*—The rays of an oblique pencil diverging from an object point do not meet in one point in the image space; they do, however, pass through two "focal lines," lying approximately at right angles to each other. Of these the "primary" focal line is a short arc of a circle in a plane perpendicular to the axis of the lens, while the "secondary" line is more exactly a small figure of eight at right angles to the circular arc. The lens is astigmatic, and the nearest approach to point coincidence is a small circle, the "focal circle," lying between the two focal lines, and this is in many cases treated as the image of the object point.

(iv.) *Curvature.*—The focal circles corresponding to a series of object points lying in a plane perpendicular to the axis do not lie in a plane, but form a curved surface, cutting the axis at right angles. The image field corresponding to a plane object field is curved.

(v.) *Distortion.*—This is produced when the image field is a point-for-point representation of the object field, but on a scale which varies with the obliquity of the central rays of the pencil considered. Thus a straight line in the object field at right angles to the axis will be represented by a line in the image field, but this line will no longer be straight.

The above constitute von Seidel's five aberrations.

§ (12) Chromatic Aberration.—The position of the image corresponding to a given object point depends on the refractive index of the material of the lens, and this varies with the wave-length of the light used.

The images therefore formed by light of different wave-lengths will vary in size, and if white light is employed the resulting image will show coloured fringes. This defect is known as chromatic aberration. The various defects are fully discussed in the separate articles already mentioned, to which reference should be made.

Tabulated results of R. Zsigmondy. See *ibid.* § (4).

LIGHT, DIFFRACTION OF

IT is known[1] that the effect at any point of a wave of light may be found by calculating the effect due to each element of the wave and taking the sum.

Now let the displacement[2] over a small area dS at a point Q (*Fig.* 1) of a wave front be given by the expression $A \sin (2\pi/\lambda)(vt)$

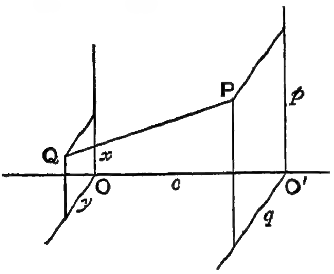

FIG. 1.

where t is the time, we proceed to find the displacement at a point P where QP is equal to r.

Since the intensity of the light, measured by its energy, diminishes as the square of the distance from the source and the energy of wave motion is proportional to the square of the amplitude, the amplitude will be inversely proportional to r. Moreover, since the disturbance at P has travelled from Q, a distance r, with speed v, the time occupied has been r/v. Thus the phase of the disturbance at P at time t will be the same as that at R, a time r/v previously. The amplitude is also clearly proportional to A, the amplitude at Q. Hence we have for the disturbance at P the expression

$$\frac{kA\,dS}{r} \sin \frac{2\pi}{\lambda}(vt - r),$$

k being a constant factor, and the whole effect at P is found by integrating this over the wave surface through Q. It will depend on the limits of this surface.

In this expression we have neglected the effect of the obliquity of QP to the directions of propagation and vibration at Q. We shall limit the discussion to the consideration of small areas about Q over which these angles do not vary much, and their effects may be considered constant and included in the factor k.

We assume that the front of the wave is parallel to the plane of the aperture. Take any point O in this plane as origin and two lines at right angles in the plane as axes of x and y respectively.

Consider a plane through P parallel to the wave front and let a line OO′ perpendicular to the wave meet this plane in O′, let OO′ be equal to c and let p, q be the distances of P from O′ measured parallel to the axes, then the co-ordinates of P are p, q, c, and we have

$$r^2 = PQ^2 = (p-x)^2 + (q-y)^2 + c^2.$$

Thus

$$r = c\left\{1 + \left(\frac{p-x}{c}\right)^2 + \left(\frac{q-y}{c}\right)^2\right\}^{\frac{1}{2}}$$

$$= c + \tfrac{1}{2}\frac{(p-x)^2 + (q-y)^2}{c} \text{ approximately.}$$

The result obtained by substituting this value of r in the expression for the disturbance for certain forms of the aperture can be evaluated in terms of integrals known as Fresnel's Integrals.[3]

We can, however, simplify the expressions by supposing the screen on which the effect is produced to be far from the aperture, so that p, q, and c are large compared with x and y.

In practice this is realised by placing a convex lens behind the aperture and observing the effect on a screen at the principal focus of the lens. We have as the value of r

$$r = c + \tfrac{1}{2}\frac{p^2 + q^2 - 2px - 2qy + x^2 + y^2}{c},$$

and on this assumption we can neglect $x^2 + y^2$ in comparison with the other quantities. Hence

$$r = c + \tfrac{1}{2}\frac{p^2 + q^2}{c} - \frac{2px}{c} - \frac{2qy}{c}$$

$$= f - \frac{2px}{c} - \frac{2qy}{c} \text{ say,}$$

where f is written for $c + \frac{1}{2}(p^2 + q^2)/c$. But p and q will in all cases be small compared with c, thus in the denominators we may replace c by f, and we have finally

$$r = f - \frac{2px}{f} - \frac{2qy}{f}.$$

Moreover, $dS = dxdy$, and the expression for the disturbance at P becomes

$$\frac{kA}{f}\iint dxdy \sin \frac{2\pi}{\lambda}\left\{vt - f + \frac{2px}{f} + \frac{2qy}{f}\right\}, \quad (1)$$

where f has been written for r in the denominator.

[1] See "Light, Propagation of," also "Light, Rectilinear Propagation of."

[2] Displacement is used as a general term, it may represent electric or magnetic force or may stand for an actual change of position of an electron, or of a particle of the ether.

[3] See Preston's *Light*, § 161.

(i.) *Rectangular Aperture.*—The expression given in (1) applies to an aperture of any form; thus for a rectangular aperture of sides $2a$, $2b$ parallel to the axes of x and y respectively the limits will be $-a$ to $+a$ and $-b$ to $+b$, and we have

Disturbance

$$=\frac{kA}{f}\int_{-a}^{+a}\int_{-b}^{+b}dxdy\sin\frac{2\pi}{\lambda}\left(vt-f+\frac{2px}{f}+\frac{2qy}{f}\right).$$

On integrating this we find for the intensity at P, represented by the square of the resultant amplitude, the expression

$$16a^2b^2\left\{\frac{f\lambda}{2\pi pa}\sin\frac{2\pi pa}{f\lambda}\right\}^2\left\{\frac{f\lambda}{2\pi qb}\sin\frac{2\pi qb}{f\lambda}\right\}^2,$$

or, as it may be written,

$$\bar{A}^2\times\left(\frac{\sin\theta}{\theta}\right)^2\left(\frac{\sin\phi}{\phi}\right)^2, \quad . \quad . \quad (2)$$

where $\bar{A}$ represents the area of the parallelogram and

$$\theta=\frac{2\pi pa}{f\lambda},\quad \phi=\frac{2\pi pb}{f\lambda}.$$

(ii.) *A Narrow Rectangular Slot.*—An important case occurs when one side of the aperture, say a, is very small in comparison with the other.

The angle θ is then always very small and the value of $\sin\theta/\theta$ is unity. The amplitude then varies as $\sin\phi/\phi$. This has a maximum when ϕ is zero, it is then equal to unity; it is a minimum—zero—for $\phi=\pi, 2\pi\ldots$ and a maximum for values between, which are given by the equation $\tan\phi=\phi$. These, it can be shown, are somewhat less than the odd multiples of $\pi/2$ excluding the first, but gradually approach them. The intensities of these maxima decrease somewhat rapidly. Thus the field consists of a bright band in the centre flanked on each side by a series of dark lines, equally spaced, with bright bands of rapidly decreasing brightness between; the distances between the maxima of the bright bands are unequal, but decrease as the distance from the central bright band increases.

(iii.) *Circular Aperture.*—Another case of importance when dealing with optical instruments occurs when the aperture is a circle. The diffraction pattern will be a series of circles having their centre at the point where a normal to the wave front through the centre of the aperture meets the screen and the distribution of the light will be the same along any radius of these circles. We can find it for the radius through the axis of x for which q is zero, p will then be the distance of the point from the centre of the diffracted rings. Thus we have

$$\text{Disturbance}=\frac{kA}{f}\int\int dxdy\sin\frac{2\pi}{\lambda}\left(vt-f-\frac{px}{f}\right), \quad (3)$$

the integrals being taken over a circle of radius a.

Let r, θ be the polar cos of $Q(x, y)$ relative to O.

Then $x=r\cos\theta$, $dxdy=rdrd\theta$; the limits for r are 0 to a, and for θ, 0 to 2π.

The disturbance

$$=\frac{kA}{f}\int_0^{2\pi}\int_0^a rdrd\theta\sin\frac{2\pi}{\lambda}\left(vt-f-\frac{pr\cos\theta}{f}\right)$$

$$=\frac{kA}{f}\sin\frac{2\pi}{\lambda}(vt-f)\int_0^a\int_0^{2\pi}rdrd\theta\cos\frac{2\pi}{\lambda}\left(\frac{pr\cos\theta}{f}\right),$$

for the term in the integral involving the quantity $\sin(2\pi/\lambda)(pr\cos\theta/f)$ clearly vanishes. The above expression can be integrated in a series,[1] and we find

Amplitude of disturbance

$$=\pi a^2\left\{1-\tfrac{1}{2}\left(\frac{m}{1!}\right)^2+\tfrac{1}{3}\left(\frac{m^2}{2!}\right)^2-\tfrac{1}{4}\left(\frac{m^3}{3!}\right)^2+\ldots\right\}, \quad (4)$$

where m is written for the value of

$$\frac{2\pi a}{\lambda}\cdot\frac{p}{f}.$$

The quantity p/f measures the sine of the angular radius of a ring as seen from the centre of the aperture, or since it is small we may take it as the angular radius. The series can be shown to be convergent. It has a first maximum when m is zero and passes through a series of maxima and minima as given in the following table taken from Verdel's *Optique Physique*:[2]

INTENSITY OF LIGHT DIFFRACTED BY A CIRCULAR APERTURE

Maxima.		Minima.	
m/π.	Intensity.	m/π.	Intensity.
0	1	0·610	0
0·819	0·01745	1·116	0
1·333	0·00415	1·619	0
1·847	0·00165	2·120	0
2·361	0·00078	2·621	0

If we call ϕ the angular deflection of the rings as seen from 0 we have approximately $m=(2\pi a/\lambda)\phi$; the diameter of the rings is 2ϕ, thus the diameters of the rings are given by the expression $(m/\pi)(\lambda/a)$, where m/π has the values given in the table; the width of the first dark ring is thus $0·610\ \lambda/a$. Hence the image of a point of light such as a star formed by the object glass of a telescope of aperture $2a$ is a disc having an angular breadth measured from the centre of the object glass of $0·610\lambda/a$. This disc is surrounded by a number

[1] See Preston's *Light*, § 163.
[2] See also *ibid.* § 163.

of rings of rapidly decreasing brightness with dark spaces between in which there is no light.

This assumes that the object glass is free from aberration, so that the wave from the distant point after passing the lens is accurately a sphere with the principal focus as centre.

LIGHT, DOUBLE REFRACTION OF

It is to Fresnel that we owe the earliest complete theory of double refraction applicable to both biaxial and uniaxial crystals, and though he based it on the hypothesis of the vibration of ether particles, the laws at which he arrived follow rigidly as a deduction from the electromagnetic theory.

If a particle in an isotropic elastic medium be displaced a short distance, the symmetry of the medium requires that the force called into play through the elasticity of the medium and which tends to bring the particle back to its equilibrium position should be in the direction of motion. The same is true if the displacement be electric or magnetic; the electric or magnetic force of restitution is proportional to the displacement and acts in that direction. It may be written as Kp, if p is the displacement and K a constant representing the electric—or magnetic—elasticity of the medium.

But in an anisotropic medium which has different properties in different directions this is no longer true; the force of restitution is not, in general, co-linear with the displacement.

In a crystal, however, there are three directions mutually at right angles along which the force of restitution is in the direction of displacement; these directions are known as the axes of the crystal. Now suppose that the forces produced by a displacement p along each of the axes respectively are a^2p, b^2p, and c^2p respectively. Consider a plane wave travelling through the crystal and construct an ellipsoid having its centre on the wave and its axes equal to $1/a$, $1/b$, and $1/c$ respectively. This ellipsoid was called by Fresnel the Ellipsoid of Elasticity. The wave front we are considering will cut the ellipsoid in an ellipse, and the direction of the two axes of this ellipse are found, both by theory and experiment, to be the only possible directions of vibration for light travelling in the direction in which the plane wave is being propagated.

In an isotropic medium the disturbance which constitutes the light can take place in any direction in the plane of the wave; in a crystal it is resolved into two in the direction OP, OQ of the two axes of this ellipse. Moreover, it can be shown that these two disturbances travel with different speeds; their velocities are given by 1/OP and 1/OQ respectively. The wave is thus split into two plane polarised waves, each travelling with the speed appropriate to its direction of vibration, and these velocities are, in each case, inversely proportional to the radius vector of Fresnel's ellipsoid drawn in the direction of vibration. Moreover, the possible directions of vibration for any plane wave are the axes of the section of Fresnel's ellipsoid by the wave. Thus a knowledge of Fresnel's ellipsoid enables us to calculate the velocity of wave propagation in all directions in the crystal. It is shown in treatises on electricity that, on the electromagnetic theory of light, the quantities a^2, b^2, c^2 are the three principal coefficients of inductive capacity of the medium, denoted usually by K_1, K_2, K_3. Again, it is known[1] how to determine the wave surface in any medium, crystalline or isotropic, when the velocity of wave propagation is known for all directions.

To describe the wave surface corresponding to an interval of time t we draw all possible wave fronts in the positions they would occupy at the instant t and describe the envelope of the series of planes thus obtained.

When this is done for a crystal in which the wave velocities are determined, as described above, a surface of somewhat complicated form is the result. The surface, known as Fresnel's wave surface, has two sheets, and its sections by the three principal planes of the crystal are in each case a circle and an ellipse. Assuming that a, b, c are in descending order

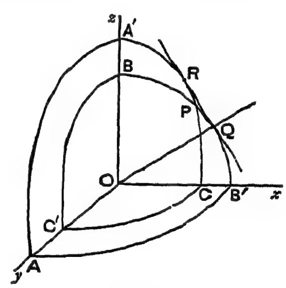

Fig. 1.

of magnitude, the sections will be as shown in *Fig.* 1.

In this figure Ox, Oy, Oz are the three crystallographic axes. Along them distances OA, OB, etc., are taken, such that

$$OA = OA' = a; \quad OB = OB' = b; \quad OC = OC' = c.$$

AA′, BB′, and CC′ are joined by circles of radii a, b, c respectively, while ellipses of semiaxes b and c, c and a, and a and b respectively join BC′, CA′, and AB′.

The circle BB′ cuts the ellipse CA′ in P,

[1] See article "Light, Propagation of."

and RQ is a common tangent to both circle and ellipse.

If we imagine the curve A′A to be turned about Oz so that A always lies on the ellipse AB′, the shape of the curve altering according to the law given by Fresnel until, ultimately, it coincides with A′PB′, it will trace out one octant of the outer sheet of Fresnel's wave surface.

Similarly, if BC′ rotates about the same axis, C′ remaining on the circle C′C, while the shape alters as required by Fresnel's laws until the curve coincides with BPC, it traces out the inner sheet of the wave surface.

Careful experiment [1] has verified to a high degree of accuracy the fact that this surface does represent the form of the wave in a biaxial crystal.

The quantities a, b, c measure respectively the velocities of waves in which the vibrations are parallel to the three axes respectively; thus the refractive indices corresponding to these waves are $1/a$, $1/b$, and $1/c$. If the mean refractive index $1/b$ differs less from the minimum $1/a$ than the maximum $1/c$ differs from the mean, *i.e.* if $1/b - 1/a$ is less than $1/c - 1/b$, the crystal is said to be positive; if, on the other hand, $1/b - 1/a$ is greater than $1/c - 1/b$, the crystal is negative.

According to the construction already explained, in order to find the position of the wave front which, after a time t, corresponds to a given wave front XY, we describe the wave surface for time t, taking any point in XY as centre, and draw a tangent plane parallel to XY.

It is clear from the shape of the surface that two such planes can, in general, be drawn, one touching each sheet; thus a given wave travelling through the crystal will break up into two; each of these will, as has already been pointed out, be polarised. The lines joining the centre of the surface to the points of contact of these two tangent planes are the rays corresponding to the two wave fronts.

But it is clear also, from the figure, that in the plane perpendicular to the mean axis in which the circle of radius b intersects the ellipse semiaxes a and b in the point P, there is a common tangent RQ to the ellipse and circle, and a plane through RQ at right angles to the plane xOz touches both the ellipse and circle. In the direction of the normal to this plane there will be only a single wave. The line OQ, which is at right angles to this wave, is known as an optic axis of the crystal. There will be a similar axis lying also in the plane zOx, but on the opposite side of Oz. Thus the crystal has two optic axes; light waves travelling along these are not doubly refracted. We can put this from another point of view, thus: The wave velocities are determined by the two axes of the elliptic section in which Fresnel's ellipsoid is cut by the plane of the wave. But an ellipsoid has two sections which are circular. If then the wave coincides with either of these, the two velocities of propagation become equal, each being equal to b, for this quantity can be proved to be the reciprocal of the radius of the circular section. Thus the two waves which, in general, are found, in this case coalesce and travel through the crystal with velocity b. The normals to these two sections are the two optic axes.

The optic axes lie in the plane containing the axes of greatest and least velocity. These axes bisect the angles between the optic axes, and are known as the acute bisectrix and the obtuse bisectrix of the angle between the optic axes.

A special significance attaches to the line OP joining O to P, the point of intersection of the circular and elliptic section of the wave surface. It is clear from the figure that two tangents can be drawn to the surface, touching it at the same point P; one of these touches the circle, the other the ellipse. The full investigation shows that, in reality, the surface has a tangent cone at P, and any plane touching this cone is also tangent to the surface. Now the ray corresponding to any wave plane is the line joining the centre to the point in which the plane touches the surface. All the planes, then, which touch the surface at P have the same ray and the same ray velocity. Thus the line OP is known as the axis of single ray velocity.

We arrive at the case of a uniaxial crystal by supposing two of the principal velocities to become equal; suppose, for example, that $a = b$; then Fresnel's ellipsoid becomes a spheroid, with axes $1/a$ and $1/c$, generated by the revolution of an ellipse about the axis Oz. The optic axes close up to this line. The section of this spheroid by any plane through its centre, other than the plane of xOy, is an ellipse, but one axis of each of these ellipses is equal to $1/a$; thus one wave of the two into which an incident wave is divided travels with constant velocity a and is refracted according to the ordinary law; the other suffers extraordinary refraction.

The wave surface becomes a sphere and a spheroid, the points A′B′ of *Fig.* 1 coincide, while the ellipse AB becomes a circle of radius a. The points Q, P, and R all coincide with A′ and B′. Thus Huyghens' construction, described earlier, follows as a deduction from Fresnel's more general theory. This also has been verified by experiment.[2]

LIGHT FILTERS

§ (1) INTRODUCTION.—Light filters are used in many branches of physical work to modify the intensity or colour of the light passing through them. Either liquid filters in the form of solutions, or solid filters consisting of coloured glasses or stained films are commonly employed, though in some special cases gases have been used as filters.[1]

Liquid filters consist of solutions of coloured salts or dyes held in glass troughs with parallel sides, while coloured glasses and stained films of gelatine or collodion are used in a great variety of forms. The use of solutions has the advantage that they are very readily prepared and that, if they consist of inorganic salts, they are easily definable, so that standard filters can be prepared from a published description. To a lesser extent the same is true of dye solutions, but since dyes vary considerably in their purity, it is more difficult to state formulae for liquid dye filters in a form which can easily be duplicated, and solutions of dyes are often unstable, the dyes changing or precipitating. Such liquid filters are therefore often the cause of unsuspected errors.

If coloured glasses could be obtained in a great variety of absorptions, and could be reproduced exactly, they would undoubtedly be the most convenient for filters of all kinds. They are usually very stable to light, extremely convenient in use, not easily being damaged, and are cheap to produce, since it is only necessary to grind the two surfaces of the optical glass to optical planeness and to make the filter of a definite thickness. Unfortunately, it seems to be very difficult for glass makers to reproduce the colour of different meltings with any approach to exactness, and the number of coloured glasses available is quite limited, so that it is not possible to obtain in glass filters an approach to the range of colour which is available by the use of dyes.

The earlier stained filters were made by the use of collodion in which basic dyes were incorporated, but the difficulty of coating collodion accurately upon glass, as also the unsatisfactory nature of most of the basic dyes, has led to the almost complete replacement of collodion by gelatine as a vehicle for the acid dyes which are now used for the preparation of light filters. Modern gelatine light filters are therefore prepared by coating gelatine containing the necessary dyes upon plate glass, the coating being done by means of one of the coating machines commonly used for the preparation of photographic plates. The gelatine film, after drying, is stripped off the glass and can be used as a gelatine film filter or can be cemented between optical glasses of any required quality by means of Canada balsam.

On a small scale, filters are generally made by coating the glass to be cemented with the dyed gelatine and then cementing a cover-glass directly on to the dry gelatine film. This method is not advantageous on the large scale, since the coating of the large glasses is tedious and expensive; the coating is likely to vary in thickness from the centre to the edge owing to surface tension, and there is always danger that the drying gelatine in contracting will bend the glass, thus interfering with its optical properties. This latter difficulty can be mitigated to some extent by the addition of glycerine to the gelatine solution when coating the glass.

The colour of a filter is of course conditioned by its selective spectral absorption; thus a red filter absorbs the blue and green regions of the spectrum, a blue filter the red, yellow the blue, and a green both the red and the blue regions. This selective absorption is best expressed by means of the absorption curve of the filter, which can be measured by means of a spectrophotometer. The filter is placed in front of the instrument, and the light passing through the filter and also passing into the instrument without going through the filter is analysed in the spectroscope. A narrow region of the spectrum is isolated, and the absorption of the filter for each region of the spectrum in turn is measured photometrically. Then, if I be the intensity of the light passing through the filter, and I_0 that which has not undergone absorption, the transparency of the filter will be I/I_0, and this is usually expressed as a percentage if the transmission is required. From Lambert's law, however, $I=I_0e^{-kd}$.[2] This is more conveniently written using 10 as the logarithmic base, and for a light filter in which the thickness is constant it becomes

$$I=I_0 10^{-E},$$

where E is the absorption constant of the filter, and consequently

$$E=-\log\frac{I}{I_0}.$$

As a result of the Fechner law, absorption curves of filters expressed by plotting E against λ correspond more accurately to the appearance of the transmission as seen by the eye than those obtained by plotting the transparency, and these curves are used throughout the literature dealing with light filters.

[1] Thus bromine gas has been used as a filter for the ultra-violet by R. W. Wood and Plotnikoff.

[2] It seems to be customary to refer to this as "Lambert's law," but the originator of it was Bouguer (see his *Essai d'optique*, 1729), and the law of the absorption of light should certainly be called "Bouguer's law."

Following Potapenko,[1] light filters are classified preferably according to their absorption spectrum and not according to the purpose for which they are to be used, since if this latter course is taken the same filter will be classified in many different ways; thus the red filter suitable for three-colour photography is also used as a contrast filter in commercial photography, as a photomicrographic filter, and in spectroscopy, while there are undoubtedly many other uses to which it can be put. Classifying filters, therefore, according to their spectral absorption, we may divide them into:

(i.) Selective filters, which transmit only a selected region of the spectrum, more or less narrow.

(ii.) Compensating filters, which have a more gradual absorption, and which transmit in

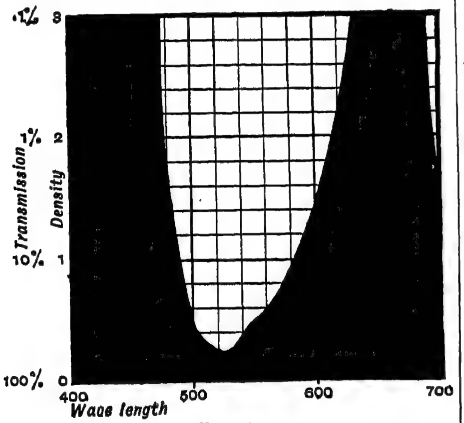

FIG. 1.

greater or less intensity practically the whole spectrum.

(iii.) Subtractive filters, which remove only a small portion of the spectrum, transmitting the remainder, so that for every selective filter we can theoretically have a corresponding subtractive filter.

The selective and subtractive filters will therefore have a comparatively sharp absorption curve, while compensating filters will generally be gradual in their absorption. Monochromatic filters (which is the title used by Potapenko for the filters here called selective) are those which transmit only a narrow region of the spectrum, so narrow that the term *monochromatic* is not entirely inappropriate, though it must be understood that no filter can be strictly monochromatic in the true sense of the word unless used with a linear emission spectrum. An example of a selective filter is shown in *Fig.* 1, which is the absorption spectrum of a typical green filter used in three-colour photography. *Fig.* 2 shows a narrow banded monochromatic filter;

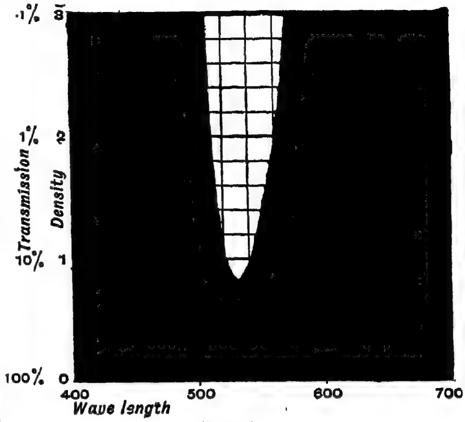

FIG. 2.

Fig. 3 a compensating filter used for compensating the spectrum of a vacuum tungsten lamp to balance daylight; and *Fig.* 4 is the subtractive filter which is complementary to the green filter shown in *Fig.* 1.

§ (2) APPLICATION OF LIGHT FILTERS — PHOTOGRAPHY.—Filters used in photography may be classified according to their use under the heads of:

(i.) *Orthochromatic filters*, used to correct the selective sensitiveness of photographic materials

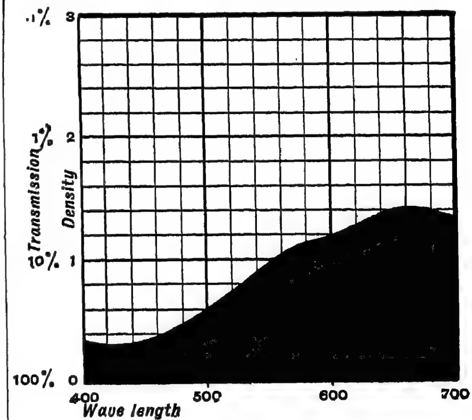

FIG. 3.

in order to give a reproduction of the brightness of coloured objects more closely approximating that perceived by the eye.

(ii.) *Contrast filters*, used selectively to modify the brightness of some special colour or group of colours.

[1] G. V. Potapenko, *Journal Russian Physical and Chemical Society*, 1916, xlviii. 790; English translation, *British Journal of Photography*, 1921, lxviii. 507. This is by far the fullest and best article published on light filters.

(iii.) *Selective filters*, for two- or three-colour photography, with their corresponding synthetic projection filters if the processes of colour photography used are of the additive type.

(iv.) *Compensating filters*, used to adjust the light entering a photographic system in order

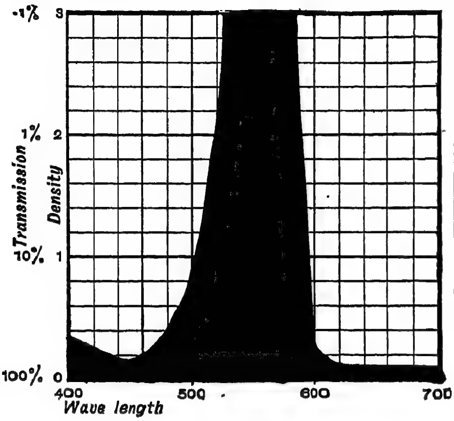

FIG. 4.

to fulfil some particular condition required in colour photography.

(i.) *Orthochromatic Filters.*—Since photographic plates are more strongly sensitive to blue light than to any other spectral region, and since the maximum of the visual sensitiveness is in the yellow-green, and the blue and blue-violet are comparatively dark colours to the eye, orthochromatic filters are yellow in colour and absorb the ultra-violet, violet, and to a lesser extent the blue. The orthochromatic filters used in photography often do not perform their task completely, since the removal of the light of short wave-lengths naturally increases the exposure, and it is often impossible to give sufficient exposure to use the filter required for complete correction. It is very common, therefore, in photography to compromise by using a filter which removes most of the violet and ultra-violet but does not fully correct the uneven sensitiveness of the plate.

The earlier orthochromatic filters used by photographers were made of glass which was coloured by carbon in the pot, and which was brown rather than yellow, transmitting a large amount of ultra-violet light; and even when dye filters were used, dyes which transmitted a large amount of ultra-violet light were often employed through lack of sufficiently rigorous spectroscopic examination.

The number of dyes suitable for the preparation of orthochromatic filters is very limited. Of those giving a sharp absorption in the violet, with a complete absorption of the ultra-violet, picric acid and the picrates are the most satisfactory, but unfortunately they are very unstable and can scarcely be used in practice. Until 1906 the best dye available was Tartrazine, but this has a very considerable transmission in the ultra-violet and was replaced for filter-making in that year by a dye manufactured by the Hoechst Dye Works under the name of "Filter Yellow." During the war, a dye having almost as great stability as Filter Yellow with a considerably sharper absorption was prepared from phenyl glucosazone and was used for light filters, especially for aerial photography, under the title of "Eastman Yellow" (*Fig.* 5).

In order to enable landscapes to be taken in which the clouds are well rendered without unduly increasing the exposure, graded filters have been employed, these being placed in front of the lens in such a way that the strongly absorbing region of the filter corresponds to the sky and the weaker absorption to the foreground. Filters are sometimes made having the upper half coloured and the lower part clear, which seem to be as satisfactory in practice as the graded filters, provided they are not used too far from the lens. A complete

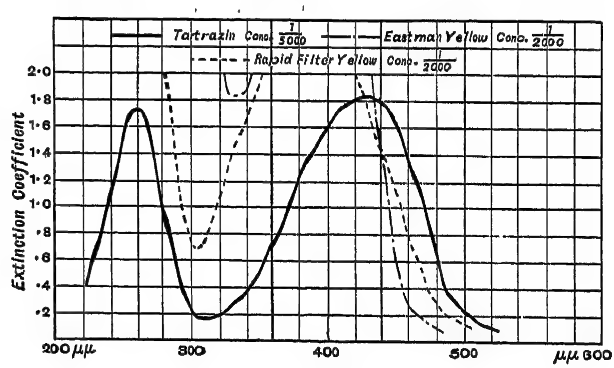

FIG. 5.

discussion of the use of graded filters will be found in a paper by J. Weissmann.[1]

(ii.) *Contrast Filters.*—The preparation of contrast filters is in many ways easier than that of orthochromatic filters, since many dyes are available for the preparation of red or green filters. The greatest difficulty arises when it is necessary to remove the extreme red from a green or blue filter. Only one blue

[1] *Photographische Rundschau*, 1913, p. 182.

dye and three green dyes are known which have not a sharp transmission band at the red end of the visible spectrum. These are Toluidine Blue, which has no transmission band in the red of shorter wave-length than 750 $\mu\mu$; Anthraquinone Green, which is the green dye corresponding to Toluidine Blue; Filter Blue-Green, of which the composition is unknown, but which extends in absorption to at least 800 $\mu\mu$ and at the same time has greater transmission in the green than Anthraquinone Green; and Naphthol Green, which absorbs at least as strongly as Filter Blue-Green, but which unfortunately has a great deal of general absorption, especially in the blue-green and blue regions of the spectrum, so that it is impossible to use it in blue filters, and it greatly lessens the transmission of green filters. Since the first three of these dyes have only been introduced in the last twelve years, the older blue and green light filters all show a very considerable transmission of red light. Attempts have been made to diminish this by the use of Methylene Blue, but unfortunately this dye is unstable and is rapidly destroyed by heat, so that it is not at all suitable for use in light filters.

A set of contrast filters which will satisfy almost all photographic requirements will include a strong yellow filter cutting at about 500 $\mu\mu$; an orange filter cutting at 570 $\mu\mu$; a red cutting at 590 $\mu\mu$; and a deep red cutting at 610 $\mu\mu$, in addition to the orthochromatic filters and to green and blue filters which can conveniently be those used also for tricolour photography.

(iii.) *Selective filters* used in colour photography will include for ordinary work a set of red, green, and blue filters so adjusted that they just overlap and that they give approximately even exposures when used with daylight upon the most highly sensitive panchromatic plates available. For colour cinematography a somewhat lighter set of filters may be used, though it is not possible to lighten the red filter very much, a filter cutting at 575 $\mu\mu$ being the lightest filter that can be used to give at all satisfactory rendering.

For two-colour photography as deep a red filter is required as for three-colour work. The exact shade of the two-colour green filter has been a matter of some discussion and a good deal of experiment. Most workers use the tricolour green, though a somewhat bluer green has often been advocated. The disadvantage of too blue a green is that foliage and grass tend to be reproduced as brown, and for taking filters for two-colour work the tricolour red and green filters would seem on the whole to be the most suitable.

In the additive projection processes the filters must be adjusted to the light source used so that the screen is white. For most work the same red and green filters that are used for taking will be satisfactory for tricolour projection, a lighter blue being used according to the colour of the illuminant employed. For two-colour projection filters a much bluer green than that used for taking is naturally required, and the filter should be rather a blue-green than a green.

(iv.) *Compensating filters* are of special importance in connection with the screen plate processes of colour photography. In these processes the three-colour unit filters of the screen must be adjusted in area and colour so that the screen itself is neutral when looked at by a white light, while the emulsion sensitiveness, the colour of the screen units, and the compensating filter must be so adjusted that greys are reproduced as greys in the finished picture. Normally, the emulsion has predominating blue sensitiveness, and the compensating filter must therefore be yellow, though not infrequently a brownish or pinkish filter is required. Such compensating filters are usually adjusted by trial and error.

§ (3) PHOTOMETRY.—When comparing light sources of different colours upon the photometer the colour difference introduces difficulty in making an accurate balance. This difficulty can be much lessened by the use of a colour filter adjusted to equalise the colour in the two fields of the photometer, the transmission of the filter being first determined by a set of observations. Such photometric filters will be of two types: yellowish filters for reducing high efficiency lamps to the colour corresponding to lower efficiencies, and bluish filters for the inverse process. The absorptions of such filters must naturally be gradual, and they should not display any very marked spectral bands or rapid changes in their spectral curve.

§ (4) MICROSCOPY.—For photomicrography filters are employed especially in the photography of stained sections or other objects displaying strong colour. Thus, if any colour is to be rendered as dark as possible, it must be viewed or photographed by light which is absorbed by the colour, that is, by light of the wave-lengths contained within its absorption band. On the other hand, when a subject is of a uniform colour, in order to render detail it must be examined by the light which it transmits; thus, if the usual insect preparations, which are strongly yellow, are photographed by blue light as on an ordinary plate, a black detailless mass is shown in contrast to the background, while the use of a strong yellow or red filter will enable the whole of the detail of the structure to be photographed. Filters for microscopy are arranged so that they can be used in pairs, the spectrum being thus divided into monochromatic portions. By the examination of any specimen through

these filters singly and in pairs the best choice of the filters for use can be made. Light filters are also valuable for visual use with the microscope. Thus, blue and green filters are convenient for modification of the intensity of the light and for the restriction of the spectral region used in visual work. A deep blue filter is especially useful where the highest resolving power visually possible is required, as in the visual examination of diatom structures. Yellow, orange, and red contrast filters are convenient in the observation of detail in insect mounts or as contrast filters for stained preparations.

§ (5) Spectroscopy, Photo-chemistry, etc.—Light filters are often used in spectroscopy for the elimination of portions of the spectrum, such as the absorption of other orders when using a grating spectroscope. They are also of particular service in spectro-photometry for the elimination of scattered light. When using an absorption spectro-photometer for the measurement, for instance, of a solution of bichromate, suppose that the slit is set just inside the absorption band; then, one of the spectra is darkened throughout its length by the equalising apparatus, while in the other spectrum the red, orange, and yellow are entirely undarkened. The light from these regions of the spectrum will be scattered throughout the field and will change the apparent colour of the green or blue light transmitted by the solution at the edge of the absorption band. Satisfactory results in the use of the instrument can be obtained by the employment of filters which will absorb the whole of the red and yellow light, transmitting only the region in which measurements are required.

Monochromatic filters are often of use in spectroscopy and in general physical work, but unfortunately it is not possible as a general rule to get monochromatic filters of great efficiency. The transmission of most monochromatic filters is only 10 per cent or less if the filters are really narrow, and this loss of light seriously limits their application. There is one monochromatic filter, however, which is very efficient. This is the filter resulting from the employment of didymium salts, which have an extremely sharp absorption band between 550 $\mu\mu$ and 580 $\mu\mu$, thus cutting out very cleanly the mercury yellow lines. By the combination of this filter with a strong yellow filter, the green line of the mercury lamp can be obtained in high intensity and almost entirely free from other radiation, thus supplying the strongest monochromatic source of light known. This is of particular advantage in work with the interferometer.

§ (6) Optical Properties.—The optical effects produced by the use of colour filters in front of lenses may be divided into two classes: the first includes those resulting from the use of a theoretically perfect filter; the second, those which result from imperfections in the filters, that is, from departures from conditions of plane parallelism in the faces and of equality in thickness between the filters of a set. Computation shows that the effects resulting from the use of perfect filters are too small to be of any practical importance, the effect both on spherical aberration and on curvature of field being well within the limit of tolerance, while the effect of the dispersion on the difference in image size between different colour filters of a set is also negligible. The effects upon the definition and size of image introduced by the use of filters which are imperfect are very much more complicated than those which result from the use of perfect filters. Since the errors of surface may be of any type, the investigation of the effects produced can only be performed experimentally. The most convenient testing apparatus consists of a telescope objective of about four feet focal length on which the filter is placed, the image of a test object being examined by means of an eyepiece.[1]

C. E. K. M.

LIGHT, INTERFERENCE OF

§ (1) Introduction.—The problem of the interference of light and its historical development are closely bound up with the question of the nature of light. Two theories of light have held sway at different periods in the history of optical science, namely, the wave theory and the corpuscular or emission theory. According to the former, which was first definitely propounded by Huygens in 1678, light is a wave motion propagated in a continuous hypothetical medium called the ether, which is supposed to pervade all space. Although Huygens regarded the waves as longitudinal, he was able to explain a number of phenomena, such as reflection and refraction, but he could not account for the rectilinear propagation of light. For this reason the theory was not accepted by Newton, who elaborated the corpuscular or emission theory, according to which luminous bodies emit material corpuscles which travel along straight paths, the sensation of vision being produced by the mechanical impact of these corpuscles on the retina. This theory leads to the correct law of refraction, but it also leads to the result that the velocity of light should be greater in a dense medium than in a less dense one. The opposite result follows from the wave theory and has been experimentally proved to be correct; this forms a crucial

[1] Cp. C. E. K. Mees, *British Journal of Photography*, 1917, p. 462.

test of the two theories. The fact that the emission theory was not finally overthrown until the beginning of the nineteenth century, when interference was explained on the basis of the wave theory, is largely due to its being held by such a great authority as Newton.

§ (2) MATHEMATICAL ANALYSIS.—The interference of light may, according to the wave theory, be expressed in mathematical form as follows.

The general differential equations of wave motion in a homogeneous medium are given by

$$\frac{\partial^2\xi}{\partial t^2}=V^2\left(\frac{\partial^2\xi}{\partial x^2}+\frac{\partial^2\xi}{\partial y^2}+\frac{\partial^2\xi}{\partial z^2}\right)$$

and similar equations in η and ζ, where t is the time, (x, y, z) are rectangular co-ordinates, V is the velocity of propagation of the wave motion, and (ξ, η, ζ) are, according to the elastic wave theory, the components of the displacement of an ether particle from its position of rest or, according to the electromagnetic theory, the components of the electric or magnetic field strengths.

When the disturbance travels in the direction of the x axis this reduces to

$$\frac{\partial^2\xi}{\partial t^2}=V^2\frac{\partial^2\xi}{\partial x^2}.$$

Confining our attention to the case of a wave propagated along the direction of the x axis and writing λ for $V\tau$, we find that the disturbance in the wave may be represented by the equation

$$\xi=A\cos\frac{2\pi}{\tau}\left(t-\frac{x}{V}\right)=A\cos 2\pi\left(\frac{t}{\tau}-\frac{x}{\lambda}\right).$$

This represents a wave, for at a given point —for which x is constant—the motion repeats itself at times t, $t+\tau$, $t+2\tau$, etc., and at a given time—for which t is constant—it repeats itself at the points x, $x+\lambda$, $x+2\lambda$, etc., or x, $x+V\tau$, $x+2V\tau$, etc. Thus it can be represented by a cosine curve, repeating itself at lengths λ, 2λ, . . . which moves forward with speed V.

A is the amplitude, τ the period of vibration, and λ the wave-length of the vibratory motion of the ether particle. The intensity of such a light wave is proportional to A^2, for it is proportional to the kinetic energy of the vibrating ether particle, and this in turn varies as the square of the velocity of vibration; the velocity is given by the equation

$$\frac{\partial\xi}{\partial t}=-A\frac{2\pi}{\tau}\sin\left(t-\frac{x}{V}\right),$$

and the average value of its square is proportional to A^2.

We may now consider the effect of two light waves of the same period propagated in a homogeneous medium, the vibrations being supposed parallel. They may be represented by

$$\xi_1=A_1\cos 2\pi\left(\frac{t}{\tau}-\frac{x}{\lambda}\right)$$

and $$\xi_2=A_2\cos 2\pi\left(\frac{t}{\tau}-\frac{x+\delta}{\lambda}\right),$$

where A_1, A_2 are the amplitudes of the two motions, and $2\pi\delta/\lambda$ is the phase difference, that is, the crests of the one wave are always a distance δ ahead of those of the other. Now, according to the principle of the superposition of wave motion, the resultant motion of a particle simultaneously subjected to a number of different displacements is obtained by summing up the components of these displacements. Thus in the case of the two given light waves the resultant displacement is given by

$$\xi=\xi_1+\xi_2=\left(A_1+A_2\cos 2\pi\frac{\delta}{\lambda}\right)\cos 2\pi\left(\frac{t}{\tau}-\frac{x}{\lambda}\right)$$
$$+A_2\sin 2\pi\frac{\delta}{\lambda}\sin 2\pi\left(\frac{t}{\tau}-\frac{x}{\lambda}\right).$$

Now let

$$A_1+A_2\cos 2\pi\frac{\delta}{\lambda}=A\cos 2\pi\frac{\Delta}{\lambda}$$

and $$A_2\sin 2\pi\frac{\delta}{\lambda}=A\sin 2\pi\frac{\Delta}{\lambda}.$$

Then $$\xi=A\cos 2\pi\left(\frac{t}{\tau}-\frac{x+\Delta}{\lambda}\right),$$

where

$$A^2=A_1^2+A_2^2+2A_1A_2\cos 2\pi\frac{\delta}{\lambda}.$$

The resultant motion is thus given by a wave which has the same period as the original wave, but a different amplitude, and is in a different phase. If the original phase difference $2\pi(\delta/\lambda)=2n\pi$, that is, if $\delta=2n(\lambda/2)$, where n is a positive integer, A has its maximum value, A_1+A_2. On the other hand, if $2\pi(\delta/\lambda)=(2n+1)\pi$, that is, if $\delta=(2n+1)(\lambda/2)$, A has its minimum value, A_1-A_2. If δ is an odd number of quarter wave-lengths,

$$\xi_2=A_2\sin 2\pi\left(\frac{t}{\tau}-\frac{x}{\lambda}\right),$$

and $A^2=A_1^2+A_2^2$, that is, the total intensity is equal to the sum of the intensities of the two waves. If $A_1=A_2$ the total intensity is four times that of each wave when $\delta=2n(\lambda/2)$, and is zero, that is, the waves interfere, when $\delta=(2n+1)(\lambda/2)$. This does not mean that any energy is destroyed; what happens is that the distribution of the energy is modified.

The treatment may be extended to the case of any number of waves, but the brief sketch just given serves to illustrate the method whereby the phenomenon of interference may be explained by means of the wave theory of light.

§ (3) Young's Experiment.—True interference of light was first observed by Young; the experimental arrangement he employed was described in his lectures which were published in 1807. Light from a slit was allowed to fall on a screen in which there were two small pinholes placed close together. Interference bands were then observed on another screen placed in a position where the rays, after being diffracted at the pinholes, overlapped. The phenomenon is really one of interference of diffracted light,[1] because the rays which pass directly through the pinholes will not overlap. It will be of interest, however, to consider the explanation of the phenomenon by means of the wave theory on the assumption that the two pinholes do act as sources of light in which the vibrations bear a constant phase relationship to each other, for, as will be seen later, it is possible to obtain the necessary conditions by optical means. Let S_1, S_2 (*Fig.* 1) represent two

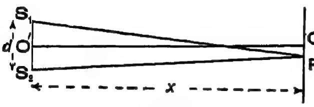

Fig. 1.

pinholes acting as sources of light. If we assume that the ether particles at S_1 and S_2 are vibrating parallel to each other in the same phase, and that the waves being sent out have the same amplitude and the same period, we may consider the effect at a point P on a screen OP, set parallel to the line joining S_1S_2, at a position where the beams from S_1 and S_2 overlap. Draw $O'O$ through the mid-point O' of S_1S_2 perpendicular to the screen. Let $S_1S_2=d$, $O'O=x$, and $OP=y$. Then

$$S_1P^2=x^2+\left(\frac{d}{2}+y\right)^2, \quad \text{and } S_2P^2=x^2+\left(\frac{d}{2}-y\right)^2.$$

Therefore $\quad S_1P^2-S_2P^2=2yd.$

If d and y are each small in comparison with x, we have

$$S_1P+S_2P=2x.$$

Thus $\quad S_1P-S_2P=\frac{yd}{x}.$

If the difference S_1P-S_2P is equal to an even number of half wave-lengths, that is $2n(\lambda/2)$, where n is an integer and λ is the wave-length, the waves will reinforce each other; there will therefore be a maximum intensity at P when

$$y=\frac{2nx\lambda}{2d}.$$

If, however, the difference S_1P-S_2P is equal to an odd number of half wave-lengths, that is $(2n+1)(\lambda/2)$, the waves will interfere; there will therefore be darkness at P when

$$y=\frac{(2n+1)x\lambda}{2d}.$$

It may easily be shown that, if a line is drawn on the screen so as to pass through P and be perpendicular to OP, the total disturbance at a point P′ on this line is the same as at P, if PP′ is small. Thus the appearance on the screen will be that of a series of parallel alternating bright and dark bands,[2] the distance between the centres of two consecutive bright bands or dark bands being given by

$$D=\frac{x\lambda}{d}.$$

The central band of the system, that is the one at O, is bright.

The positions of these bands or fringes depend on the wave-length of the light used. Thus, if white light is employed, there will be an infinite series of bright and dark bands corresponding to the infinite range of wave-lengths in white light. The result will be that only a few bands near the centre will be at all clear, the outer ones overlapping each other; the central band will be white. Thus, in order to obtain a considerable number of bands, monochromatic light must be employed.[3]

The above treatment will hold for all cases where the interfering beams come from two real or virtual images of one and the same luminous point. This requirement is fundamental for the production of interference fringes, it being impossible to obtain interference between beams which come from two entirely independent sources. The reason for this is that the phase of the disturbance from a given source, even if of constant wave-length, alters frequently and irregularly, so that there can be no fixed relationship between two independent sources. If, however, the two sources are real or virtual images of the same source, there will be a constant phase relationship between the vibrations in the two and interference systems will be observable. In such a case the source must have been maintained in regular vibration for millions of periods.

It is interesting in this connection to note that the number of fringes which can be observed gives us information with regard to the number of regular vibrations performed

[1] Diffraction phenomena, which may be looked upon as a special class of interference phenomena depending on the restriction of apertures, will not be discussed in this article.

[2] The bands are only approximately straight; actually they are the sections of a system of hyperboloids of revolution round the line S_1S_2 having S_1 and S_2 as foci.

[3] See, however, later on under "Achromatic Fringes," § (5).

by each molecule in the luminous source before a sudden change in phase takes place, for at the nth dark fringe interference takes place between vibrations which left the two sources at times $n\tau$ apart, where τ is the period of vibration. In the case of sodium light Fizeau counted about 50,000 fringes, while in more recent times path differences corresponding to as many as a million fringes have been obtained in the case of certain kinds of monochromatic light.

§ (4) Methods of producing Interference Fringes.—A great number of methods of producing interference fringes of the type just discussed have been devised, but they all practically depend on the formation, by means of some optical system, of two images (real or virtual) of a narrow source of light, such as an illuminated slit. These images then act as secondary sources, fringes being observed in the region where the beams of light which come from these sources overlap. In each case the distance D between consecutive bright or dark bands is given by

$$D=\frac{x\lambda}{d},$$

where x = distance between sources and plane in which the bands are observed,
d = distance between the secondary sources,
λ = wave-length.

Some of the more important optical systems devised for the purpose mentioned may be described as follows.

(i.) *Fresnel's Two-mirror System.* — This is one of the systems that Fresnel [1] suggested for the purpose of overcoming the objection that diffraction plays a part in Young's experiment. A plan of the arrangement is shown in *Fig.* 2.

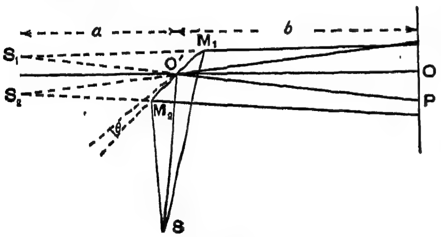

Fig. 2.

The light from a slit S is reflected from two plane mirrors $O'M_1$, $O'M_2$, the normals to which are inclined at a small angle θ, the line of intersection of the mirrors being parallel to the length of the slit. The reflected beams of light appear to come from S_1 and S_2, the images of S in the two mirrors, and interference bands parallel to the slit are obtained on a screen OP, where the two beams overlap. Now let $O'S=a$ and $O'O=b$. The angle subtended by S_1S_2 at O′ is equal to twice the angle between the mirrors. Also S_1 and S_2 are situated as far behind the mirrors as S is in front of them. Thus it follows that $O'S_1=O'S_2=O'S=a$, and $S_1S_2=2a\theta$.

Hence $$D=\frac{(a+b)\lambda}{2a\theta}.$$

The Fresnel mirror system may be modified by the introduction of a lens to form two real images of the slit.[2] This is the arrangement which Righi [3] used in his experiment for demonstrating the existence of light-beats.

(ii.) *Vautier's Three-mirror System.*—In this system [4] three equidistant mirrors are set up approximately parallel to each other, the inner one being silvered on both sides and the others on their inner sides only. The two interfering beams of light are formed by reflection first at each of the two outer mirrors and then at the central mirror. If the mirrors were set accurately parallel to each other the beams would be contiguous and no interference would take place; one of the outer mirrors is therefore set up so as to make a small angle with the others. Vautier has also employed an arrangement whereby the light incident on the mirrors is rendered parallel by the introduction of a lens; the beams after reflection then pass through another lens which forms two real images of the source of light.

(iii.) *Michelson's Mirrors.*—Michelson [5] forms two virtual images of a source by double reflection at two mirrors which are inclined to one another at an angle which is very little less than 90°. The arrangement has the advantage over that of Fresnel that it does not require such accurate adjustment of the mirrors.

(iv.) *Fresnel's Bi-prism.* — Fresnel [6] also obtained interference fringes by making use of refraction instead of reflection to form two adjacent virtual images of a source. The light from a slit S (*Fig.* 3) is refracted by the

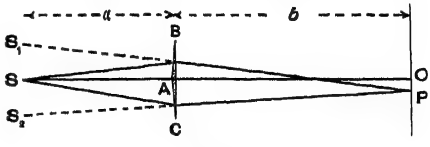

Fig. 3.

bi-prism ABC, the edge A of the obtuse angle dividing the light into two beams which, after

[1] A. Fresnel, *Œuvr. compl.* i. 150, 186; ii. 17, 52.

[6] A. Fresnel, *Œuvr. compl.* i. 330.

refraction, appear to come from S_1 and S_2. Interference fringes can then be observed in the region where the two beams overlap, provided that the edge A is accurately parallel to the slit S. Let δ be the deviation produced by each half of the prism, μ the refractive index of the prism, and $\alpha = \angle ABC = \angle ACB$. Then

$$S_1S_2 = 2a \sin \delta = 2a(\mu - 1)\alpha,$$

if α is very small, where $a = SA$.

Thus the bi-prism is equivalent to a pair of Fresnel mirrors inclined at an angle $(\mu - 1)\alpha$. The distance between two consecutive bright or dark bands on a screen OP at a distance b from the bi-prism is then given by

$$D = \frac{(a+b)\lambda}{2a(\mu - 1)\alpha}.$$

If white light is used, there is greater overlapping of the bands due to different colours than with Fresnel's mirrors, because in the expression for D a decrease in the value of λ is accompanied by an increase in the value of μ, owing to the dispersion caused by the prism.

A simple and very useful method of measuring S_1S_2 has been suggested by Glazebrook.[1] A convex lens is inserted between the bi-prism and the microscope which is used for measuring the separation of the bands, and is adjusted so as to form images of S_1 and S_2 in the focal plane of the microscope. The distance d_1 between these images is measured. The lens is then moved into the second position, in which it forms images of S_1 and S_2 in the focal plane of the microscope, the distance d_2 between these images being measured. Since the magnification in the one position is the reciprocal of the magnification in the second position, it follows that

$$S_1S_2 = \sqrt{d_1 d_2}.$$

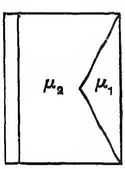

FIG. 4.

A modified form of Fresnel bi-prism, due to Winkelmann,[2] is illustrated in *Fig.* 4. The bi-prism, of refractive index μ_1, is mounted in a cell containing a liquid, such as benzene, of refractive index μ_2, the cell being covered by a plane parallel piece of glass. In this case

$$D = \frac{(a+b)\lambda}{2a(\mu_1 - \mu_2)\alpha},$$

where the symbols have the same significance as before. The advantage of this arrangement is that the obtuse angle of the bi-prism may be made much less obtuse than in the case of the bi-prism used in air.

[1] R. T. Glazebrook, *Physical Optics*.
[2] A. Winkelmann, *Zeits. Instrumentenk.*, 1902, xxii. 275.

(v.) *Bi-plates.*—Another method of obtaining two adjacent virtual sources for producing interference fringes is to use a bi-plate,[3] which consists of two parallel plates of glass of equal thickness (preferably cut from the same piece of glass) inclined to one another (*Fig.* 5).

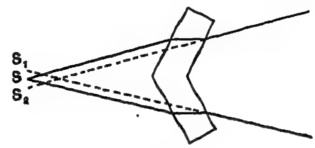

FIG. 5.

The beams of light after refraction appear to come from the virtual images S_1 and S_2. Two real images of S_1 and S_2 are formed by the introduction of a lens. Now the lateral displacement of a ray in passing through a parallel plate of thickness t is given by

$$\frac{t \sin (i - r)}{\cos r},$$

where i and r are the angles of incidence and refraction respectively. Hence

$$S_1S_2 = \frac{2t \sin (i - r)}{\cos r} = 2t \sin i \{1 - \cot i \tan r\}.$$

If the plates are inclined at angle 2θ we have $i = 90° - \theta$ approximately. Therefore

$$\sin i = \cos \theta, \quad \cos i = \sin \theta, \quad \cot i = \tan \theta,$$

$$\sin r = \frac{\cos \theta}{\mu}, \quad \cos r = \frac{\sqrt{\mu^2 - \cos^2 \theta}}{\mu},$$

$$\tan r = \frac{\cos \theta}{\sqrt{\mu^2 - \cos^2 \theta}},$$

where μ is the refractive index of the glass. Thus

$$S_1S_2 = 2t \cos \theta \left\{1 - \frac{\sin \theta}{\sqrt{\mu^2 - \cos^2 \theta}}\right\},$$

and the value of D may then be deduced.

(vi.) *Billet's Split Lens.*—In this system[4] (*Fig.* 6) two real images, S_1 and S_2, of an

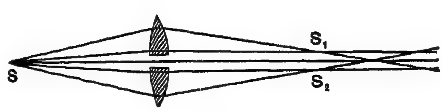

FIG. 6.

illuminated source are formed by two halves of a lens which can be separated or brought close together by means of a micrometer screw, the motion being along a line perpendicular to the optical axis.

(vii.) *Meslin's Split Lens.*—This is a modification of the previous arrangement, the

[3] J. Jamin, *Cours de physique*, 1866 (3), 524.
[4] F. Billet, *Ann. Chim. et Phys.*, 1862 (3), lxiv. 386.

two halves being relatively displaced along the optical axis.[1] The two real images, S_1 and S_2 (*Fig.* 7), are then formed on the optical axis and interference fringes can be observed in the region between S_1 and S_2. The points of equal phase difference in this case lie on ellipsoids of revolution, having S_1 and S_2 as

FIG. 7.

foci. A system of semicircular[2] fringes is then obtained. In both this and the previous case the distance S_1S_2 can be calculated from the separation and the optical constants of the lens halves.

(viii.) *Fresnel's Three-mirror System.*—In this system three mirrors—M_1, M_2, and M_3 (*Fig.* 8)—are employed. One of the secondary

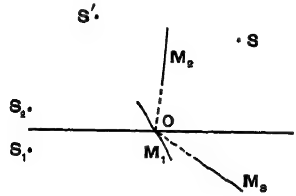

FIG. 8.

sources is the image S_1 of S in the central mirror M_1. The other secondary source S_2 is the image in M_3 of S′, which in turn is the image of S formed in M_2. Thus one of the beams is once reflected at M_1, while the other is twice reflected at M_2 and M_3. The mirrors M_2 and M_3 are set up in such a position that their planes intersect at O, the centre of M_1, making approximately equal angles with the plane of M_1. The central band of the interference system is black, from which Fresnel concluded, as Young had done in order to explain the black centre in Newton's rings, that there is a loss of optical path of $\frac{1}{2}\lambda$ by reflection at a glass surface.

For modifications of the Fresnel three-mirror system see Quincke[3] and Mascart.[4]

(ix.) *Lloyd's Mirror.*—This is a somewhat simpler arrangement[5] than the previous one. Interference takes place between the direct beam from a source S (*Fig.* 9), and the beam reflected from a single mirror (a piece of black glass is suitable) at almost grazing incidence, the second beam appearing to come from the virtual image S′. In this case again the central band of the interference system is

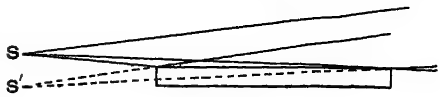

FIG. 9.

dark. Owing to the asymmetry of the optical system only one half of the fringe system can be seen, unless a thin transparent plate be held in the path of the direct beam so as to introduce retardation and consequent displacement of the fringes.

§ (5) ACHROMATIC FRINGES.—We have seen that the distance D between adjacent fringes is given by

$$D=\frac{x\lambda}{d},$$

from which it is clear that D varies with the wave-length λ. If it were possible to arrange that the ratio λ/d should be constant for all wave-lengths, one would be able to obtain a system of achromatic interference fringes when using white light, for then the fringes due to the different colours would coincide. A simple method of obtaining such achromatic fringes is to use as the two sources a short spectrum and its virtual image formed by reflection in a glass plate (Lloyd mirror system). The blue end of the spectrum should be towards the plate, as the distance between the sources for blue light should be less than for red light. If the spectrum is formed by a prism it is only possible to achromatise the fringes for two colours, but if a diffraction grating is employed the superposition of fringes for two wave-lengths will secure the superposition of fringes for all other wave-lengths.

§ (6) INTERFERENCE IN FILMS AND PLATES.—The interference phenomena which we have so far discussed can only be observed when a point source or a narrow line source of light is used. There is another group of interference phenomena which can be observed when using an extended source of light. In this group are included the cases of interference in transparent films and plates. A number of such cases will now be dealt with.

§ (7) INTERFERENCE IN THIN FILMS. (i.) *Simple Cases.*—When a very thin film of a transparent substance is illuminated by a broad source of light, such as a bright sky, brilliant colours are seen; soap bubbles and thin layers of oil spread over the surface of water are familiar examples of this phenomenon. These colours are due to interference between the rays reflected from the two surfaces of the film.

[1] G. Meslin, *Comptes Rendus*, 1893, cxvi. 250, 570; *Journ. de Physique*, 1893, (3), ii. 205.
[2] Complete circular fringes are not obtained, as the beams of light overlap only on one side of the optical axis, as may be seen from the diagram.
[3] G. Quincke, *Pogg. Ann.*, 1871, cxlii. 228.
[4] E. Mascart, *Comptes Rendus*, 1887, cv. 967.
[5] H. Lloyd, *Roy. Irish Acad. Trans.*, 1837, xvii. 174.

Let us first consider the case of monochromatic light falling on a thin film which is bounded by two parallel surfaces. At present we may confine our attention to the two paths ABCDE and FDE (*Fig.* 10). The

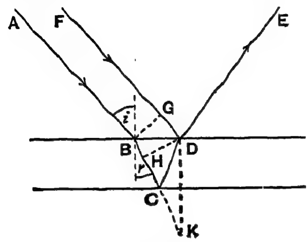

FIG. 10.

first is that of a ray which is refracted at the first surface, internally reflected at the second surface, and again refracted at the first surface; the second is that of a ray (emanating from the same point in the source) which is incident parallel to the first ray and is reflected at the first surface of the film. The difference in optical path of the two rays can easily be deduced. Let i be the angle of incidence and r the angle of refraction in the film. Draw BG perpendicular to FD and DH perpendicular to BC, and produce BC to meet the line through D normal to the film surface in K. Then BG and DH are the fronts of the incident and refracted waves respectively, so that the portions of the paths GD and BH are optically equal. Thus the path difference $d = \text{HC} + \text{CD} = \text{HK} = 2t\cos r$, where t is the thickness of the film. This is equivalent to $2\mu t\cos r$, measured in air, where μ is the refractive index of the film.

At first sight it would appear that there would be a maximum brightness when the path difference is equal to an even number of half wave-lengths and a minimum brightness when the difference is equal to an odd number of half wave-lengths This, however, does not fit in with the observed phenomena, and we can see that in the limiting case when the film is of zero thickness no light will be reflected, though we might from the above considerations have expected maximum brightness. The reason of this apparent discrepancy, as was first suggested by Young, is that light reflected at the surface of a denser medium suffers a phase change of 180°, which is equivalent to a path difference of half a wave-length. In the case of the film one of the rays is reflected without change of phase at the surface of a rarer medium, while the other is reflected at the surface of a denser medium. Thus the total retardation in the case under consideration is $2\mu t\cos r + \frac{1}{2}\lambda$. The brightness will therefore be greatest when $2\mu t\cos r$ is equal to an odd number of half wave-lengths, and least when $2\mu t\cos r$ is equal to an even number of half wave-lengths.

If now the incident light is white the light reflected from any point of the film will not include the wave-length which satisfies the equation $2\mu t\cos r = n\lambda$ at that point; the light will accordingly be coloured. If the film is of uniform thickness the colour will be uniform over the whole film.[1] Any want of uniformity in the thickness will give rise to variations in the colours observed at different parts of the film. This gives a convenient method of testing the uniformity of thickness of a film.[2]

(ii.) *Effect of Multiple Reflections* —The theory of thin films, as above sketched, is not complete, for we must take into account, as Poisson showed, the effect of multiple reflections. If d is the retardation of a ray once internally reflected, then $2d$ will be the retardation of a ray internally reflected three times, and so on. In order to sum up the effects of these multiple internal reflections it is necessary to investigate the relations between the amplitudes of the reflected rays. Let the amplitude of the incident ray AO (*Fig.* 11) be a, and the amplitudes of the reflected and refracted rays OB, OC be ab, ac respectively,

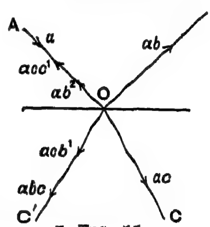

FIG. 11.

where b, c are fractions.[3] If these rays be reversed they should combine to give a ray along OA of amplitude a. The reversal of OC will give a ray of amplitude ab^2 along OA, and one of amplitude abc along the refracted path OC′. Let the components, along OA and OC′, of OC reversed be acc' and acb' respectively. Then

$$ab^2 + acc' = a \text{ and } abc + acb' = 0,$$

since there must be no resultant ray along OC′.

Thus

$$cc' = 1 - b^2 = 1 - b'^2 \text{ and } b = -b'.$$

We may calculate the resultant phase difference for the reflected beams, taking into account the multiple internal reflections. The amplitudes of the various beams are shown in *Fig.* 12. The common phase difference of the reflected components is given

[1] This is true only if the film is so thin that the variation of the angle of incidence from one point to another does not affect the value of $2\mu t\cos r$ by more than a small fraction. If a point source at infinity is used the statement is true for any thickness of film since the angle of incidence is then constant.

[2] See article on "Interferometers: Technical Applications."

[3] G. Stokes, *Math. and Phys. Papers*, ii. 89.

by $\delta=(2\pi/\lambda)d$, where d is the common path difference.

Now let A be the amplitude of the resultant reflected beam and Δ its phase when the phase of

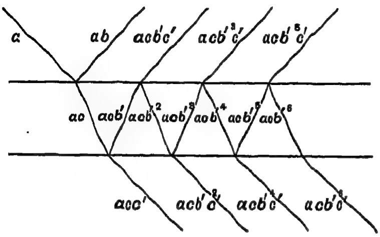

FIG. 12.

the first reflected beam is zero. Then, making use of the notation employed at the beginning of this article, we have

$$\mathrm{A}\cos\left\{\frac{2\pi}{\tau}\left(t-\frac{x}{\mathrm{V}}\right)+\Delta\right\}=ab\cos\frac{2\pi}{\tau}\left(t-\frac{x}{\mathrm{V}}\right)$$
$$+acb'c'\cos\left\{\frac{2\pi}{\tau}\left(t-\frac{x}{\mathrm{V}}\right)+\delta\right\}$$
$$+acb'^3c'\cos\left\{\frac{2\pi}{\tau}\left(t-\frac{x}{\mathrm{V}}\right)+2\delta\right\}+\ldots$$

Expanding, and equating the coefficients of

$$\cos\frac{2\pi}{\tau}\left(t-\frac{x}{\mathrm{V}}\right)\text{ and }\sin\frac{2\pi}{\tau}\left(t-\frac{x}{\mathrm{V}}\right),$$

we obtain

$$\mathrm{A}\cos\Delta=ab+acb'c'\cos\delta+acb'^3c'\cos 2\delta+\ldots,$$
$$\mathrm{A}\sin\Delta=\quad acb'c'\sin\delta+acb'^3c'\sin 2\delta+\ldots$$

Therefore

$$\mathrm{A}e^{i\Delta}=ab+acb'c'(e^{i\delta}+b'^2e^{2i\delta}+\ldots)$$
$$=ab+acb'c'\frac{e^{i\delta}}{1-b'^2e^{i\delta}}.$$

Multiplying the second term on the right above and below by $1-b'^2e^{-i\delta}$ we have

$$\mathrm{A}e^{i\Delta}=ab+\frac{acb'c'(\cos\delta-b'^2)}{1-2b'^2\cos\delta+b'^4}+i\frac{acb'c'\sin\delta}{1-2b'^2\cos\delta+b'^4}.$$

If we equate the real parts on both sides and the imaginary parts and square and add we get, on substituting

$$cc'=1-b^2\text{ and }b=-b',$$

$$\mathrm{A}^2=\frac{4a^2b^2\sin^2(\delta/2)}{1-2b^2\cos\delta+b^4}=\frac{4a^2b^2\sin^2(\delta/2)}{(1-b^2)^2+4b^2\sin^2(\delta/2)}.$$

By a similar calculation it is possible to deduce that the amplitude B of the resultant transmitted beam is given by

$$\mathrm{B}^2=\frac{a^2(1-b^2)^2}{(1-b^2)^2+4b^2\sin^2(\delta/2)}.$$

This result is to be expected, since A^2 and B^2 are the intensities of the reflected and transmitted beams, and their sum should equal a^2, the intensity of the incident beam.

The result for the reflected beam shows that the intensity is zero when

$$\delta=2n\pi,$$

that is, when $\quad 2\mu t\cos r=n\lambda,$

since $\quad \delta=\frac{2\pi}{\lambda}d=\frac{2\pi}{\lambda}\cdot 2\mu t\cos r.$

Thus, if light of wave-length λ is employed, the film or plate will appear perfectly black when $2\mu t\cos r$ is equal to an even number of half wave-lengths. This is the same result as was obtained when considering the simpler case of one internal reflection, except that there the condition was merely for minimum brightness.

It is interesting to note that the condition for zero intensity in the reflected beam corresponds to maximum intensity in the transmitted beam, and that the minimum intensity in the latter is not zero, but is such that when added to that of the reflected beam the sum is a^2. The phenomena in the two cases are complementary, but are much sharper in the reflected than in the transmitted beam.

(iii.) *Wedge-shaped Films.*—If the two plane surfaces bounding a film are inclined to each other at a small angle, a system of fringes will be observed. If white light is used the fringes will be coloured, but there is so much overlapping of the fringes that they will not be distinguishable unless the film is extremely thin and the angle of the wedge is very small. In the case, therefore, of films of appreciable thickness it is necessary to use monochromatic light, and the thicker the film the more monochromatic the light must be.

§ (8) NEWTON'S RINGS.—Newton observed that when a plane-glass surface was placed in contact with a convex spherical surface circular fringes were formed round the point of contact. These fringes, usually called Newton's rings, are due to interference in the film of air between the two surfaces. Now we have seen that where

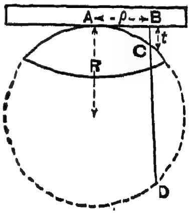

FIG. 13.

$$2\mu t\cos r=n\frac{\lambda}{2},$$

there will be maximum or minimum brightness according as n is odd or even, where μ and t are the refractive index and thickness of the film and r is the angle of refraction in the film. In the present case, if we consider the light to be incident normal to a plate of glass resting on the convex surface of a lens (*Fig.* 13), $\mu=1$ and $r=0$. Let A be the point of contact and R be the radius of

curvature of the convex surface. Then if t is the thickness of the air film at a point B, where $AB = \rho$, we have

$$\rho^2 = BC \cdot BD$$
$$= 2tR,$$

since we are considering points very close to the point of contact. Thus there will be a bright ring when

$$\rho = \sqrt{R(2n+1)\frac{\lambda}{2}},$$

and a dark ring when

$$\rho = \sqrt{Rn\lambda},$$

where n is any whole number. Newton's rings, therefore, give us the means of measuring R if λ is known.[1]

§ (9) Michelson's Interferometer.—A convenient method of observing interference phenomena in an air film of variable thickness was devised by Professor Michelson [2] The principle of the arrangement which he used is as follows. Light from a monochromatic source S (*Fig.* 14) falls on a plane-glass plate

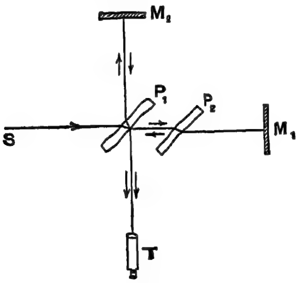

Fig. 14.

P_1 at an angle of 45°. The back surface of this plate is half silvered so that the beam of light is divided into two portions of approximately equal intensity. One of these, after transmission through P_1 and a second similar plate P_2 (unsilvered), and normal reflection at the plane silvered mirror M_1, passes again through P_2 and is reflected by the half-silvered surface of P_1 into the observing telescope T. The other portion, after internal reflection in P_1 and normal reflection at the plane silvered mirror M_2, is transmitted through the plate P_1 into the telescope. The reason for introducing the second plate, P_2, which is placed at 45° in the path of the first beam, is to make the glass paths of the two beams equal, for without it the first beam would pass once through P_1 whereas the second beam would pass through it three times. In order to obtain complete compensation of the glass paths the two plates, P_1, P_2, should be of equal thickness, preferably cut from the same piece of glass. If the air paths are now of the same length the arrangement is equivalent to a film of zero thickness, for the image of M_1 by reflection in P_1 will then coincide with M_2. One of the mirrors is provided with a micrometer screw by means of which it may be moved parallel to itself so as to introduce any desired difference in optical path. The plates and mirrors are also provided with fine adjustments to enable the image of M_1 to be brought into parallelism with M_2.

Modified forms of the Michelson interferometer are used for testing the planeness of surfaces, the homogeneity of glass blocks and prisms, and the aberrations in lenses.[3]

§ (10) Fabry and Perot Interferometer.—We have already seen, when considering the case of multiple reflections in films, that the intensities of the resultant reflected and transmitted beams are given by

$$A^2 = \frac{4a^2b^2 \sin^2(\delta/2)}{(1-b^2)^2 + 4a^2b^2 \sin^2(\delta/2)}$$

and $$B^2 = \frac{(1-b^2)^2}{(1-b^2)^2 + 4a^2b^2 \sin^2(\delta/2)}$$

respectively, where a^2 is the intensity of the incident light, b^2 is the reflection coefficient, and δ is the common phase difference between successive components of the reflected and transmitted beams. Confining our attention to the transmitted system, we see that, as δ varies, the intensity varies periodically; its maximum value, corresponding to $\delta = 2n\pi$, is a^2, its minimum value, corresponding to $\delta = (2n+1)\pi$ is $a^2((1-b^2)/(1+b^2))^2$, while an intermediate value, where $\delta = ((2n+1)/2)\pi$, is $a^2((1-b^2)^2/(1+b^4))$. It will be seen that, as the reflection coefficient increases, the minimum and intermediate values decrease, and, therefore, the maxima becomes sharper. *Fig.* 15 shows the types of intensity curves obtained,

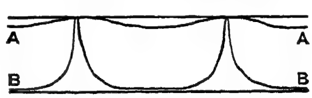

Fig. 15.

for normal incidence, with unsilvered (AA; $b^2 = \cdot 04$), and silvered (BB; $b^2 = \cdot 75$) plates. Thus by using a high reflection coefficient one obtains sharp bright lines on a dark background. The case for the reflected system is exactly reversed and is illustrated by *Fig.* 15 turned upside down. In this case,

[1] See article on "Spherometry."
[2] A. A. Michelson, *Am. J. Sci.*, 1882, xxiii. 395; *Phil. Mag.*, 1882, (5) xiii. 237.
[3] See article on "Interferometers: Technical Applications"; also F. Twyman, *Opt. Soc. Trans.*, 1920–21, xxii. No. 4.

if the reflection coefficient is high, one obtains sharp dark lines on a bright background.

The above fact has been made use of by Fabry and Perot[1] in their interferometer, which consists of two glass plates, the neighbouring faces of which are lightly silvered. One plate is fixed, and the second plate, which is set approximately parallel to the first, can be moved parallel to itself so that the thickness of the air film between the plates can be varied at will.

§ (11) Lummer and Gehrcke Interferometer.—The brightness of the reflected beams can also be increased by increasing the angle of incidence. Lummer and Gehrcke[2] have employed this principle in their application of interference methods to spectroscopy. They use a plate of glass (*Fig.* 16), at the end of one face of which is cemented a small right-angle prism. The incident light passes through the prism into the plate, and the beams of light which emerge, after successive internal reflections, from both sides of the plate can be examined by means of a telescope.

It might at first appear that the phenomena observable with the Lummer and Gehrcke

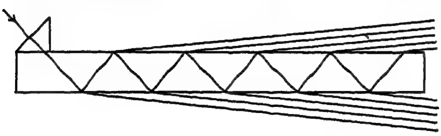

Fig. 16.

plate are due to diffraction effects, and this for two reasons. Firstly, there is a striking resemblance between the plate and the echelon grating, the path difference of successive beams increasing by definite steps. Secondly, it is well known that in interference systems such as we are considering the angular separation between the fringes decreases rapidly as the angle of incidence is increased, so that we might expect that in the case of the Lummer and Gehrcke plate, where the beams leave the plate at practically grazing emergence, the fringes could not be resolved. This, however, is not so, for, as one may easily calculate, the angular separation between successive fringes increases again as one approaches the limiting case of grazing emergence until it very nearly reaches the value for normal incidence. The phenomenon is, therefore, one of pure interference.[3]

§ (12) Interference in Multiple Thick Plates.—When two plates of glass are inclined to each other at a small angle (*Fig.* 17), a beam of light incident on one of the plates is divided into a number of components by multiple reflections between the plates. If the plates are of the same thickness some of these components are capable of interfering with each other. Thus in *Fig.* 17 the paths

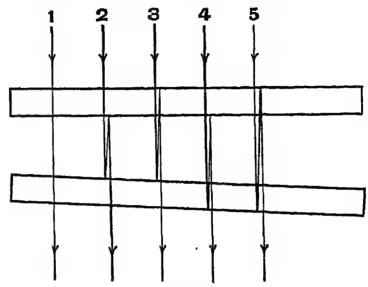

Fig. 17.

of the rays 3 and 4 are approximately equal, and, owing to the small inclination of the plates, such rays will form a series of interference fringes. Brewster[4] observed this phenomenon in 1817, and a modification of the arrangement has been employed by Jamin[5] in his interference refractometer. The principle of this instrument is illustrated in *Fig.* 18. A and B are two plates of optical glass, mounted parallel to each other and inclined at an angle of 45° to the line joining the centres of the surfaces a_1, b_1; the other surfaces, a_2, b_2, are silvered. If the plates have exactly the same thickness and the

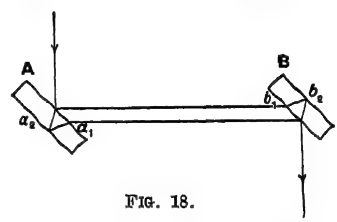

Fig. 18.

same refractive index, and are placed accurately parallel to each other, the optical paths of the two beams shown in *Fig.* 18 will be equal. On slightly rotating one of the plates about a horizontal or a vertical axis a path difference is introduced and a system of interference fringes can then be observed.

The Jamin refractometer can be used for measuring the refractive indices of gases or of transparent liquids or solids. Thus, for example, a plate of glass may be introduced into the path of one of the beams, in consequence of which there will be a displacement

of the fringe system. The amount of this displacement depends on the thickness and refractive index of the plate, and may be determined by placing in the path of the other beam a compensator consisting of two exactly similar small-angle glass wedges, of known refractive index, which can be slid relatively to each other so as to form a plate of uniform but variable thickness. The compensator is adjusted until the centre of the fringe system is brought to its original position.[1]

In cases where it is desired to compare the refractive indices of similar gases, liquids, or plates of glass, that is, when the displacement of the fringe system is relatively small, one can employ a Jamin compensator for bringing the fringe system back to its zero position. This consists of two glass plates fixed to a common axis and inclined to each other at a small angle. If the compensator is set up so that each of the plates is in the path of one of the interfering beams, small relative retardations can be introduced by rotating the compensator about its axis. The amounts of these retardations may be calculated or may be obtained by calibrating the compensator by means of auxiliary experiments.

Modifications of the Jamin interference refractometer, necessitating the employment of only one glass plate, have been used by Mascart,[2] Lummer,[3] and Ketteler.[4] The system employed by Mascart and Lummer has recently been applied by Waetzmann[5] to the study of the aberrations in lens systems. Zehnder[6] and Mach[7] introduced two auxiliary mirrors, as illustrated in *Fig.* 19, in order to separate the interfering beams as much as possible.

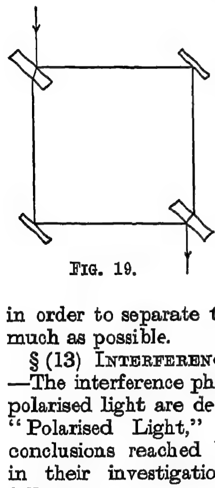

FIG. 19.

§ (13) INTERFERENCE OF POLARISED LIGHT.—The interference phenomena connected with polarised light are described in the article on "Polarised Light," *q.v.*, but the general conclusions reached by Fresnel and Arago[8] in their investigations may be stated as follows:

(i.) Two rays of light polarised at right angles do not interfere destructively under the same circumstances as two rays of ordinary light.

(ii.) Two rays of light polarised in the same plane interfere like two rays of ordinary light.

(iii.) Two rays polarised at right angles may be brought to the same plane of polarisation without thereby acquiring the quality of being able to interfere with each other.

(iv.) Two rays polarised at right angles, and afterwards brought to the same plane of polarisation, interfere like ordinary light if they originally belonged to the same beam of polarised light.

§ (14) APPLICATIONS OF INTERFERENCE PHENOMENA.—In addition to those mentioned in this article[9] the following applications of interference fringe systems to physical measurements, etc., may be mentioned: refractometry,[10] standardisation of wave-length and structure of spectral lines,[11] comparison of length gauges,[12] numerous physical and engineering problems,[13] and colour photography (Lippmann process).[14]

LIGHT, INTERFERENCE OF, IN MULTIPLE THICK PLATES; JAMIN'S REFRACTOMETER. See "Light, Interference of," § (12).

LIGHT, PROPAGATION OF

HUYGHENS' PRINCIPLE

LIGHT is a form of energy which affects the nerves of the eye and is propagated by wave motion. The vibrations which constitute the waves are transverse to the directions in which they travel.

Since Fresnel introduced the conception of transverse wave motion a gradually increasing store of theoretical and practical evidence has been accumulated to demonstrate its truth. Until recently it was supposed that the mechanism concerned with the transmission of these vibrations resembled more or less that which regulates the propagation of transverse waves in an elastic solid. Recent discoveries have shown conclusively that light is an electromagnetic phenomenon, and that light waves obey the same laws as waves of electric and magnetic force. In the present article we are concerned chiefly with questions which are independent of the physical properties of the medium concerned in the transmission of the light. All we need to consider

[1] For the purpose of determining the centre of the system of monochromatic fringes a system of coloured fringes formed by white light is superimposed on the other system.

are the rapid periodic changes of some vector quantity which, like other vectors, can be represented by a straight line in that it has length and direction.

While it is frequently convenient to visualise this vector as an actual displacement, it must be borne in mind that the changes which constitute light are electromagnetic in their nature; we cannot explain all the complex phenomena involved by the simple vibrations of ether particles.

Consider now a luminous source, O, *Fig.* 1. Light vibrations are emitted in all directions from this source, travelling outwards in waves with definite velocity. At one instant the disturbance will have reached a surface such as ABC, and all points of that surface will be in the same state of motion or, put in technical terms, in the same phase. Such a surface is known as a wave front. After another interval, the disturbance will have travelled on to A′B′C′, and this will have become the front of the wave. Light energy starting from O is, after a time, distributed over the surface ABC, and later, after another interval of time, over A′B′C′. If the medium in which the light is travelling is isotropic, that is, has identical properties in all directions, the speed of the light will be the same whatever be the direction of its motion, and it is easily seen that the surface ABC and A′B′C′ are both spheres with O as centre. If, however, the speed with which the light travels is different in different directions, as in a crystal, this is no longer the case; the wave front is no longer a sphere, but will take some other form depending on the properties of the medium.[1] Suppose, now, the source of light to be a long way off, the curvature of the portion ABC of the wave front with which we are dealing becomes less and less as the distance from the source is increased, and ultimately we arrive at a plane wave front, travelling always parallel to itself with a velocity which—in a crystalline substance—depends on the direction of its motion, but in an isotropic substance is a constant, independent of the direction.

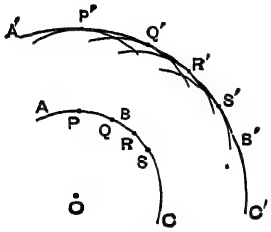

FIG. 1.

We may, however, regard the problem of the propagation of the waves from a rather different standpoint. At a given instant a certain state of disturbance exists over the surface ABC which, after a certain interval of time, has given rise to the disturbance existing over A′B′C′. How are these connected, and how can we pass from the conditions over ABC to those over A′B′C′? The answer to this question was given by Huyghens (Traité de la Lumière). Consider each point of ABC as the origin of a disturbance travelling outwards in a wave similar to that from the original source O, and draw the wave fronts corresponding to each of these points, P, Q, R, S, *Fig.* 1, and to the interval required by the principal wave to travel from ABC to A′B′C′. In the case of an isotropic medium these wave fronts will all be spheres; in a crystal they will have a more complicated form. In any case, however, it is possible to describe a surface which envelops or touches them all. According to Huyghens, this surface is the new position of the wave front; the disturbances due to the various secondary waves cancel each other everywhere, except on the envelope, while the resulting disturbance over the envelope is exactly that produced at the instant in question by the original wave-emanating front.

If we take, for simplicity, the case of a plane wave ABC in an isotropic medium, the secondary waves are clearly spheres of equal radii, with the various points of the wave as centre, while their envelope is a plane A′B′C′ parallel to ABC and at a distance from it equal to the radius of one of the secondary waves, that is, to the distance the disturbance has travelled in the interval of time under consideration.

This result is a consequence of the principle of Interference in Wave Motion, and though the arguments by which Huyghens supported it are not conclusive, it is shown in treatises on Theoretical Optics that the construction he gave is correct, and, when the form of the secondary waves is known, may always be applied to determine the form and position of the wave front, which represents the state of the primary disturbance.

We may also invert the procedure and apply it to finding the form of the wave surface diverging from a point in the following manner.

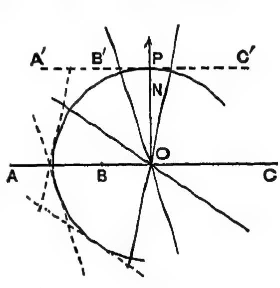

FIG. 2.

Consider a large number of plane waves all passing through the same point O, *Fig.* 2, but having various directions. After a given interval of time, t seconds say, each of these will have moved parallel to itself through a

[1] See "Light, Double Refraction of."

distance proportional to t and to the velocity of light measured in the direction in which the plane is moving. We shall have a series of planes corresponding with the original series but arranged round O—if the velocity of light in the medium is the same in all directions, these planes will all be equidistant from O—more generally they will be at varying distances, depending on the varying velocity of the light. In any case the planes will all envelop or touch a closed surface surrounding O, and this surface will determine the position which a disturbance emanating from O has reached in the time t seconds.

Moreover, if a wave front A′B′C′ corresponding to the wave ABC which passes through O touch the surface at P, the line OP constitutes the ray corresponding to this wave front and determines the direction in which a disturbance at O in the plane ABC is propagated, while ON, drawn at right angles to ABC, is the wave normal. If the medium is isotropic, the various planes such as A′B′C′ are all equidistant from O; the envelope of these planes, the wave front at time t, is clearly a sphere and the ray OP and the wave normal ON coincide.

In general this is not the case, and we have to distinguish between ON which determines the direction in which the wave travels, and OP the ray the direction in which the disturbance at O in the wave front ABC is propagated.[1] A distinction must also be drawn between the wave velocity, the velocity, that is, with which the wave front moves forward along ON, and the ray velocity, the velocity with which the disturbance travels along OP.

LIGHT, RECTILINEAR PROPAGATION OF

When the state of motion of an electrified particle is altered, a pulse of electric and magnetic force is emitted from the particle and travels out into space at a high velocity. This pulse carries with it a definite amount of electromagnetic energy.[2] If the motion of the particle be periodic the single pulse becomes a series of pulses. Energy is propagated outwards from the particle in waves; if the frequency in the waves lies within certain limits,[3] they affect the nerves of the eye and are known as light waves, producing the sensation of sight.

If we are dealing with a small luminous source O (*Fig.* 1) in an isotropic medium, the waves travel outwards in spheres from O. Let BAC be the position of a wave front at a time t. After an interval of time the light reaches an eye at E. The effect at E is due to the disturbance which at the previous time t existed over the surface BAC, and may be found by calculating the effect due to

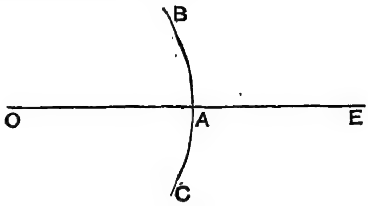

Fig. 1.

each element of that surface and taking the sum.[4]

But the eye does not recognise the surface BAC as the source of the light; it appears to come in a straight line from O, and the only portion of BAC which is effective in illuminating E is the portion A which lies directly between O and E. This rectilinear propagation is, it can be shown, a direct consequence of the fact that the wave-length of light is very small compared with the other distances concerned; it ranges from $\cdot 8\mu$ in the red[5] to $\cdot 4\mu$ in the violet. While the complete proof of this is a question of complicated mathematics, the following argument will indicate in a general way the reasons for it.

Imagine the source to be at a long distance behind the wave so that the portion of the spherical wave considered is practically plane. Let EA (*Fig.* 2), drawn perpendicular to the

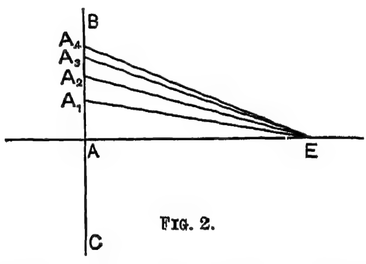

Fig. 2.

wide front BAC, be equal to a, and let λ be the wave-length. Take a series of points A_1, A_2, A_3 . . . on the waves at distances $a+\frac{1}{2}\lambda$, $a+\lambda$, $a+\frac{3}{2}\lambda$, . . . etc., from E, and describe a series of circles on the wave front with centre A and radii AA_1, AA_2, etc., thus dividing the front into a series of zones or rings. These are known as half-period elements. The disturbance which reaches E from A_1 is opposite in phase to that from A and therefore interferes with it; that from A_2 is in the same phase as that from A but opposite to that from A_1; thus, on the whole, the

[1] See "Light, Double Refraction of."
[2] See "Wireless Telegraphy," § (1), Vol. II.
[3] "Eye, The," § (6), etc.

[4] See "Light, Propagation of."
[5] The value of μ is 10^{-6} metres.

effect of the second half-period element is opposite to that of the first, while that of the third is of the same sign as the effect from the first. We may thus write the effect at E as

$$m_1 - m_2 + m_3 - \ . \ . \ ., \text{etc.}$$

The quantities m_1, m_2, etc., will be proportional to the areas of the consecutive half-period elements; they will also depend on the angles between the lines EA_1, EA_2, etc., and the direction of propagation, and will fall off slightly as these increase, while the increasing distance of each element from E will lead to the same result. Now to find the outer radius AA_n of any ring we have

$$EA_n^2 = AA_n^2 + b^2,$$

$$AN_n^2 = \left(b + \frac{n\lambda}{2}\right)^2 - b^2 = bn\lambda + \frac{n^2\lambda^2}{4}$$
$$= bn\lambda \text{ approximately,}$$

since λ^2 may be neglected.

Thus the area of the nth ring is given by $\pi(AA_n^2 - AA_{n-1}^2)$, and this is equal to $\pi b\lambda$, which is the same for all the rings.

Thus to our approximation, so far as the areas of the rings go, the quantities m_1, m_2, etc., representing the amplitudes of the disturbances at E due to the consecutive rings are equal; they decrease, however, in consequence of the increase of the angle AEA_n and of the distance EA_n as we get further from A. Thus in our series

$$S = m_1 - m_2 + m_3 \ . \ . \ . \ ;$$

the terms gradually decrease, but the difference between consecutive terms is small. The sum of such a series can be shown to be half the first term, for

$$S = \tfrac{1}{2}m_1 + \tfrac{1}{2}\{(m_1 - m_2) - (m_2 - m_3) + (m_3 - m_4) \ . \ . \ . \ \};$$

and the quantity within the bracket {. . .} is negligibly small, since each term is very small and the terms are alternately positive and negative.

Thus the amplitude of the disturbance at E due to the whole wave is just half that due to the first half-period element; the effective portion of the wave is limited to a small area about the point in which it is cut by the line joining the eye to the source of light. Light travels in a straight line from the source to the eye.

LONGITUDE, DEFINITION OF. See "Surveying and Surveying Instruments," § (5).

LUMEN: the unit of luminous flux. See "Photometry and Illumination," § (2).

LUMETER: a portable illumination photometer. See "Photometry and Illumination," § (62).

LUMINESCENCE OF LUMINOUS COMPOUNDS, CAUSE OF. See "Luminous Compounds," § (7).

LUMINESCENT MATERIALS, USES OF. See "Luminous Compounds," § (8).

LUMINESCENT SUBSTANCES, light emitted by, when exposed to α-rays; particularly zinc sulphide. See "Luminous Compounds," § (2).

LUMINOUS COMPOUNDS

THE discovery of self-luminous compounds dates back to the days of alchemy. They were originally prepared at Bologna by calcining crystals of barium sulphate with organic matter such as flour. This operation converted the sulphate into the sulphide which after exposure to daylight appears luminous when placed in the dark. The salt was known as "Bolognian phosphorus" owing to its similarity as regards luminescence to phosphorus which was discovered before it. Another luminous compound was prepared by roasting oyster shell with sulphur. This yielded calcium sulphide and was known as "Canton's phosphorus." This salt was greatly improved by Balmain, who found that very minute quantities of other substances such as bismuth mixed with it added greatly to its luminosity. This substance emits a bluish light for several hours after exposure to light. It was first employed about 1877 on watch and clock dials, but was practically discarded about twenty years ago, largely

for the reason that it was necessary to expose the article to light to render the luminous paint effective.

§ (1) Radioactivity.—After the discovery of radium and other radioactive substances it was found that the rays from these substances were capable of exciting certain materials to the emission of visible light, even when those materials were not previously exposed to light. Becquerel[1] examined the luminescence produced in a number of materials when exposed to the rays from radium. The substance to be studied was placed in the form of powder above the radium on a thin sheet of mica. The following table shows the relative intensities of the luminescence excited in various substances:

Substance.	Intensity.	
	Without Screen.	With Screen of Black Paper.
Hexagonal zinc blende .	13·35	0·04
Barium platino-cyanide	1·99	0·05
Diamond	1·14	0·01
Double sulphate of uranium and potassium	1·00	0·31
Calcium fluoride . .	0·30	0·02

The values of the intensities given in the second column are those when the rays from the radium fall on the powder after passing through the thin sheet of mica supporting the powder. The mica sheet is so thin that only a small percentage of the α-rays emitted by the radium is absorbed. The intensity of the luminescence produced by the rays after passing through a sheet of black paper in addition to the mica is shown in the last column and is in each case given relative to that without the screen taken as unity. The sheet of paper is sufficiently thick to absorb most of the α-rays. It will be observed that there is a great diminution in luminosity when the rays are passed through the paper, which shows that the luminescence produced without the screen is mainly due to the α-rays. The material which shows the greatest effect is zinc sulphide—so-called "Sidot's hexagonal zinc blende." This gives by far the greatest luminescence of all materials hitherto examined when exposed to rays from radium.

§ (2) Luminescent Substances.—The light emitted by different materials when exposed to α-rays differs very markedly. Zinc sulphide preparations have a yellowish-green hue; willemite gives a very bright green hue; calcium tungstate has a bluish-green tint; cadmium phosphate a decided red colour. Calcium sulphide is very similar to willemite, but its phosphorescence is more persistent; calcium salicylate is similar to calcium tungstate.

[1] *Comptes Rendus*, 1899, cxxix. 912.

Some of these substances become luminous under the action of X-rays and ultra-violet light, but the effect due to these rays gives no definite guidance as to the effect to be expected when exposed to the rays from radium. For instance, the double sulphate of uranium and potassium is more luminous than hexagonal zinc sulphide under the action of X-rays, but the reverse is true of radium rays; under the influence of these rays calcium sulphide gives a blue luminescence, but is hardly affected by X-rays. Hence substances which are very luminescent under the action of X-rays do not necessarily produce the brightest luminous mixtures when radium is used.

The luminosity of zinc sulphide, and in fact that of all the other responsive salts, depends upon the state of its purity. Very pure zinc sulphide shows but little luminescence under the action of the rays from radium. It requires a trace of an impurity in it to produce the best effect. The luminosity depends upon the nature and the amount of this impurity—the colour of the luminescence also changes as the impurity is varied. There are therefore grades of zinc sulphide, depending upon the nature and amount of impurity present, which vary greatly in their response to the rays.

To test the suitability of any given material as a base for a luminous compound it is necessary either to add radium directly to the substance and compare the resulting luminosity with that of a good grade of zinc sulphide or else to bring the α-rays to play on the materials in a manner similar to that employed by Becquerel in his original investigation. The following method of examination is due to Viol and Kammer[2] and has been found very satisfactory. A plate of polonium about 20 millimetres in diameter is prepared which serves as an intense source of α-rays. With a suitable polonium plate a superficial luminescence can be obtained in zinc sulphide equal to that obtained by the addition of several hundred microgrammes of radium element per gramme of zinc sulphide. By holding this plate over two adjacent specimens of zinc sulphide or other material it is possible to determine with ease and rapidity the relative values of their α-ray luminescence.

At present the responsive base most commonly used for luminous compounds is zinc sulphide and the luminosities of other compounds are usually referred to that of a standard grade of this material.

§ (3) Preparation of Zinc Sulphide Luminous Compound.—There are two methods[3]

[2] *Am. Electrochem. Soc. Trans.*, 1917, xxxii. 381.

[3] The writer is indebted to Mr. F. H. Glew for details of these methods of preparation.

employed of mixing the radium salt with the sulphide, which may be called the dry method and the wet method respectively. Each of these methods has its own advantages, but of the two the latter is the more satisfactory.

(i.) *The Dry Method.*—Suppose it is desired to make a luminous compound containing a specified amount of radium per gramme of compound. A tube of known radium content is taken and its contents transferred into a well-polished agate mortar. The amount of zinc sulphide to be mixed with this quantity of radium to make a compound of the required strength is weighed out and placed in a watch-glass near at hand. When transferring the radium from the tube to the mortar it is difficult to remove all the salt, as some of it adheres to the walls of the tube even though the latter is tapped during the operation. Most of the remaining salt may, however, be removed by putting a little of the zinc sulphide into the tube and rubbing it on the inside walls by means of a small camel-hair brush. Only a very small quantity of the sulphide need be used for this purpose. The operation may be repeated five or six times so as to ensure that most of the material clinging to the walls is removed. Having now transferred the radium into the mortar it is ground for about twenty minutes into a fine powder. A small quantity of zinc sulphide is afterwards added, say about 1 gramme, and mixed with the radium by means of a spatula; no pressure is applied to the salt so as to preserve the zinc sulphide crystals, which should be kept as large as possible to obtain the best results. More sulphide is added and again thoroughly mixed with the mixture already in the mortar. If the quantity of zinc sulphide is not too large it may all be added little by little to the radium, stirring constantly and keeping about two grammes of sulphide in hand for final washings of camel-hair brush, spatula, and funnel used to transfer the compound from mortar to bottle. It is advisable not to fill the bottle too full so that the compound may be well shaken in it for final mixing.

(ii.) *The Wet Method.*—For this method it is necessary to use a radium salt which is soluble in water, the bromide or the chloride is suitable for the purpose. A tube containing a measured amount of one of these salts is taken and its contents dissolved in a known volume of distilled water with a trace of hydrochloric acid added to ensure that all the salt passes into solution. Suppose it is necessary to make a certain amount of luminous compound of a given strength. A volume of the solution containing the required amount of radium is measured out and placed in a shallow porcelain dish. If the volume of solution is greater than that necessary just to moisten the whole mass of the zinc sulphide required to make up the compound, it is advisable to evaporate off some of the water. Having reduced the volume of the solution the whole of the zinc sulphide is slowly added to it until all the liquid is absorbed. The dish is now placed in a water bath and allowed to remain there until the salt is thoroughly dry, occasionally lightly stirring the whole mass with a glass rod to break up any lumps that may be formed. When quite dry any small lumps may be smoothed out on a piece of ground glass by means of a flexible palette knife of gold, platinum, or bone, afterwards mixing thoroughly on the ground glass. Very little pressure should be used during this process, in order to avoid breaking up the zinc sulphide crystals. This method ensures that the radium is uniformly mixed with the sulphide and in this respect is superior to the dry method.

The dry method of preparation is very useful in the case of salts that are insoluble or only slightly soluble in water, but the wet method is more accurate. Also, whereas a given quantity of luminous compound of any desired strength can be readily made by the latter method, the quantity of compound of given strength which can be made by the former method depends upon the amount of radium which the tube to hand contains.

§ (4) Application of the Compound to Dials, etc.—The radium compound can be applied to dials, etc., by mixing the powder with some binding material such as celluloid, crystal, or copal varnish. The best method of mixing is to place a little heap of the compound in the form of powder in the middle of a watch-glass, and then to add a few drops of turpentine to the base of the heap. The turpentine is drawn up by capillarity into the body of the powder driving the air out in front of it. Varnish is then added, the minimum possible quantity being used, and the whole thoroughly mixed with the brush which is finally going to be used for the application of the paint. It is most readily applied by means of a fine sable brush. In painting a dial, for instance, successive coats of the paint are applied, each coat being allowed to dry thoroughly before putting on the next. It will be seen later that the addition of the varnish cuts down the luminosity of the powder by about 75 per cent even though the minimum amount of varnish be employed in the mixing. It is important, therefore, to keep the amount of varnish as small as possible. If the object painted is not protected by a glass cover or by some other means, it is advisable to give it a final coat of varnish for a protection. When the paint is to be applied directly to silver, iron, brass, or copper, a preliminary

coating of zinc white mixed with the varnish should be given. It is inadvisable to use white lead for this purpose because zinc sulphide reacts with this compound producing a dark sulphide which will reduce the luminosity of the paint.

Painted surfaces should not be submitted to measurement of luminosity for at least seven days after the final coat of varnish has completely dried. The manipulation of the compound in powder and liquid form permits the escape of emanation, the presence of which enhances the luminous effect; after a time this again accumulates, but it does not reach a state of radioactive equilibrium on account of the porosity of the varnish. A sufficient amount, however, is held by the varnish to give a very appreciable increase in the luminosity after a few days' time.

§ (5) Measurement of Radium Content.—The radium content of a luminous compound is usually measured by one of the γ-ray methods (see under "Radium"). The compound, after being made, is hermetically sealed in a glass tube and put aside for about four weeks before it is compared with the radium standard. During this interval emanation is accumulating and this reaches a state of radioactive equilibrium with its products in about a month's time. The curve shown in *Fig.* 1 shows the

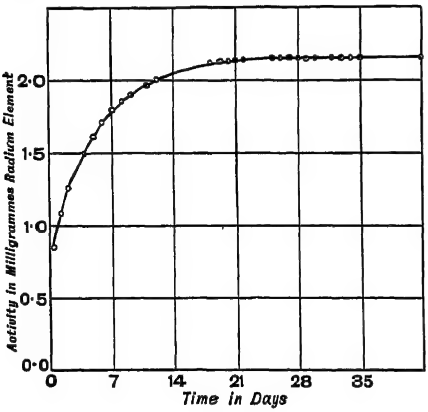

Fig. 1.

increase of the γ-ray activity of a tube of radium compound prepared by the dry method from the day it was sealed up until it reached a state of radioactive equilibrium. The amount of radium per gramme of compound is generally small and it requires a few grammes of the compound in order to carry out an accurate comparison with the standard. On this account the γ-rays emitted by the radium in the compound have to pass through a considerable thickness of material before they leave the tube, and the absorption taking place has to be corrected for in deducing the true radium content from the actual observations. Suppose that the tube containing the radium compound is cylindrical. Let I be the measured intensity of the γ-radiation emitted and I_0 the intensity if no absorption had taken place. Neglecting the correction due to the obliquity of the rays it can be readily shown that [1]

$$\frac{I}{I_0}=\frac{1}{\mu a\sqrt{\pi}}\sum_{r=1}^{r=\infty}(-1)^{r+1}\frac{(2\mu a)^r}{\underline{|r+1}}\cdot r\cdot\frac{\Gamma r/2}{\Gamma(r+1)/2}$$

$$=C_0+C_1(\mu a)+C_2(\mu a)^2+\ldots,$$

where μ is the coefficient of absorption of the rays per centimetre thickness of the compound and a the radius of the tube in cm.

The values of the constants C_0, C_1, C_2 . . . are given in the following table:

Coefficient.	Value.	Coefficient.	Value.
C_0	+1·000000	C_7	−0·001642
C_1	−0·848826	C_8	+0·000347
C_2	+0·500000	C_9	−0·000067
C_3	−0·226354	C_{10}	+0·000012
C_4	+0·083333	C_{11}	−0·000002
C_5	−0·025869	C_{12}	+0·000000
C_6	+0·006944		

The mean value of the absorption coefficient of the rays in zinc sulphide in the powdered form may be taken as 0·10 per cm. Also the absorption coefficient of the rays in soda glass is 0·10 per cm., so that we have the following table giving the ratio of the true to the apparent or measured radium content for tubes of different external diameters:

External Diameter of Containing Tube. Cm.	$\frac{\text{True Content.}}{\text{Apparent Content}}$
0·5	1·02
1·0	1·04
1·5	1·065
2·0	1·09
2·5	1·11
3·0	1·13

§ (6) Luminosity.—The luminosity of radium compound is measured by the photometric method.[2] The luminosity falls off with time. This loss of brightness is not due to any change in the radium, because it takes about 1700 years for the radium to decay to half value. The cause is to be sought for in the deterioration of the zinc sulphide, brought about by the continued bombardment of the crystals by the α-particles.

(i.) *Rate of Decay of Luminosity of Dry Material.*—An extensive investigation of the

[1] See Owen and Fage, *Phys. Soc. Proc.*, 1921, xxxiv. I. 27.
[2] See "Photometry and Illumination," § 125.

loss of brilliancy of radium compound has been carried out by Paterson, Walsh, and Higgins.[1] *Fig.* 2 is a curve which shows the variation with time of the luminosity of a sample of compound containing 0·2 mgm. radium element per gramme. The same type of curve is obtained whether the sample is prepared by the dry or by the wet method. After attaining its maximum value at the end of about 10 to 20 days after mixing the luminosity begins to decrease, at first very gradually and then more rapidly, until, after a period of about six to seven weeks from the date of mixing, the rate of decay appears to obey an exponential law, that is, the ratio of the rate of decay of luminosity at any time to the luminosity at that time is constant, so that if B is the luminosity at any time t, and B_0 the initial luminosity, then $B = B_0 e^{-kt}$, where k is a constant. At the end of about 200 days, however, the luminosity begins to diminish at a slower rate than that to be expected from the above law. This

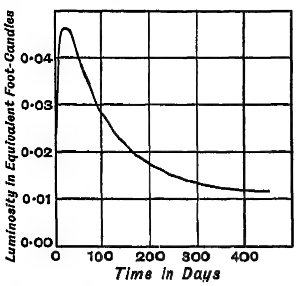

FIG. 2.

would indicate that there is an effect superposed on the normal decay operating in the reverse direction, which becomes relatively more and more important as the luminosity becomes smaller. After about 500 days the luminosity attains a value which is sensibly constant. This period, however, is not the same for all compounds, as in some the rate of decay diminishes more rapidly than in others.

(ii.) *Effect of Radium Content.*—The effect of the amount of radium present per gramme of compound on the rate of decay of luminosity is shown in *Fig.* 3. The curves refer to two samples of compound prepared at the same time with an identical quality of zinc sulphide, the one sample (top curve in figure) containing twice as much radium per gramme as the other. The initial brightness is approximately in the direct ratio of the radium content, but the rate of decay of compound of smaller content is slower, so that the ratio of the luminosities of the two samples gradually approaches unity as time goes on. Hence if a compound is to be used for a long period of time, there is very little advantage to be gained, except from the point of view of initial brightness, by increasing the radium content beyond a certain value. For short-period use, say three to four months, the radium content may

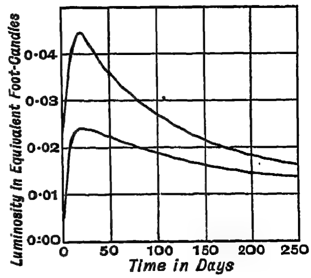

FIG. 3.

be usefully as high as 0·2 milligramme of radium element per gramme of compound. If the compound is likely to be required for more than six months, the use of a compound containing more than 0·1 milligramme of radium element per gramme of compound can only be justified by the need of greater brilliancy during the early part of the life.

(iii.) *Effect of Thickness.*—The effect of thickness of material on the luminosity is shown[2] in *Fig.* 4. The curves refer to a compound containing 0·15 milligramme radium element per gramme. When freshly made the ratio of the luminosity of a thickness of 0·3 mm. of compound to that of a thickness of 1·5 mm. is 0·63 (curve A). After an interval of 100 days (curve B) this ratio increases

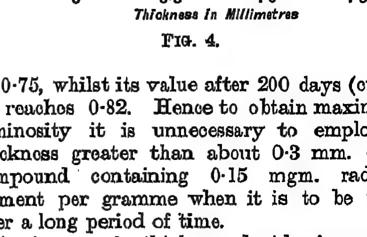

FIG. 4.

to 0·75, whilst its value after 200 days (curve C) reaches 0·82. Hence to obtain maximum luminosity it is unnecessary to employ a thickness greater than about 0·3 mm. of a compound containing 0·15 mgm. radium element per gramme when it is to be used over a long period of time.

An increase in thickness, besides increasing up to a certain point the initial brightness, also tends to accelerate the decay of luminosity—the effect is similar to that of increasing the

[1] *Phys. Soc. Proc.*, 1917, xxix. 215.

[2] Clinton, *Illum. Eng.*, 1918, xi. 260.

percentage amount of radium in the composition. This can be explained by the fact that in the greater thicknesses the front layers of material will receive additional bombardment from the radium in the deeper layers, and will therefore glow brighter, but have a shorter life, than if a thinner layer of material were used.

(iv.) *Rate of Decay of Luminosity of Varnish Material.*—The above results apply to luminous compounds in the dry state. When mixed with varnish and applied to dials, etc., the rate of decay of luminosity is different. The results obtained with six metal dials used for aeroplane instruments are given in the following table:

Dial.	Initial Luminosity (per cent of Standard).	Luminosity after Twelve Months (per cent of Standard).	Decay of Luminosity (per cent of Initial Luminosity).
1	94	59	63
2	82	45	55
3	94	57	61
4	63	33	52
5	91	39	43
6	52	24	46
		Average . .	53

The dials were all ordinary metal dials painted with a matt black surface, and having the luminous compound laid on in fine lines about 0·2 mm. to 0·3 mm. high to mark the graduations and figures of the dial. They were painted with different samples of luminous compound containing 0·2 mgm. radium element per gramme.

The rate of decay of luminosity of the dials is noticeably lower than that of the compound before application, the half-value period of the painted dial being about twelve months, whereas that of the dry powder is only about five months (see *Fig.* 2). The initial luminosity of the painted dial is also smaller, being of the order of $\frac{1}{3}$ or $\frac{1}{4}$ of that of the compound before application. The radium content of the varnish material may therefore with advantage be higher than that of the dry material. For short-period use it may be advantageous for some purposes to use varnish material containing as much as 0·3 mgm. or 0·4 mgm. radium element per gramme, but for long-period use the most suitable radium content is 0·2 mgm. per gramme, and maximum luminosity may be obtained by using one gramme of compound to paint an area of about 30 square centimetres.[1] It is important that the interval between the preparation of the compound in the dry state and its application to the dial should be as short as possible, as the deterioration in luminosity takes place from twice to three times as rapidly in the powder as in the painted dial. These differences between the dry and varnish compounds are due to the fact that the varnish impedes the activity of the α-ray bombardment from the radium and thereby causes an effective lowering of the radium content of the compound with a subsequent reduction of both the initial luminosity and also the rate of decay.

§ (7) Cause of Luminescence of Luminous Compounds.—Marsden[2] studied the effect of continued bombardment of α-particles on a screen of zinc sulphide and found that the actual number of scintillations produced by a constant source of α-particles changes very little with time of exposure, but that the brightness of the scintillations rapidly diminishes. Pure zinc sulphide does not exhibit the scintillation effect, but a salt containing an amount of impurity of the order of 1 per cent does. Assuming then that the scintillations are due to the presence of this impurity, only a small fraction of the total number of molecules are concerned in the effect. Rutherford[3] explained the scintillation effect by assuming that the impurity causes the presence of a number of "active centres" in the salt which are on the average uniformly distributed among the inactive molecules. When an α-particle strikes an active centre the latter is dissociated and emits light, but it is no longer effective in producing light when struck again by an α-particle. The effect of the continued bombardment by α-particles is thus to destroy gradually the active centres. Since probably many thousands of these centres initially lie in the path of the α-particle the effect of a continued bombardment will not cause an appreciable diminution in the number of scintillations, but it will diminish their intensities, for the intensity of a scintillation on the average will be proportional to the number of active centres remaining. These conclusions agree with the experimental results of Marsden. The theory in its simple form fails, however, to represent exactly all the facts which later experiments have brought to light. For instance, Paterson, Walsh, and Higgins (*loc. cit.*) found that the luminosity of a luminous compound at first rises rapidly to a maximum and then decreases according to an exponential law for about 200 days. After that time the rate of decrease of luminosity becomes slower and slower, the brightness tending to approach a limiting value which is not zero. Rutherford's theory gives a good approximation for the early period of decay, but fails increasingly at the later period. The theory has been extended by Walsh,[4] who assumes that the active centres which have been struck by α-particles, and according

[1] See Glew, *Opt. Soc. Trans.*, 1916, xvi. 276.

[3] *Ibid.*, 1910, lxxxiv. 561.

[4] *Ibid.*, 1917, xciii. 550.

to Rutherford's theory are put completely out of action from the point of view of luminescence, commence to recover according to an exponential law. With this modification the theory represents the observed facts much more accurately.

§ (8) Uses of Luminescent Materials.—Daylight luminous paints can only be used in exposed situations so that daylight can freely be absorbed to be given out again at night. Some use has been made of this class of luminous paint in shipping—luminous life belts are employed which may be clearly seen at night when thrown into the water; floating buoys can also be distinguished at night.

Much more use can be made, however, of luminous paints which are independent of daylight. Paper, porcelain and metals, dials of all sorts bearing figures and lines, are now used. In the case of some instruments, such as those used in aeroplanes, the requirements of luminosity are most important and outweigh other considerations as to cost and length of effective life. For such purposes grades of luminous paint are prepared which give the highest initial brightness. These have a high radium content and consequently a short effective life. For many other purposes such as that of illuminating marching compasses, dials of wrist watches, etc., a paint of lower initial luminosity is prepared, and this has the advantage of a lower cost and a longer life. For watches, push buttons, etc., of the better grade an effective life of ten years or more is desirable, and assuming that a luminosity of 25 per cent of the original is still satisfactory, a luminous paint containing about 100 microgrammes of radium element per gramme of compound should answer the requirement. Compounds with more radium than this would have a shorter effective life, and compounds with a smaller proportion of radium a longer effective life.

During the war much use was made of radium luminous compound in the dry powder form for gun-sights, to facilitate accurate night-firing. For this purpose the powder was sealed up in small flat glass tubes, their internal bore from back to front not exceeding about 0·4 mm., their other dimensions depending upon the class of instrument to which they were attached. For illuminating at night the cross wires of telescopic gun-sights attached to big guns, the powder was placed in glass tubes of about 0·5 mm. bore bent into circular forms to fit the metal tube of the gun-sight and situated near the plane of the cross wires. This device did away with the necessity of having glow-lamps for illuminating purposes with the attendant risk of detection by the enemy.

MAGNETIC ROTATORY POWER

§ (1) Faraday's Experiments.—The phenomenon of *magnetic rotation* of the plane of polarisation of light was discovered by Faraday in 1845, and described by him in a paper "On the Magnetisation of Light."[1] A ray of light issuing from an Argand lamp was polarised in a horizontal plane by reflection from a surface of glass, and the polarised ray passed through a Nicol's eyepiece revolving on a horizontal axis. Between the polarising mirror and the eyepiece two powerful electromagnetic poles were arranged; they were separated from each other by about 2 inches in the direction of the line of the ray, which passed either by the side of them or between

[1] *Phil. Trans.*, 1846, p. 1.

them in such a way that the ray was nearly parallel to the magnetic lines of force. A piece of dense optical glass (borosilicate of lead), which he had described in 1830, about 2 inches square and 0·5 inch thick, was placed lengthways between the poles. The eyepiece was turned to extinguish the polarised ray, but this was transmitted again when the current was passed through the electromagnet. The image of the lamp flame was, however, extinguished again by rotating the eyepiece to the right or to the left according to the direction of the current in the electromagnet.

The rotation was found to be proportional to the intensity of the magnetic force and to the length of the column of glass exposed to it. Smaller rotations were produced by other glasses, by some crystals, by water, alcohol, ether, various oils, and a large range of aqueous solutions, but no action was detected in the case of gases. When the medium possessed a natural rotatory power, the magnetic rotations were superposed upon (*i.e.* added to or subtracted from) the natural rotations.

§ (2) Apparatus and Methods of Measurement. — The type of apparatus used for

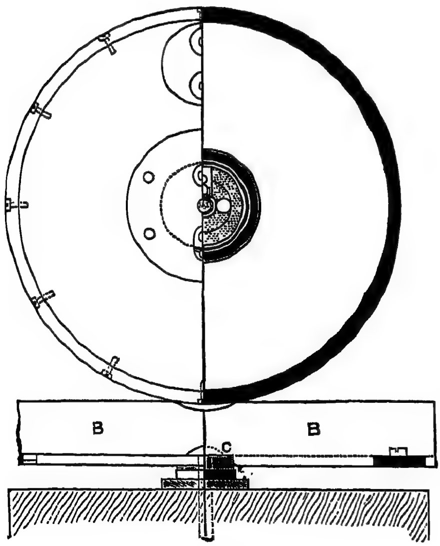

Fig. 1.

measurements of magnetic rotatory power is shown in *Figs.* 1 and 2, whilst the electrical connections are shown in *Fig.* 3.[1]

[1] *Trans. Chem. Soc.*, 1913, ciii. 1322 and 1331.

A coil of insulated copper wire A is wound in the form of a bobbin on a brass tube provided with a thin lining of cold water to

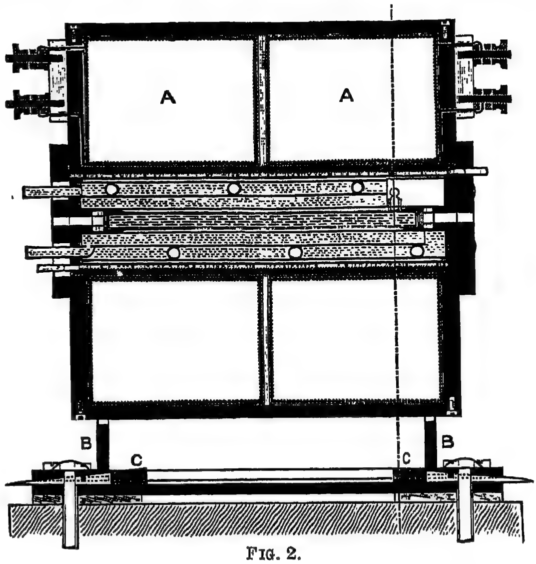

Fig. 2.

protect the material under examination from the heat of the magnet. The coil is enclosed by iron (or mild steel) end-pieces and a length of iron pipe; and movable pole-pieces are provided to lead the lines of force to the axis of the magnet. The magnet is mounted on rails, BB, so that it can be rolled away from the axis of the polarimeter, and wedges CC are provided for bringing the axis of the magnet into line with the axis of the polarimeter.

The substance to be examined (usually a liquid) is enclosed in a double water-jacket, connected to a thermostat. A correction must be applied for the discs at the end of the tube, since these produce a magnetic rotation of light; this correction is usually determined by introducing half-a-dozen discs together, and calculating the effect for a single disc; a group of discs, or a short rod of glass, may also be used to explore the strength of the magnetic field along the axis. In view of the variations which are usually found, it is convenient to standardise the apparatus by making measurements of the magnetic rotation produced by a tube of water, and using this as a basis of comparison for other liquids.

As the resistance of the magnet increases with rising temperature, a series of resistances is provided (*Fig.* 3) which can be cut out as the magnet becomes hot. Casual variations in the voltage on the mains are compensated by a sliding resistance and a carbon resistance, the constancy of the current being checked by

a null method, as shown in *Fig.* 3. Measurements are made with the current in each direction, the normal value of the readings

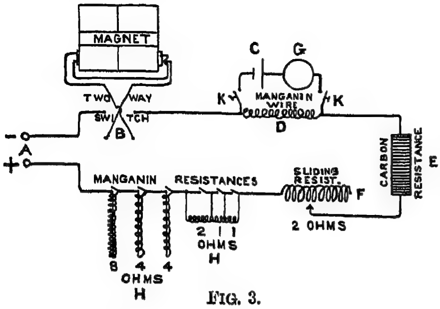

FIG. 3.

in the apparatus shown being about ±5°, or 10° in all.

In calculating the *molecular magnetic rotation* of a liquid, the formula generally used is

$$\text{Mol. rot.} = \frac{r \times M}{d} \div \frac{r_0 \times M_0}{d_0},$$

where r and r_0 are the observed rotations for the substance and for water, M and M_0 are their molecular weights, and d, d_0 their densities.[1]

§ (3) INFLUENCE OF THE MEDIUM.—The molecular rotations of a large number of compounds have been investigated, especially by Sir William Perkin.[2] The main result of these researches, which need not be described in detail, is to show that the molecular magnetic rotatory power of a substance is essentially an *additive property*, made up of the sum of the *atomic rotations* of the constituent atoms. This property is therefore closely analogous to the *molecular refraction* of a compound, but differs from it in that the influence of chemical constitution is more pronounced. Measurements of magnetic rotatory power can, therefore, be used to throw light on the constitution of compounds of doubtful molecular structure, *e.g.* in cases of dynamic isomerism, where ordinary chemical methods are not available.

§ (4) RELATION BETWEEN REFRACTION AND MAGNETIC ROTATION.—Drude[3] has deduced the following relationship. If the refractive index n can be represented with sufficient accuracy by the equation

$$n^2 = a + \frac{b}{\lambda^2 - \lambda_1{}^2},$$

then the magnetic rotation can be represented by the formula

$$\delta = \frac{1}{n}\left(\frac{a'}{\lambda^2} + \frac{b'\lambda^2}{(\lambda^2 - \lambda_1{}^2)^2}\right).$$

This formula was tested with satisfactory results in the case of carbon disulphide and of creosote (*sic*), but in view of the slender character of the data used for the test, and the fact that two arbitrary constants, a' and b', are available for adjustment, in addition to the three constants a, b, and λ, used to express the refractive power, the value of this formula does not appear to be very great.

§ (5) NATURAL AND MAGNETIC ROTATORY DISPERSION.—Six years after Faraday had discovered the "magnetisation of light," Wiedemann[4] made comparative measurements of the natural and magnetic rotations in turpentine for five wave-lengths in the solar spectrum, and concluded that the two rotations were proportional throughout the spectrum. This relation, which is generally known as *Wiedemann's Law*, has been verified in the case of quartz[5] and of sodium chlorate,[6] and is perhaps generally true for optically active crystals. In the case of optically active liquids, however, it generally fails, and the approximate agreement between the magnitude of the two dispersions, which is occasionally observed, is probably only a coincidence.[7] It is, however, important to notice that the simple dispersion formula

$$\alpha = \frac{k}{(\lambda^2 - \lambda_0{}^2)},$$

which serves to express the natural rotatory dispersion in a wide range of compounds, can be used equally well for magnetic rotatory dispersions, although its validity cannot be subjected to the same drastic tests, on account of the small magnitude of the readings which are usually obtained. Until more exact measurements are available, this simple two-constant formula may be used to represent the data for magnetic rotatory dispersion, in preference to Drude's formula, which involves five constants and demands a knowledge also of the refractive dispersion of the compound.

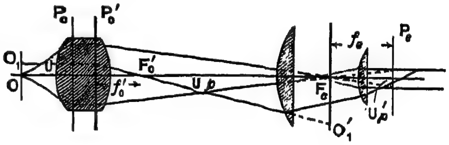
MICROSCOPE, OPTICS OF THE

I. INTRODUCTION

THE compound microscope consists of an objective which forms an inverted real image of the object under observation, and of an eyepiece by which the primary image is further magnified and either presented to the eye of the observer as an inverted virtual image, or projected upon a screen or photographic plate as an erect real image.

As the instrument can be usefully employed only within that part of its field for which the aberrations are sufficiently well corrected, the effects produced may be legitimately discussed with the aid of the first approximation theory of Gauss and Abbe; for as all the rays from any one object-point must pass very nearly through the conjugate image-points, the latter may be definitely located by the intersection of any two suitably selected rays starting from the object-point, and any one single ray traced from the object-point must be a geometrical locus of the image.

Referring to the accompanying diagram which represents an object OO_1 observed



through an objective of which only the outside surfaces are indicated, and through an eyepiece of the usual Huygenian type, it is assumed that the instrument has been focussed so that the rays from the axial object-point O, if not intercepted, would produce a primary image at F_e, the first or anterior principal focus of the eyepiece, and that the further refraction of these rays by the eyepiece lenses would therefore lead to their emergence from the eye-lens as a bundle of parallel rays which would be interpreted by the observer as coming from a very distant virtual image-point. To determine the image of the extra-axial object-point O_1, a ray

starting from this point in a direction parallel to the axis of the instrument is selected. By the general theory of lenses referred to, such a ray will emerge from the objective as if it had proceeded without deviation to the second or upper principal plane P'_0 of the objective and had there been bent so as to go through the second or upper focal point F'_0 of the objective, the axial distance from P'_0 to F'_0 representing the equivalent focal length f'_0 of the objective. This ray represents a geometrical locus of the image, and as a perfect objective would give an image at right angles to the optical axis of the similarly orientated object OO_1, $F_eO'_1$ must be the primary image, and similar triangles with a common corner at F'_0 at once give its magnification as

$$M_o = -\frac{F'_oF_e}{f'_o}, \quad . \quad . \quad . \quad (a)$$

the minus sign being added in accordance with convention because the image is inverted.

F'_oF_e, which is thus disclosed as a very important dimension, is known as the "optical tube-length" of the microscope, to distinguish it from the usually not very different "mechanical tube-length," which is measured from the lower to the upper extremity of the actual metal tube of the instrument.

Equation (a) supplies the means of determining the equivalent focal length f'_o, and as this is one of the chief characteristics of an objective, the method must be briefly described. The actual size of the primary image can obviously be read off if the image is received *directly* on a divided scale or "eyepiece micrometer." If such a micrometer, of Ramsden form, is available, it can be used as it is. Usually, however, microscopes have only Huygenian eyepieces and a simple glass-disc micrometer which can be laid upon the internal field-diaphragm of any of these. In such a case the field-lens of the eyepiece to be employed *must* be removed; this will reduce the field and will cause a great loss of sharpness in the extra axial images, but this must be put up with, as the field-lens, if left in position, would greatly reduce the size of the primary image and would therefore utterly falsify the results. By observing a "stage micrometer" divided in the same unit of length as the eyepiece micrometer, M_0 may then be measured at any extension of the draw-tube. A first measurement should be made with the draw-tube completely pushed in; let the result be

$$M_o^{(1)} = -\frac{F'_oF_e}{f'_o}.$$

The right side of this equation contains two unknown quantities and cannot therefore be solved for f'_0. But if now a second measurement of M_0 is made with extended tube-length, F'_oF_e will obviously be increased by the amount of the extension D which can be measured by an ordinary scale, and a second equation will be obtained,

$$M_o^{(2)} = -\frac{F'_oF_e + D}{f'_o},$$

and combination of this (by subtraction) with the equation for $M_o^{(1)}$ gives at once

$$f'_o = -\frac{D}{(M_o^{(2)} - M_o^{(1)})}.$$

When the equivalent focal length is thus determined, the location of F'_0 may be ascertained by measuring directly the location of the eyepiece micrometer with reference to the upper end of the tube, and by calculating F'_oF_e from the equation of the first observation.

The location of the upper focal plane with reference to the lower end of the tube varies considerably in different objectives, especially in those of low power. This explains why objectives of the same equivalent focal length may give decidedly different magnifications when exchanged on the same mechanical tube-length. Opticians frequently misstate the focal length of low-power objectives deliberately in order to make the magnification produced by them agree with what is traditionally expected from given focal lengths. There is also a traditional custom of assigning to ordinary objectives of high power a longer focal length than they really possess—a nominal $\frac{1}{12}$ inch being usually a $\frac{1}{14}$ inch; disagreements up to 20 per cent between the directly measured and the stated focal length need not therefore be taken as indicative of errors in the measurements.

The eyepiece magnifies the primary image just as an ordinary magnifying glass magnifies a real object, and M_e may therefore be taken as equal to the quotient of the adopted distance of distinct vision (conventionally 250 mm. or 10 inches) by the equivalent focal length of the eyepiece; f_e may be determined by the method already described by temporarily attaching the eyepiece to the lower end of the microscope tube, or any of the usual optical bench methods may be used. The total magnification of the instrument will then be $M = M_0 \times M_e$. The total magnification may be determined directly by projecting the image of a stage micrometer upon a scale at the conventional distance of distinct vision from the eyepiece, or more strictly from the bright disc of light ("Ramsden circle") seen a little above the eye-lens; this may be done visually by looking with one eye at the image of the stage micrometer and projecting the latter by binocular vision upon a scale held at the conventional distance from the other eye, or a real image of the stage micrometer may be projected upon a white surface and measured. A very clever simplification of this process is due to Mr. E. M.

Nelson; it consists in determining once for all the apparent diameter of the field-stop of each eyepiece when projected at the distance of distinct vision by one of the methods already referred to. The total magnification of any objective at any tube-length is then obtainable by a single observation by noting how many divisions of a stage micrometer are embraced by the field of the eyepiece in use. Thus, supposing that the actual diameter of the field of the eyepiece had been found as 162 mm. at the conventional distance of 250 mm., and that a certain optical combination was found to cover the diameter of this field with ·257 mm. of a stage micrometer, the total magnification would be

$$\mathrm{M} = -\frac{162}{\cdot 257} = -631 \text{ times.}$$

As owing to the very sensible distortion of all eyepieces the magnification is not a very accurately defined number, this process is amply sufficient and is certainly by far the most convenient.

Abbe preferred a totally different way of viewing the magnifying action of the compound microscope. Referring to the ray traced in the diagram from the extra-axial object-point O_1, it is obvious that if the eye were placed at F'_o the objective would act as an ordinary magnifying glass (provided the focus be slightly adjusted) and present the object under an angle U_p. Therefore Abbe called the ratio of the distance of distinct vision to the equivalent focal length of the objective the "initial magnifying power" of the objective and used this number as a constant of the objective. Following the ray from O_1 further, it is seen that it emerges from the eyepiece at an angle U'_p with the axis; therefore the object is seen through the whole microscope under this increased angle, and looking upon this increase of the angular subtense of the image as the characteristic function of the eyepiece, Abbe called the ratio $\tan U'_p/\tan U_p$ the "angular magnification of the eyepiece" and determined the total magnification as the product of the initial magnification of the objective and of the angular magnification of the eyepiece. If the numbers are correctly determined, the resulting magnification is necessarily the same as that found by the older and more familiar method. The data supplied with the Zeiss apochromatic objectives and their compensating eyepieces are based on this system, which has been copied by other makers of lens systems of these types.

On the older and preferable system the change of magnification due to change of tube-length is attributed to the objective; on the Abbe system it falls upon the eyepiece, the 12-times compensating eyepiece for the Continental tube-length being, for example, optically identical with the 18-times eyepiece for the English tube.

The Gauss theory of lenses may be applied to the microscope as a whole by tracing parallel bundles of rays in both directions through the entire instrument and so locating its principal planes and focal planes. The compound microscope is then found to be equivalent to a concave lens of very short focal length, and this aspect supplies the simplest solution of the problem of visual depth of focus. By the Gauss theory a lens must have an equivalent focal length $f' = -\mathrm{L/M}$ in order to produce a magnification of M times at a distance L from its second focal plane, and the object must be placed at a distance $l = f'/\mathrm{M}$ from its first or anterior focal plane, in order to yield a sharp image. Elimination of f' from the two equations gives $l = -\mathrm{L/M}^2$. If L is put as the conventional least distance of distinct vision to which the usual magnification numbers are referred, *i.e.* L = −250 mm., the distance of the object from the first focal plane must be $l = -250/\mathrm{M}^2$. The normal eye can be accommodated for any distance up to infinity, and can therefore see objects *in* the first focal plane of the complete microscope. Therefore l represents the total range of distance of the object accessible to a normal eye without change of focal adjustment of the instrument. The depth of focus (as it is usually called) due to accommodation of the eye is therefore $= 250/\mathrm{M}^2$, or

at magnification 10: depth of focus 2·5 mm.,
at magnification 100: depth of focus ·025 mm.,
at magnification 1000: depth of focus ·00025 mm.

At high magnifications the depth of focus is thus shown to be an evanescent quantity, and the extremely high demands by microscopists as to delicacy and reliability of the fine adjustment of the focus is fully justified. It should be added that if the object is embedded in a medium denser than air the depth of focus is increased in direct proportion to the refractive index of the medium. A second part of the focal range of optical instruments, due to the finite wave-length of light, will be referred to subsequently. It is not sufficiently large to modify seriously the requirements as to delicate focal adjustment. On the other hand, it represents the only available latitude of focal adjustment when the microscopic image is projected upon a screen or upon a photographic plate.

The most important property of a microscope is its resolving power. The naked normal eye can see small objects, such as points or parallel lines when separated by a distance from centre to centre of about ·1 mm. The microscope greatly diminishes this least distance, and it soon became a matter of great

interest to define this increased resolving power, to discover the laws on which it depends, and to ascertain whether there is any definite limit to it. The most obvious conclusion from geometrical optics that this ought to be a mere question of magnifying delicate detail up to the size which the normal eye can appreciate was soon realised as being quite wrong. It was found that any given optical combination yielded additional detail only up to a certain moderate magnifying power, beyond which the image became coarser or more fuzzy, without disclosing any additional detail. Carefully conducted experiments then led to the conclusion that the resolving power of well-corrected microscope objectives grew very nearly in direct proportion to the angle between the extreme marginal rays which could enter an objective from any one object-point, and this angle (twice the angle U in the diagram) therefore became the recognised criterion of resolving power, and was adhered to until about 1873. In that year Abbe published the first short account of his researches on microscopic vision, which were based on the diffraction of light produced by the delicate structure of microscopic objects. He proved that the resolving power is strictly proportional to the *sine* of half the angle which up to then had been accepted as the criterion, but is further proportional to the refractive index of the medium in which that angle is measured. He introduced the now universally accepted term "Numerical Aperture" for the true measure of resolving power thus discovered and gave it the symbol NA, which is therefore defined by

$$\mathrm{NA} = \mathrm{N} \cdot \sin \mathrm{U},$$

if U is the angle of the most oblique ray which can enter the microscope objective and N the index of the medium in which the angle is measured. Abbe also introduced a convenient direct-reading instrument, the "Apertometer," by which the numerical aperture can be determined. In the case of "dry" objectives, *i.e.* those in which a layer of air intervenes between the object and the front lens, the NA may be accurately determined without any instrument by placing the tube of the microscope in a horizontal position, setting up two candles at a distance of about 50 cm. from the objective and moving them at right angles with the optical axis until the images of the flames are on the point of disappearing at opposite edges of the clear aperture of the objective under test as seen by the eye looking down the tube of the microscope. The triangle formed by the two flames and the focal point of the objective then obviously has the angle 2U at the latter point, and U can be calculated by measuring the sides of the triangle.

The resolving power resulting from the Abbe theory for regularly spaced lines or rows of dots is expressed by the formula

$$d = \frac{\frac{1}{2}\text{ wave-length}}{\mathrm{NA}},$$

in which d is the centre-to-centre distance of the lines or rows of dots and the wave-length is the usual tabulated one, measured *in air*. As NA = N . sin U, and as sin U cannot exceed unity, the formula shows at once that the only possibilities for increasing resolving power beyond that usually realised lie in either the use of light of very short wave-length (ultra-violet), or in embedding the object in a medium of the highest possible refractive index and designing the objective so as to admit the widest possible cone of rays in the embedding medium. Both possibilities have been explored by Zeiss, the first by microscopes containing only quartz and fluorspar lenses and working with nearly monochromatic ultra-violet light, the second by a few immersion objectives using monobromide of naphthalene (N = 1·65) as immersion and embedding medium.

II. Optical Design of Microscope Objectives

§ (1) Historical Notes.—Although John Dollond had discovered in 1757 how chromatically and spherically corrected telescope object-glasses can be produced by combining suitably curved crown and flint lenses, opticians did not succeed in usefully applying this principle to the small lenses required for the microscope until some fifty years later. The early small achromatic lenses were invariably composed of a nearly equiconvex crown lens and a nearly plano-concave flint lens and were at first not cemented together. Although the microscopic object is always located at the shorter conjugate distance, the telescopic practice of turning the convex side of an achromatic lens towards the object was mechanically copied, with the result that even the achromatised lens had to be severely stopped down in order to reduce spherical aberration and coma to tolerable magnitude. Charles Chevalier of Paris first pointed out the absurdity of this procedure, and a very considerable advance immediately followed the simple reversal of the lens. He also was one of the first opticians who cemented the two components together and thus greatly reduced the difficulty of both making and mounting the lenses with sufficient precision. A further extension of the power of microscope objectives was secured by placing several achromatic lenses one behind the other, but without any definite principle as to relative power and separation of the components.

A most important advance in this respect

is due to a highly gifted English amateur, J. J. Lister (father of the late Lord Lister), who discovered in 1830 that every achromatic lens of the externally plano-convex form, which at that time was exclusively used for microscope objectives, has two pairs of conjugate points for which it is free from spherical aberration. Purely by wonderfully accurate experimental trials on the microscope he located one of these pairs of "aplanatic points" as realised when the lens produces a real inverted image of some definite magnification. Having adjusted the instrument for the corresponding tube-length he then tried another lens of the same type placed at various distances in front of the first (between it and the object), and found that a distance could be found at which complete freedom from spherical aberration of the combination was again secured. Obviously the front lens then produced a sharp and erect virtual image of the object at the first aplanatic point of the back lens. The doublets produced in this way not only had the advantage of freedom from spherical aberration at a much larger aperture than had previously been found attainable, but could also be freed from coma in the outer part of the field by selecting a suitable ratio between the focal lengths of the components, and the field was very much flatter than with the close combinations previously used. The type originated by Lister is in fact so excellent that it is almost exclusively used to this day for the lower powers of the microscope; it must, however, be added that the freedom from spherical aberration of the two separated components is no longer adhered to, for it has been found that still better results, especially as regards the higher aberrations, are obtainable by combining a spherically under-corrected back lens with an over-corrected front lens. The Lister principle admits of repeated application, for a third lens may obviously be placed in front of a doublet so as to increase the magnification still further, and such triplets were very soon constructed under Lister's advice.

These triplets, however, have not survived. When the Lister type of doublet is found insufficient, which happens when the numerical aperture approaches the modest value of ·3, the optician now adopts a type originated by Amici, consisting of two over-corrected cemented back lenses and a simple thick plano-convex front lens. Whilst actually simpler than the Lister triplets, this type offers far superior possibilities of good correction of all the important aberrations and allows of raising the numerical aperture to ·8 or even ·85, which corresponds to the admission of a cone of rays from any one point of the object of an angular extent of 106° to 116°. The vast majority of ordinary high-power microscope objectives correspond to this Amici type, with occasional modifications such as a triple cemented back lens instead of the more usual binary form.

The final steps in the perfecting of the microscope objective are almost entirely due to Abbe, who was the first to apply rigorous computing methods to the problem.

§ (2) Ray-tracing Methods for Microscope Objectives. (i.) *Fundamental Formula.*—The angles of incidence and of obliquity of the rays passing through a microscope objective are so large—reaching 30° and more even in the lower powers—that analytical methods of approximation are almost useless for purposes of ray-tracing. This must be done by rigorous trigonometrical formulae in strict accordance with the law of refraction.

The formulae almost universally used for this purpose appear to be due to Bessel (Discussion of the Königsberg Heliometer, in *Astronomische Untersuchungen*, Königsberg, 1841), but the slightly modified form given below is that found in Steinheil and Voit's handbook of applied optics.

Referring to *Fig.* 1, let the ray entering a refracting spherical surface AP at P be defined

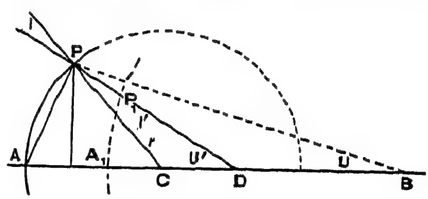


Fig. 1.

by its angle of obliquity U and by its intersection length AB, for which we introduce the symbol L. If C is the centre of curvature of the refracting surface and r its radius, simple trigonometry gives the angle of incidence CPB, with symbol I, by

$$\sin I = \frac{L-r}{r}\sin U. \qquad (1)$$

If we apply the same symbols, but distinguished by a dash, for the data of the refracted ray, the law of refraction next gives

$$\sin I' = \frac{N}{N'}\sin I. \qquad (2)$$

The angle at the centre of curvature ACP is exterior to both the triangle PCB formed by the incident ray and the triangle PCD formed by the refracted ray, hence

$$ACP = U + I = U' + I',$$

from which we obtain

$$U' = U + I - I'. \qquad (3)$$

The triangle PCD then gives the intersection length of the refracted ray

$$L' - r = \sin I' \frac{r}{\sin U'}, \quad . \quad . \quad (4)$$

$$L' = (L' - r) + r, \quad . \quad . \quad . \quad (5)$$

and the problem is solved.

An interesting and highly useful relation results by introducing the value of sin I given by (1) into (2), then this value of sin I′ into (4), namely,

$$(L - r)N \sin U = (L' - r)N' \sin U'. \quad . \quad (6)$$

The standard computing formulae may occasionally become objectionably inaccurate in the value of U′ found by them. U′ is found according to (3) by adding to the given U the change of direction of the ray $= I - I'$. If the angles of incidence and refraction are unusually large, as happens frequently at cemented contact surfaces and also in the front lenses of high-power objectives, then I and I′ are found by their sines or log-sines in a part of the table where a small change of the sine, and especially of its log, corresponds to a large change in the angle, and the latter becomes correspondingly uncertain. In such cases a more accurate value of $I - I'$ may be derived from the less accurate value of I and I′ obtained by (1) and (2) by a transformation of (2); by (2)

$$\frac{\sin I}{\sin I'} = \frac{N'}{N},$$

therefore $$\frac{\sin I - \sin I'}{\sin I + \sin I'} = \frac{N' - N}{N' + N},$$

and the formulae for sums and differences of sines give

$$\tan \tfrac{1}{2}(I - I') = \tan \tfrac{1}{2}(I + I')\frac{N' - N}{N' + N}. \quad . \quad (7)$$

The value of $I - I'$ obtained from this formula has, in the case of logarithmic calculation, only about one-third of the inaccuracy of the value obtained from (1) and (2) for glass-air refractions: in the case of contact surfaces the advantage is very much greater owing to $N' - N$ being then small compared to either N′ or N.

The accuracy of the L′ obtained from (5) will be insufficient when r is much larger than L′, because the quantity really determined directly from the data is $(L' - r)$, and if this is large, the usual logarithmic calculation will give only a few reliable decimal places and L′ will be uncertain accordingly. Moreover, there is no safeguard in the formulae against numerical errors, and as such an error at one surface will falsify the whole result, a reliable check is highly desirable. Both these desiderata are met in a most perfect manner by a simple formula proposed by Conrady: Draw the chord PA from the pole of the surface to the point of incidence. Triangle ACP is isosceles, and the angle at $C = U + I = U' + I'$, consequently the angle

$$APC = 90° - \tfrac{1}{2}(U + I) = 90° - \tfrac{1}{2}(U' + I').$$

The angles APB and APD between the chord and the incident and refracted ray exceed the angle APC by I and I′ respectively, and are therefore $90° - \tfrac{1}{2}(U - I)$ and $90° - \tfrac{1}{2}(U' - I')$ respectively. With these values the triangles APB and APD give at sight the check results

$$PA = L \sin U \sec \tfrac{1}{2}(U - I),$$

$$L' = PA \operatorname{cosec} U' \cos \tfrac{1}{2}(U' - I'). \quad (5) \text{ check.}$$

The value of L′ so found should agree within the limit of accuracy of the calculations with that by (5): as the value of L′ from the check formula is always more consistent with the corresponding value of U′, and usually also more accurate, the value of L′ found by the check should invariably be selected for retention. The value of PA found incidentally is also highly useful for other parts of the calculations of a lens system. It gives, for instance, convenient expressions for the rectangular co-ordinates of the point of incidence P with reference to the optical axis and the pole of the surface, for in the triangle APQ the angle at A is

$$= 90° - \tfrac{1}{2}(U + I) = 90° - \tfrac{1}{2}(U' + I').$$

Hence

$$X = PA \sin \tfrac{1}{2}(U + I), \quad Y = PA \cos \tfrac{1}{2}(U + I). \quad (8)$$

A still more convenient exact formula for X is obtained by continuing the trace of the refracting surface to its second intersection A′ with the optical axis and joining P and A′. The right-angled triangles PAQ and A′PA are similar and give

$$\frac{X}{PA} = \frac{PA}{2r},$$

or $$X = \frac{(PA)^2}{2r}. \quad . \quad . \quad . \quad (8^*)$$

This utility of PA for other purposes is the reason why the check formula is given in two parts; so computed it gives by its first part a value of PA which is proved to be correct by the verification of L′ and may therefore be used with absolute confidence.

(ii.) *Sign Conventions.*—The computing formulae (1) to (8) have been deduced for one particular case in which all the quantities entering into them were treated as positive. The formulae can be rendered valid for all possible cases by adopting appropriate sign conventions. Many of the sign conventions proposed in books on optics break down under certain special conditions. The following conventions are free from this objection, and also give the usual signs of focal lengths and other data, the optical axis being taken as horizontal:

(*a*) Intersection lengths L or L′ and radii of curvature are given the positive sign if the

intersection points or centres of curvature lie to the right of the refracting surface.

(*b*) The acute angle U between the optical axis and the incident ray is given the positive sign if a clockwise turn would carry a ruler through this acute angle from coincidence with the optical axis to coincidence with the ray.

(*c*) The signs of the starting values having been determined by the preceding rules, those of the derived quantities are fixed by the usual rules of algebra and trigonometry.

The angles entering into calculations of optical instruments are almost invariably acute, hence no ambiguity can ordinarily arise. The only exception is the angle U+I at the centre of curvature, which frequently slightly exceeds 90° in the front lenses of oil-immersion objectives. But as it is found by addition of two acute angles of definitely known sign, no doubt can arise in this case.

As the direction in which the light travels does not enter into the above sign conventions, the formulae can be used with equal confidence and without any modification for calculations in either direction, which at times proves very advantageous, especially in eyepieces.

In the case of microscope objectives the formulae are used exclusively for the tracing of rays from an original object-point on the optical axis of the system, and as the latter must be a perfectly centred one, the final as well as all the intermediate images will also lie on the optical axis. There is in fact complete symmetry with reference to the optical axis, and the result found for one ray at a given initial inclination U to the optical axis applies equally to rays of that inclination leaving the object point in any other azimuth with reference to the optical axis; in other words, the calculation for one ray covers a complete narrow circular zone of the system.

In this simplest case of the application of the general formulae the continuation of the tracing of a ray through a following surface also assumes a very simple form, for if A_1P_1 in *Fig.* 1 represents such a surface at axial distance d' from the preceding one, the obvious relations exist:

$$L_1 = L' - d', \quad U_1 = U', \quad N_1 = N', \quad . \quad (5^*)$$

and with these as starting values the ray can be traced through the new surface.

§ (3) Paraxial Rays.—Rays starting from the object-point at different values of U will in general give a different position of the respective final image-points, thus disclosing the longitudinal spherical aberration of the system, which must be sufficiently corrected if the system is to be a useful microscope objective.

The usual first approximation in the correction of spherical aberration consists in bringing together the image-points produced by the marginal zone and by the paraxial zone respectively. The computing formulae already given are easily adapted to the tracing of paraxial rays by noting that for these rays which pass very close to the axis all the angles will necessarily be very small; hence the difference between the sines and the angles themselves (measured in radians) becomes negligible, and cosines and secants become equal to one. If the paraxial angles and intersection lengths are distinguished by using small letters instead of capitals, the computing formulae therefore will be

$$i = u\frac{l-r}{r}, \quad . \quad . \quad . \quad . \quad (1p)$$

$$i' = i\frac{N}{N'}, \quad . \quad . \quad . \quad . \quad (2p)$$

$$u' = u + i - i', \quad . \quad . \quad (3p)$$

$$l' - r = i'\frac{r}{u'}, \quad . \quad . \quad . \quad (4p)$$

$$l' = (l' - r) + r, \quad . \quad . \quad (5p)$$

$$l_1 = l' - d', \quad u_1 = u', \quad . \quad . \quad (5p)^*$$

$$(l-r)N \, . \, u = (l'-r)N'u'. \quad . \quad (6p)$$

In the check formula the chord PA becomes indistinguishable from the ordinate of the point of incidence, with symbol y, and the check therefore is

$$y = l \, . \, u, \quad l' = \frac{y}{u'}. \quad . \quad (5p) \text{ check.}$$

Equation (7) becomes

$$i - i' = (i + i')\frac{(N' - N)}{(N' + N)}, \quad . \quad (7p)$$

and the equations for X give

$$x = \tfrac{1}{2}y(u + i) \, . \, \frac{y^2}{2r}. \quad . \quad . \quad (8p)$$

Strictly these formulae should be computed with a very small initial value of u. But inasmuch as (1p) to (7p) are all linear equations, it is evident that if a calculation first carried out with an appropriately small value of the initial u were repeated with $k \, . \, u$ as the initial inclination of the ray (k being any number whatever), all the other angles would come out at k times the first values, whilst the intersection lengths would be absolutely unchanged. As the latter are the quantities of chief interest, the initial u at the first surface of any one system may therefore be chosen quite freely, and in order to make the application of the sine condition as simple as possible it is most convenient to choose as the nominal value of the initial u the exact value of sin U for the corresponding marginal ray. Identity of the value found for the final u' of the system with the final value of sin U′ of the marginal ray then indicates fulfilment of the sine condition without a calculation of any kind.

It is, of course, necessary to bear in mind that these convenient large nominal values of the paraxial angles are fictitious when their absolute values are required for any special purpose.

§ (4) Special Formulae for Plane Surfaces.—Rays may be traced through plane surfaces at right angles to the optical axis by the general formulae by using a fictitious radius of curvature of such great length that the corresponding spherical surface only departs by a small fraction of a wave-length from a plane within the full aperture at which the surface works. But special formulae are far more convenient. Putting equation (1) into the form

$$\sin I = \sin U\left(\frac{l}{r} - 1\right),$$

it is seen that for $r = \infty$ we have $I = -U$. Equation (4) similarly shows that for a plane $I' = -U'$. With these special values of I and I′ equation (3) gives $\sin U' = N/N' \sin U$, and on introducing the special values into the check-formula a formula for L′ results, namely,

$$L' = L \tan U \cot U' = L\frac{N' \cos U'}{N \cos U},$$

by introducing the relation existing in this case between sin U and sin U′. The paraxial equations are easily deduced from the above and give the complete set of computing formulae:

$$I = -U, \quad I' = -U', \qquad \text{Pl}(1)$$

$$i = -u, \quad i' = -u', \qquad \text{Pl}(1p)$$

$$\sin U' = \frac{N}{N'} \sin U, \qquad \text{Pl}(2)$$

$$u' = \frac{N}{N'}u, \qquad \text{Pl}(2p)$$

$$L' = L \tan U \cot U', \qquad \text{Pl}(3)$$

$$l' = l \cdot \frac{N'}{N}, \qquad \text{Pl}(3p^*)$$

or

$$L' = L\frac{N'}{N} \cdot \frac{\cos U'}{\cos U}. \qquad \text{Pl}(3^*)$$

Pl(3*) is more easily computed than Pl(3), and gives a more accurate result if the angles are small. Pl(1) and (1p) do not enter into the calculation, but are important for certain general discussions.

§ (5) Spherical Aberration. (i.) *General Formulae.*—When a paraxial and a marginal ray are traced from an original object-point through a system, the difference $(l' - L')$ at any one surface indicates the longitudinal spherical aberration. Whilst the aberration is most easily found in this way it is obtained in a form which is highly misleading as to the real seriousness of the defect which is indicated, and even more so with reference to the real contribution to the total aberration by the separate surfaces. These undesirable peculiarities of the longitudinal spherical aberration become apparent and its laws are disclosed by finding a direct expression for it in terms of the computed angles and intersection lengths.

Standard equation (1) may be written

$$\frac{\sin U}{\sin I} = \frac{r}{L - r},$$

which gives by simple transformations

$$(a) \quad \frac{r}{L} = \frac{\sin U}{\sin I + \sin U},$$

and

$$(b) \quad \frac{L - r}{L} = \frac{\sin I}{\sin I + \sin U};$$

(*a*) may be further transformed into

$$\frac{r}{L} = \frac{\sin I + \sin U - \sin I}{\sin I + \sin U} = 1 - \frac{\sin I}{\sin I + \sin U},$$

and if this equation is multiplied throughout by N/r it gives

$$(c) \quad \frac{N}{L} = \frac{N}{r} - \frac{N}{r} \cdot \frac{\sin I}{\sin I + \sin U}.$$

Standard equation (4) is identical in form with (1), and treated in the same way as the latter gives

$$(d) \quad \frac{N'}{L'} = \frac{N'}{r} - \frac{N'}{r} \cdot \frac{\sin I'}{\sin I' + \sin U'}.$$

As (*d*) applies to the ray after refraction, the N′ sin I′ in its last term is equal—by the law of refraction—to N sin I in (*c*), hence we may combine (*c*) and (*d*) by subtracting the first from the second and treating N sin I as a common factor in the last terms, leading to

$$(e) \quad \frac{N'}{L'} - \frac{N}{L} = \frac{N' - N}{r} + \frac{N \sin I}{r} \cdot \left(\frac{1}{\sin I + \sin U} - \frac{1}{\sin I' + \sin U'}\right).$$

Taking $1/(\sin I + \sin U)$ outside the bracket, using (*b*), and in the bracket the formula for the sum of two sines, gives for the final term :

Final term

$$= \frac{N(L - r)}{rL} \cdot \left(1 - \frac{\sin \frac{1}{2}(U + I) \cos \frac{1}{2}(I - U)}{\sin \frac{1}{2}(U' + I') \cos \frac{1}{2}(I' - U')}\right).$$

By standard equation (3) $U + I = U' + I'$, hence the sines of half these angles cancel each other. Bringing the simplified bracketed term to a common denominator and applying the formula for the difference of two cosines next gives

$$\text{Final term} = 2\frac{N(L - r)}{rL} \times \frac{\sin \frac{1}{2}(I - U + I' - U') \sin \frac{1}{2}(I - U - I' + U')}{\cos \frac{1}{2}(I' - U')}$$

By elimination of U′ from the last numerator by (3): $U' = U + I - I'$, the final term takes its definitive form, and on introduction into (e) gives

$$\frac{N'}{L'} = \frac{N}{L} + \frac{N'-N}{r}$$

$$+ 2\frac{N(L-r)}{rL} \cdot \frac{\sin\frac{1}{2}(I'-U)\sin\frac{1}{2}(I-I')}{\cos\frac{1}{2}(I'-U')} \quad (9)$$

as a trigonometrically exact equation from which the laws of longitudinal spherical aberration can be deduced. If an object-point at any given distance, L, is considered, the first two terms on the right of (9) will be constant, hence variation of L′ for rays at different inclinations, U, can only result from the final term which is thus pointed out as the one which determines the spherical aberration. Its value depends chiefly on the two sines in the numerator which for moderate values of the various angles will, as was proved for the paraxial region, vary very nearly in direct proportion with the initial U of any one ray, and therefore also in proportion with the distance, Y, from the optical axis at which any ray penetrates the refracting surface. In first approximation the spherical aberration expressed by the last term therefore grows with the square of the aperture, and as a consequence becomes small of the second order for the paraxial region. For paraxial rays equation (9) therefore becomes

$$\frac{N'}{l'} = \frac{N}{l} + \frac{N'-N}{r}, \quad . \quad . \quad (9p)$$

which will be recognised as one of the best-known and most useful formulae for the tracing of paraxial rays.

By deducting (9*p*) from (9) and making very slight reductions a perfectly general and rigorous direct expression for the longitudinal spherical aberration at any spherical surface is obtained, namely

$$l' - L' = (l - L)\frac{N}{N'} \cdot \frac{l'L'}{lL}$$

$$+ 2\frac{N}{N'}(L-r)\frac{l'L'}{rL} \cdot \frac{\sin\frac{1}{2}(I'-U)\sin\frac{1}{2}(I-I')}{\cos\frac{1}{2}(I'-U')}, \quad (9^*)$$

in which the second term again represents the new spherical aberration produced by the refraction, whilst the first term shows how the spherical aberration $(l - L)$ of the incident rays combines with the new aberration; in other words, the first term expresses the addition theorem of longitudinal spherical aberration. It is seen that $(l - L)$ has to be multiplied first by N/N′, which may vary from about ·6 for a refraction from air into dense glass to about 1·7 for a refraction from dense glass into air. This product is further multiplied by the ratios of the conjugate distances of the paraxial and marginal ray respectively: each of these ratios may vary from zero if an incident ray parallel to the optical axis (l or $L = \infty$) is rendered convergent or divergent by the refraction, to infinite value if a convergent or divergent ray is rendered parallel to the optical axis by the refraction at the surface. The extraordinary extent to which the longitudinal spherical aberration is frequently found to fluctuate from surface to surface when common sense and experience render it obvious that the real departures of the rays from their ideal course is quite slight is thus fully explained. The second term in (9*) is easily seen to have similar misleading factors, so that the amount of the new aberration is also found in a form which requires careful scrutiny before making up one's mind as to whether the aberration is really serious or not. Strong evidence is frequently found in actual optical designs that even experienced practical computers are not sufficiently aware of the very indirect and misleading nature of the indications which the longitudinal spherical aberration supplies as to the real seriousness and magnitude of the defect at any one surface.

(ii.) *Conditions for Minimum Spherical Aberration.*—An extremely interesting and important question, especially in connection with microscope objectives, is whether the aberration produced by a spherical surface can become small or zero for pencils of finite aperture. One such case is quite obvious, for if the object-point is infinitely close to the refracting surface, then L will be infinitely small, rays at any practicable angle, U, will meet the surface very close to the optical axis so that the curvature of the surface will be inappreciable and its tangent plane may be substituted. In accordance with the formulae for plane surfaces, the L′ will then also be infinitely small and there is no scope for spherical aberration. This most obvious case is taken advantage of in all high-power microscope objectives to reduce the magnitude of the aberration which would arise at the first surface next the object if the latter were at a considerable distance, simply by making the "free working distance" very small.

Two other cases can be deduced from equation (9*). Discussion of its final term by which the new aberration is determined shows at once that this term will be zero if $L = r$, that is, for rays directed towards the centre of curvature. Under these conditions $L - r$ will be zero, which alone is sufficient. But in addition $\sin\frac{1}{2}(I - I')$ will also be zero, as for rays passing radially there is no deviation. It follows that for rays directed towards points close to the centre of curvature the aberration is small of the second order. This second case is also made use of in microscope

objectives of high power: it accounts for the very usual meniscus form of the lens next above the front lens. The second lens thus receives the diverging rays at small angles of incidence on its concave first surface and keeps the spherical aberration down to a manageable magnitude.

(iii.) *Aplanatic Refraction.*—In all cases not coming under the two which have been discussed all the factors entering into the aberration term of (9*) will have finite values, with the possible exception of $\sin \frac{1}{2}(I'-U)$. If this factor became zero the aberration would again vanish; that is the third and most important case of aplanatic refraction at a spherical surface.

$\sin \frac{1}{2}(I'-U)=0$ implies $I'=U$

and also $\sin I'=\sin U$.

By combining equations (1) and (2) it is easily found that quite generally

$$\sin I'=\frac{N}{N'}\,\frac{L-r}{r}\sin U.$$

If, as in the special case under discussion, $\sin I'=\sin U$, the general equation takes the form

$$1=\frac{N}{N'}\,\frac{L-r}{r},\quad\text{or}\quad\frac{L-r}{r}=\frac{N'}{N},$$

from which follows

$$\frac{L}{r}=\frac{N'+N}{N},\quad\text{or } L=r\frac{N'+N}{N}.$$

If L satisfies this equation there will be no spherical aberration, no matter how large the angles may be, right up to grazing incidence or emergence of the rays. As refractive indices are always positive, the case can only arise when L and r have the same sign, which implies that the object point lies on the concave side of the refracting surface. For refraction from air ($N=1$) into glass (say, $N=1{\cdot}5$) the equation gives $L=2{\cdot}5r$, so that the diagram used in deducing the standard computing formulae approximately represents this third case of aplanatic refraction. Several other interesting relations apply in this case. By (3) $I'-U=I-U'$, hence the case also implies $I=U'$, and if this is followed up by the aid of (2) and (4) in the same way as before it leads to

$$L'=r\frac{N'+N}{N'},$$

which for the numerical example already used gives $L'=1{\cdot}667r$. Combination of the equations for L and L′ gives the additional interesting relations

$$\frac{L'}{L}=\frac{N}{N'}\quad\text{and}\quad\frac{1}{L}+\frac{1}{L'}=\frac{1}{r}.$$

Finally, the two conditions to be fulfilled,

$$\sin I'=\sin U$$

and $$\sin I=\sin U'$$

give, on dividing the second by the first,

$$\frac{\sin U'}{\sin U}=\frac{\sin I}{\sin I'}=\frac{N'}{N}$$

by the law of refraction.

Therefore $\sin U'/\sin U=N'/N=$ a constant for the surface, and this supplies the highly important further information that the optical sine condition is fulfilled in this third case of aplanatic refraction. The two conditions to be fulfilled, $\sin I'=\sin U$ and $\sin I=\sin U'$, also show, inasmuch as the angle of incidence in the less dense medium may reach but cannot exceed 90°, that the angle of convergence U or U′ in the denser medium has the same range, that is, this case permits of dealing with cones of rays up to an included angle of 180° between opposite extreme marginal rays in the denser medium quite independently of the values of N and N′. It is this unconditional freedom from spherical aberration for cones of rays of the widest possible angular extent which renders this third case of aplanatic refraction so extremely valuable in the design of microscope objectives. It may indeed be stated that microscope objectives of high aperture are possible only by making use of this property of spherical surfaces. The curved side of the front lenses always corresponds fairly closely to the conditions which have been deduced. If the conjugate points are a little nearer to the refracting surface than is required for exact aplanatism, then a very considerable collective refraction can be secured accompanied by spherical over-correction such as is usually only obtainable at the expense of a dispersion of the rays. Front lenses therefore depart from the exact theoretical position of the aplanatic points more frequently in this sense than in the opposite sense of too great a distance of the conjugate points from the refracting surface.

It is an obvious conclusion drawn from the above discussion that if the aberration accompanying a given deflection $(I-I')$ is desired to be large, as most often happens at the dispersive contact surfaces at which over-correction is produced, then a large value of $(I'-U)$ must be aimed at by having the conjugate points as far as possible away from the aplanatic position. Hence for conjugates lying at the concave side of a surface their distance should be a large multiple of the radius; but still higher aberrations will be secured by having the conjugate points lying on the convex side of the surface, which is in fact the predominating practice.

§ (6) Zonal Spherical Aberration. *Expression as a Series.*—It has been proved that

the longitudinal spherical aberration grows, in first approximation, with the square of the aperture of any given lens system. The form of equations (9) and (9*), however, makes it obvious that there must be higher terms in their development in series. The type of this series may be fixed without direct mathematical investigation by the simple consideration that on account of the symmetry of a centred system with reference to its optical axis a ray from an axial object-point entering at the same angle below the optical axis as another above the axis must suffer the same longitudinal aberration as to both magnitude and sign. Two such corresponding rays will have the ordinate Y of the point of incidence as well as the chord PA of the same numerical value but of opposite sign, whence it follows at once that the series giving the longitudinal aberration in terms of powers of Y or of PA can only contain even powers of these as well as of any other direct measures of the aperture; therefore the longitudinal aberration LA′ must be represented by an equation of the form

$$LA' = c_1Y^2 + c_2Y^4 + c_3Y^6 + \text{etc.}$$

In systems of slight curvature such as astronomical object-glasses of the usual types, only the first term is sensible. Such systems can have their spherical aberration corrected in a practically perfect manner *on paper*. The very sensible residues of aberration frequently found by direct tests (such as Hartmann's) in such systems are due to a slight extent to departures from the prescribed radii and thicknesses, to a greater extent to departures from true spherical form of the polished surfaces due to elastic yielding of the lens and tools in the process of grinding and polishing, but chiefly, especially in large sizes, to want of homogeneity in the glass which at times even affects microscope objectives. Empirical "figuring" of a suitable surface is the only remedy for these technical defects, which cannot be either estimated or allowed for in the calculation of a lens system.

In lens systems of somewhat bolder design the first two terms of the LA′ series represent the longitudinal aberration with sufficient accuracy. If such a system is spherically corrected for a particular zone of its aperture (usually the extreme marginal zone) the terms in Y^2 and Y^4 must be numerically equal but of opposite sign for that zone, whilst there will be residuals of aberration of the sign of the Y^2 term between the paraxial and the corrected zone, and of the sign of the Y^4 term beyond the corrected zone, the former attaining a maximum value at $\sqrt{\frac{1}{2}}$ of the diameter of the corrected zone. Hence the rule that if the presence of zonal aberration is to be ascertained a third ray (in addition to the paraxial and marginal ones) should be traced through the system at ·7071 of the aperture selected for the marginal ray.

In systems of deep curvature, practically in all microscope objectives exceeding an NA of about ·3, still higher terms become sensible in rapid succession as the aperture increases, and a higher state of spherical correction must then be aimed at. In purely geometrical ray-tracing this is attained by demanding that the rays passing through three selected zones of the aperture shall be brought to a common focus, and it is usual to choose the paraxial, marginal, and the ·7071 zones.

If only the first three terms of the aberration series were of sensible magnitude this would lead to perfect spherical correction for the whole aperture. In reality the higher terms follow so closely on each other's heels that the tracing of intermediate rays again reveals secondary zonal variations. But there is no systematic method for the removal of these higher zonal variations.

§ (7) The Physical Aspect of Spherical Aberration. (i.) *General Consideration.*—It will have been gathered from the preceding geometrical discussion of the problem of spherical aberration that its chief weakness lies in the method of measuring the magnitude of the defects which the longitudinal spherical aberration indicates. It is usually attempted to estimate the true magnitude by discussion of the series for LA′ with a view to determining the smallest diameter of the confused pencil of rays resulting from the aberration. It is then assumed that the focus of the instrument will be adjusted so as to throw this smallest possible geometrical image upon the retina of the eye (or upon the photographic plate) and that each object-point will be seen or photographed as a dot of the size of this "circle of least confusion." When the spherical aberration is of very considerable magnitude, these assumptions are very nearly correct. Cases of that kind, however, are of extremely rare occurrence in practically useful optical instruments. Telescopes and microscopes of the present day are expected to realise the full theoretical resolving power of a perfectly corrected instrument as defined by the integration of the light effect at a perfect focus in accordance with the undulatory theory of light. As the limit of defining power so determined is decidedly stringent, only small amounts of aberration can be tolerated. In this, practically the only interesting case, the geometrically determined circle of least confusion becomes absolutely useless as a measure of the size of the actual image of a point: as will be shown, the geometrical circle of least confusion may be four or more times the size of the image really seen by the eye before any sensible deterioration due to spherical aberra-

tion sets in. It might be argued that this must surely be in favour of adhering to the geometrical measure, inasmuch as an instrument satisfying the geometrical limit would prove quite perfect when submitted to actual test by light of finite wave-length. The answer to such an argument is that in order to reduce his circles of least confusion to the size of the physically determined image of a point, the purely geometrical designer would have to stop at a very much reduced aperture of a system of any given number of component lenses. As the true resolving power is proportional to the aperture, he would thus invariably produce a system of lower resolving power and with a smaller light gathering power than could be produced with the same number of components by taking the finite wave-length of light into account in determining the permissible aperture. Adherence to the geometrical method must therefore prove a severe, if not a fatal, handicap whenever the best possible result is to be secured with a given number of components.

Physically considered, a lens system changes the curvature of the light-waves passing through it: if perfect the system turns the spherical waves sent out by any object-point into truly spherical waves converging towards the conjugate image-point; consequently the light sent out at a given instant from the object-point towards every part of the clear aperture would a little later arrive absolutely simultaneously at the conjugate image-point and would produce a maximum brightness of the image owing to the total absence of differences of phase. The simultaneous arrival at the image-point of light traversing all parts of the clear aperture is therefore the physical definition of a perfect optical system. Inasmuch as the rays of geometrical optics are normals of the corresponding wave-surfaces, this physical definition of a focus is in the case of perfect systems identical with the geometrical one; for if the waves converging towards the image-point are spherical, then their normals, the "rays," will be radii and will therefore meet at the image-point.

(ii.) *Physical Theory.*—But whilst the geometrical theory claims a perfect point-focus, the undulatory theory merely demonstrates that there is a maximum of intensity at that point, because the light reaches it without any differences of phase. In accordance with the principle of Huygens as extended by Fresnel, even a truly spherical wave produces a light-effect outside the cone of "rays" to which it corresponds. If, in *Fig.* 2, O represents an object-point sending out spherical waves like W and if the lens system changes these waves into a form like W′ converging more or less perfectly towards an image-point O′, then, according to the principle referred to, the light-effect at any point whatever beyond W′ can be determined by considering each surface element of W′ as a luminous point sending

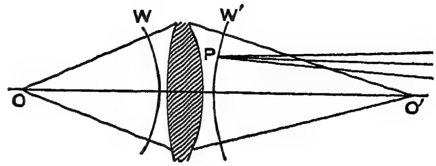

FIG. 2.

out spherical waves and by integrating the combined effect at any point of these elementary waves over the whole surface of W′. G. B. Airy [1] carried out this integration for the intensity distribution produced by a perfect lens system in the plane of the geometrical image and arrived at the well-known "spurious disc" surrounded by concentric diffraction rings of rapidly diminishing intensity. In this simplest case the light from all points of the emerging wave W′ will arrive at O′ in the same phase. If there is spherical aberration present, then the emerging waves will be distorted and will no longer be of the ideal spherical form, and there will not be a definite point like O′ at which all light arrives in the same phase. In order to discuss these cases (strictly speaking, the only ones which are of practical interest as perfect spherical correction is utterly impossible) it is necessary to determine the phase relation with which light arrives at any assumed position of the image-point. This is done by finding an algebraical expression for the total length of optical path from an object-point to the assumed image-point, in the first instance for a single spherical refracting surface.

In *Fig.* 3, let AP represent the trace of a spherical refracting surface with centre at C,

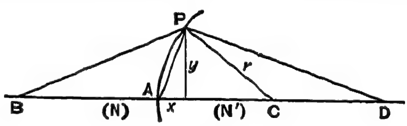

FIG. 3.

separating a medium of index N to its left from a medium of index N′ to its right; let B be the luminous object-point at distance l from the pole A, and D at distance l' from the pole the point for which the differences of optical path are to be determined, using the axial path B A D as the reference standard. Physically the refractive index represents the ratio of the velocity of light in empty space to that in the given medium, hence a path l in a medium of index N takes as long to

[1] *Camb. Phil. Trans.*, 1834.

traverse, or is optically equivalent to, a path Nl in empty space. Reducing all paths to their equivalents by this relation, there results —bearing in mind that l in the diagram is negative in accordance with the adopted sign convention—

Equivalent axial path $= N' . l' - N . l$,
Equivalent marginal path $= N' . PD - N . BP$.

Introducing the rectangular coordinates x and y of point P the second equation becomes

$$\text{E.m.p.} = N'\sqrt{(l'-x)^2+y^2} - N\sqrt{(l-x)^2+y^2},$$

in which the roots must obviously be taken with the signs of l' and l respectively. For a spherical surface $y^2 = 2rx - x^2$, hence

$$\text{E.m.p.} = N'\sqrt{l'^2 - 2x(l'-r)} - N\sqrt{l^2 - 2x(l-r)}.$$

The difference axial—marginal path will determine by how much the axial path is longer than the marginal path; or more conveniently put, it gives the lead of the marginal light. Introducing the symbol OPD for this optical path difference, it is found as

$$\text{OPD} = N'l'\left(1 - \sqrt{1 - 2x\frac{l'-r}{l'^2}}\right) - Nl\left(1 - \sqrt{1 - 2x\frac{l-r}{l^2}}\right).$$

Putting $p = x(l-r)/l^2$ and $p' = x(l'-r)/l'^2$ and developing the roots by the binomial theorem, the result is

$$\text{OPD} = N'l'[1 - (1 - p' - \tfrac{1}{2}p'^2 - \tfrac{1}{2}p'^3, \text{ etc.})] - Nl[1 - (1 - p - \tfrac{1}{2}p^2 - \tfrac{1}{2}p^3, \text{ etc.})],$$

or, differently ordered,

$$\text{OPD} = N'.l'p' - N.lp + \tfrac{1}{2}(N'.l'p'^2 - N.lp^2) + \tfrac{1}{2}(N'.l'p'^3 - N.lp^3), \text{ etc.},$$

and this is valid for any position on the optical axis of the assumed image-point D.

If the values of p and p' are reintroduced and x, in accordance with the last of equations (8), is put equal to $(\text{PA})^2/2r$, the value of OPD becomes

$$\text{OPD} = \frac{(\text{PA})^2}{2r}\left(N'\frac{l'-r}{l'} - N\frac{l-r}{l}\right) + \tfrac{1}{8}(\text{PA})^4\left(\frac{N'(l'-r)^2}{r^2l'^3} - \frac{N(l-r)^2}{r^2l^3}\right) + \tfrac{1}{16}(\text{PA})^6\left(\frac{N'(l'-r)^3}{r^3l'^5} - \frac{N(l-r)^3}{r^3l^5}\right) + \text{etc.} \quad (10)$$

Evidently the first term in $(\text{PA})^2$ will disappear if the bracketed factor becomes zero. But

$$N'\frac{l'-r}{l'} - N\frac{l-r}{l} = 0$$

can be easily converted into

$$\frac{N'}{l'} = \frac{N'-N}{r} + \frac{N}{l},$$

an equation already deduced (see (9p)) as the condition fulfilled by the location of the paraxial geometrical image of the object-point. The difference of optical paths with which a ray at finite distance from the optical axis reaches the paraxial focus is therefore

$$\text{OPD}_p = \tfrac{1}{8}(\text{PA})^4\left(\frac{N'(l'-r)^2}{r^2l'^3} - \frac{N(l-r)^2}{r^2l^3}\right) + \tfrac{1}{16}(\text{PA})^6\left(\frac{N'(l'-r)^3}{r^3l'^5} - \frac{N(l-r)^3}{r^3l^5}\right), \text{ etc.} \quad (10^*)$$

This equation obviously gives the spherical aberration in terms of differences of optical paths. The latter will be obtained in wave-lengths by multiplying the right side by the number of wave-lengths contained in one unit of length (approximately by 2000 if the millimetre is used or by 50,000 if the inch is adopted) and is seen to grow with the fourth and higher even powers of the aperture, whereas the longitudinal aberration as defined geometrically grows with the square of the aperture.

The differences of phase therefore increase very much more rapidly than the equivalent longitudinal aberration when they once have reached sensible magnitude; on the other hand, the differences of phase will remain insensible in a zone surrounding the optical axis which is much larger than that in which the longitudinal aberration remains small.

As the OPD found for a ray at a surface measures the lead which it has gained with reference to the corresponding axial ray, it is evident that the addition theorem of the OPD for a number of surfaces is the simplest possible one, namely, simple algebraical addition of the separate values found for each surface. This is, however, strictly correct only if equation (10) is used and if the l' introduced into it is the true intersection length of the marginal ray as found trigonometrically. The reason for this restriction is that in the propagation of waves of an extent which is a large multiple of a wave-length the energy represented by the vibrations travels in the direction of the geometrical rays and must therefore be traced along the latter. The direction towards the paraxial focus differs from that towards the actual intersection point of a ray at finite angles by the amount of the angular value of the spherical aberration, and a correction is called for which, although small and easily determined, is a troublesome addition to the numerical work and makes another method of calculating the OPD to be given presently decidedly more convenient.

The correction referred to brings in small additional terms of the 6th and higher even orders; it therefore does not alter the law of increase of the OPD with aperture, so that for any centred optical system the OPD as given by (10) will be expressed by an equation of the form

$$\text{OPD} = c_1Y^2 + c_2Y^4 + c_3Y^6 + \text{etc.},$$

for any assumed position of the image-point, and by an equation (10*) of the form

$$OPD_p = d_1 Y^4 + d_2 Y^6 + \text{ etc.},$$

for the paraxial image-point. The presence of a term in Y^2 for points other than the paraxial focus is of great importance in the discussion of the location of the best image and in laying down the limits of tolerance for residual spherical aberration. When the equations are written with undetermined coefficients c_1 etc., they hold for any reasonable measure Y of the aperture, as for instance the ordinate of the point of penetration of the ray through any one surface of the system, or the angle of convergence of the issuing or entering ray, for all these different measures are convertible into each other by series progressing in alternate powers of any given measure of the aperture, by reason of the symmetry of a centred system around the optical axis.

§ (8) Trigonometrical Calculation of the OPD.—Let a spherical wave OA, *Fig.* 4,

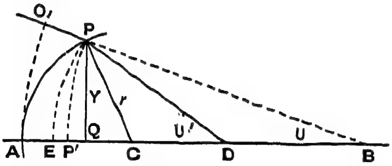

Fig. 4.

in the medium of index N to the left of the refracting surface AP, be converging towards B. While the marginal part of the wave is traversing the distance OP in the medium of index N, the axial part has entered the new medium of index N′ and the optical paths of the two parts are necessarily equal. As the marginal ray is refracted towards D in the direction given by the ordinary law of refraction a new spherical wave EP, with D as centre, would result if there were no spherical aberration. Therefore in this case the optical path AE would be equal to the optical path OP. Conversely, if the optical paths OP and AE are separately computed and found to differ, the difference will represent the OPD due to spherical aberration.

Describe an arc of a circle PP′ with B as centre cutting the axis in P′, and draw PQ perpendicular to the axis.

Then $\qquad OP = AP' = AQ - P'Q.$

Join AP and P′P. The triangles CAP and BPP′ are both isosceles. As the angle at C is $= U + I$ and the angle at $B = U$, it follows that angle $PAQ = 90° - \frac{1}{2}(U+I)$ and angle $PP'Q = 90° - \frac{1}{2}U$, whence putting $PQ = Y$

$$OP = Y(\tan \tfrac{1}{2}(U+I) - \tan \tfrac{1}{2}U).$$

The distance AE may be evaluated in the same way remembering that $PCA = U' + I'$ and $PDA = U'$, and we find

$$AE = Y(\tan \tfrac{1}{2}(U'+I') - \tan \tfrac{1}{2}U').$$

And the OPD at the marginal focus D is found by multiplying AE and OP by the respective indices and taking their difference. Thus,

$$OPD_m = N'.\, Y(\tan \tfrac{1}{2}(U'+I') - \tan \tfrac{1}{2}U')$$
$$- N\,.\, Y(\tan \tfrac{1}{2}(U+I) - \tan \tfrac{1}{2}U).$$

Whence on reduction we have

$$OPD_m = N'.\, Y \frac{\sin \frac{1}{2}I'}{\cos \frac{1}{2}(U'+I') \cos \frac{1}{2}U'}$$
$$- N\,.\, Y \frac{\sin \frac{1}{2}I}{\cos \frac{1}{2}(U+I) \cos \frac{1}{2}U}.$$

Multiplying numerator and denominator of the first term by $2 \cos \frac{1}{2}I'$, and of the second by $2 \cos \frac{1}{2}I$, the numerators of the fractions become sin I′ and sin I respectively, and as $N' \sin I' = N \sin I$ and $(U+I) = (U'+I')$ the equation becomes

$$OPD_m = \frac{N'.\, Y \sin I'}{2 \cos \frac{1}{2}(U+I)}$$
$$\left[\frac{1}{\cos \frac{1}{2}I' \cos \frac{1}{2}U'} - \frac{1}{\cos \frac{1}{2}I \cos \frac{1}{2}U}\right],$$

or on bringing the square bracket to a common denominator

$$OPD_m = \frac{N'.\, Y \sin I'}{2 \cos \frac{1}{2}(U+I)} \cdot \frac{\cos \frac{1}{2}U \cos \frac{1}{2}I - \cos \frac{1}{2}I' \cos \frac{1}{2}U'}{\cos \frac{1}{2}I \cos \frac{1}{2}U \cos \frac{1}{2}I' \cos \frac{1}{2}U'}.$$

The numerator of the second fraction can be further simplified by putting $\cos \frac{1}{2}U = \cos(\frac{1}{2}(U-U') + \frac{1}{2}U')$ and resolving, also putting $\cos \frac{1}{2}I' = \cos(\frac{1}{2}(U-U') + \frac{1}{2}I)$, which is obtained by transposing $U + I = U' + I'$, and resolving this. The numerator is then obtained in the form of four terms, two of which cancel each other whilst the other two combine and lead to the equation

$$OPD_m = \frac{N'.\, Y \sin I' \sin \frac{1}{2}(U-U') \sin \frac{1}{2}(I-U')}{2 \cos \frac{1}{2}U \cos \frac{1}{2}I \cos \frac{1}{2}(U+I) \cos \frac{1}{2}I' \cos \frac{1}{2}U'}.$$

It is more convenient for computation to replace the ordinate Y by the chord PA. Using $Y = PA \cos \frac{1}{2}(U+I)$ this gives

$$OPD_m = \frac{N'.\, PA\,.\, \sin I' \sin \frac{1}{2}(U-U') \sin \frac{1}{2}(I-U')}{2 \cos \frac{1}{2}U \cos \frac{1}{2}I \cos \frac{1}{2}I' \cos \frac{1}{2}U'}. \qquad (10^{**})$$

For a plane surface PA becomes identical with Y and as by Pl(1) $I = -U$ and $I' = -U'$, the equation for plane surfaces is

$$\text{plane}: \; OPD_m = \frac{N'.\, Y \sin U' \sin \frac{1}{2}(U+U') \sin \frac{1}{2}(U-U')}{2 \cos^2 \frac{1}{2}U \cos^2 \frac{1}{2}U'}, \qquad (10^{**})$$

in which $Y = L \tan U = L' \tan U'$.

These equations are more rapidly computed than the number of terms would suggest because they give the OPD directly, not as a small difference of two large numbers.

As it is hardly ever of interest to know the aberration at any one surface within less than 0·1 per cent, four-figure logs are quite sufficient and the cosines in the denominator rarely call for any interpolation, as the angles are usually small. The aberration at the final marginal focus of a system is strictly equal to the algebraical sum of the OPD_m values found for the separate surfaces because the ray is traced in this case along the path assigned to it by the law of refraction. There is therefore no correction of any kind to be applied to the result obtained for any one ray. On the other hand, should several rays, at different distances from the optical axis, be traced through a system, the OPD_m obtained for them will not be directly comparable, as each one will be referred to its own geometrical intersection point. General theoretical discussions are therefore preferably based on Equation (10).

The differences of optical paths are a direct measure of the distortion from true spherical form of the waves emerging from a lens system. For that reason they make possible a really valid discussion of the limits within which spherical aberration must be corrected if the full theoretical resolving and defining power of a lens system is to be realised. This discussion is of particular importance in the case of microscope-objectives on account of their deep curvatures and consequent large amount of higher aberrations : but the results are equally valid for any other kind of centred optical systems. The foundations for this treatment of the aberrations were laid by the late Lord Rayleigh.

§ (9) The Rayleigh Limit.—In 1879 Lord Rayleigh[1] arrived at the conclusion that an optical system would give an image only slightly inferior to that produced by an absolutely perfect system *if all the light arrived at the focus with differences of phase not exceeding one quarter of a wave-length*, "for then the resultant cannot differ much from the maximum." This paper ought immediately to have marked the beginning of a new epoch in the design and discussion of optical instruments. But the barren, purely geometrical treatment of the aberrations went on for many years, possibly because the conclusion was jumped at that equalisation of the optical paths from object-point to image-point (themselves rarely measuring less than eight inches) within one two-hundred-thousandth part of an inch was an impossible ideal. As will be shown, this is so far from being correct that in reality it is far easier to correct the aberrations within the Rayleigh limit than to bring the geometrical "rays" within a "circle of least confusion" of the size of the image which has for a long time been known as attainable. The adoption of the Rayleigh limit thus makes it possible considerably to increase the aperture of a lens system of given type and to come close to the full theoretical resolving power with systems which, judged geometrically, would appear hopelessly over- or under-corrected.

These remarkable and highly valuable facts are easily proved by determining the aperture at which the Rayleigh limit is reached in the presence of aberration and by establishing the relation between the physical and the geometrical measurement of the aberration.

If D_p in *Fig.* 5 is the paraxial focus of a lens system, then in the absence of aberration

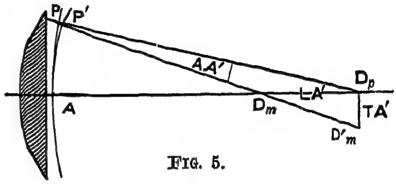

Fig. 5.

a train of spherical waves like PA would be converging towards this focus. Aberration will cause the actual waves to be distorted, and the OPD equations will determine directly the distance PP′ by which the distorted wave is separated from the corresponding ideal spherical wave. If the law of increase of the OPD with increasing aperture is known, the complete form of the distorted wave with reference to the ideal wave will be defined. In all optical instruments intended for high resolving power the angle of the cones of rays converging towards the final image point is always very small (much smaller than the exaggerated diagram suggests), the emerging waves rarely reaching an angular extent of even 5°. Under these conditions the difference between the arc AP and the ordinate Y of point P will be negligible and the differential coefficient $d(PP')/dY$ will be the measure in radians of the small angle between the ideal and the distorted wave and therefore also between their corresponding normals. The normal of the actual emerging wave represents by definition the true geometrical ray passing through any point P′. If D_m is the intersecting point of this ray, the angle $D_pP'D_m$, or the angular aberration of the ray, denoted by the symbol [AA′], is therefore defined by

$$[AA'] = \frac{d(OPD_p)}{dY},$$

no matter of what order the wave distortion may be, provided only that the angle of the cone of rays is reasonably small. If the ray at finite angle is produced to intersection at D'_m with a normal plane described through D_p, then the distance $D_pD'_m = TA'$ represents the transverse aberration and triangle $D_pP'D'_m$ gives with ample approximation

$$TA' = l'[AA'] = l'\frac{d(OPD)}{dY}.$$

[1] *Collected Papers*, i. 415-453; *Phil. Mag.*, Oct. 1879, viii. 261.

Finally the triangles $D_mD_pD'_m$ and D_mAP which are approximately similar give the longitudinal aberration $D_mD_p=LA'$ as

$$LA'=TA'\frac{L'}{Y}=\frac{l'L'}{Y}\,\frac{d(OPD_p)}{dY}.$$

These important relations between the differences of optical paths and the various measures of the corresponding geometrical aberrations may be collected in the form

$$\frac{d(OPD_p)}{dY}=[AA']=\frac{TA'}{l'}=LA'\frac{Y}{l'L'}. \qquad (11)$$

As in the case of the geometrical aberrations, so in that of the differences of optical paths the best image is usually found at some little distance from the paraxial focus. The effect of such a change of focus must therefore be determined.

Let D in *Fig.* 6 at a distance df from the paraxial focus D_p be a point for which the

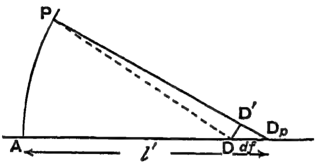

FIG. 6.

phase relation of light from P and from A respectively is to be determined. At D_p there will be a lead of the inclined ray by OPD_p. The axial path to D is shorter than that to D_p by df. The inclined path from P to D is shorter than that to D_p by the difference PD_p-PD.

In all cases of practical interest df is very small compared to DP, and the angle DPD_p measures a moderate number of seconds of arc. Under these conditions the difference between PD_p and PD will be sensibly equal to DD_p, the projection of DD_p upon PD_p. Consequently the light from P will arrive at D with a lag $=df(1-\cos DD_pD')=2df\sin^2\frac{1}{2}DD_pD'$.

Under the restriction to small angles of the cone of rays $\sin DD_pD'/2$ is sensibly equal to $Y/2l'$. Hence the phase relation at D will be

$$OPD=OPD_p-\tfrac{1}{2}df\left(\frac{Y}{l'}\right)^2, \quad . \quad (11^*)$$

in which df is treated as positive when lying towards the lens system, which is contrary to the usual sign convention but is in accordance with the general custom of treating spherical under-correction as positive.

§ (10) ABERRATION ON THE WAVE THEORY.—The principal cases of interest can now be discussed. (i.) *Ordinary or primary Spherical Aberration.*—The wave distortion for the paraxial focus will be represented by the first term of 10*, or

$$OPD_p=k\,.\,Y^4 \ (k \text{ a constant}),$$

or $$\frac{d(OPD_p)}{dY}=4kY^3=4\frac{OPD_p}{Y}.$$

By equations (11) these give the corresponding geometrical aberrations as

$$OPD_p=[AA']\,.\,\frac{Y}{4}=TA'\frac{Y}{4l'}=LA'\frac{Y^2}{4l'^2},$$

and if the last of these equivalents of OPD_p is put into (11*) the phase relation at any shifted focus is obtained as

$$OPD=\frac{Y^2}{4l'^2}(LA'-2df).$$

If $df=LA'$, that is, for the marginal focus, this gives

$$OPD_m=\frac{Y^2}{4l'^2}(-LA')=-OPD_p.$$

In the case of simple spherical aberration the axial and marginal light therefore meet with precisely the same difference of optical paths at the marginal as they do at the paraxial focus, only the sign of the difference is reversed.

If $df=\frac{1}{2}LA'$ or for the point exactly midway between paraxial and marginal focus, the difference of optical paths between axial and marginal light disappears. These relations become geometrically obvious if a diagram is drawn (*Fig.* 7). The true distorted wave represented by the thick curve bends away from the ideal wave for the paraxial focus in proportion to the fourth

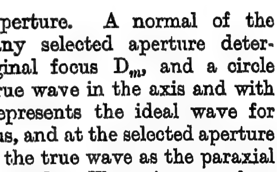

FIG. 7.

power of the aperture. A normal of the true wave at any selected aperture determines the marginal focus D_m, and a circle tangent to the true wave in the axis and with D_m as centre represents the ideal wave for the marginal focus, and at the selected aperture lies as far within the true wave as the paraxial ideal wave lies outside. The existence of an intermediate point D such that its ideal wave cuts the true one at the selected aperture is at once obvious. But it is also readily seen that this is the closest fitting spherical wave within the selected aperture, for if D were moved towards D_m the lump formed by the true wave between axis and margin would manifestly become higher, whilst if D were moved from the midway point towards D_p the intermediate lump of the true wave would diminish

to a less extent than the rapid growth of the projection of the marginal part of the true wave within the spherical wave under consideration. It may therefore be taken without algebraical proof (which, however, is easily supplied) that the residual differences of phase are smallest at the point midway between the paraxial and extreme marginal geometrical foci.

Their amount is easily determined. In the general equation

$$\mathrm{OPD}=\tfrac{1}{4}\left(\frac{Y}{l'}\right)^2(\mathrm{LA}'-2df)$$

LA′ represents the longitudinal spherical aberration for the zone of semi-aperture Y and by the law of simple spherical aberration varies with Y^2. Now let the full aperture be Y_1 and the corresponding spherical aberration LA'_1; then, by the law just referred to,

$$\mathrm{LA}'=\mathrm{LA}'_1\frac{Y^2}{Y^2_1},$$

and the equation for OPD becomes

$$\mathrm{OPD}=\frac{\mathrm{LA}'_1}{Y^2_1}\,\frac{Y^4}{4l'^2}-df\frac{Y^2}{2l'^2}.$$

This is easily proved to give a maximum value for $Y^2=dfY^2_1/\mathrm{LA}'_1$, and on putting this value of Y^2 into the equation for OPD it becomes

$$\mathrm{OPD}_{\mathrm{maximum}}=-\tfrac{1}{4}\frac{Y^2_1}{l'^2}\,\frac{df^2}{\mathrm{LA}'_1}.$$

For the best focus $df=\tfrac{1}{2}\mathrm{LA}'_1$, hence at mid-focus

$$\mathrm{OPD}_{\mathrm{maximum}}=-\tfrac{1}{16}\,\frac{\mathrm{LA}'_1Y^2_1}{l'^2}.$$

Comparing this with

$$\mathrm{OPD}_p=\tfrac{1}{4}\frac{\mathrm{LA}'_1Y^2_1}{l'^2},$$

the highly important result emerges that at the best focus midway between the paraxial and extreme marginal foci the residual differences of optical paths are of only one-quarter of the magnitude attained by them at either the paraxial or the marginal focus.

The case of simple spherical aberration was one of those on which Lord Rayleigh founded his limit. But he did not extend his work to the paraxial focus and did not observe that there is a point at which the physical aberration sinks to only one-quarter of its paraxial value.

It follows that OPD_p may be allowed to reach a whole wave-length without infringement of the Rayleigh limit for the best focus.

Again, assuming an average wave-length as ·00002″ or ·0005 mm., equation (11), combined with the equation used above, $d(\mathrm{OPD}_p)/dY=4\mathrm{OPD}_p/Y$, may be used to determine the values of the geometrical aberrations at which the Rayleigh limit is reached. We have

$$[\mathrm{AA}']\frac{Y}{4}=\mathrm{TA}'\cdot\frac{Y}{4l'}=\mathrm{LA}'\cdot\frac{Y^2}{4l'^2}$$

$$=\pm\cdot00002''=\pm\cdot0005\text{ mm.}$$

These formulae are most conveniently evaluated for the ratio of focal length to aperture—the f-numbers of photographic optics—represented by $l'/2Y$. As regards TA′ it is well known that the "circle of least confusion" of geometrical optics has a diameter equal to $\tfrac{1}{2}$TA′ and

$$\frac{\mathrm{TA}'}{2}=\mathrm{LA}'\cdot\frac{Y}{2l'}=\frac{\mathrm{LA}'}{4\text{ times the }f\text{ number.}}$$

This is directly comparable with the resolving power, which, in accordance with microscopical experience, is defined by the product of the wave-length and the f-number and means that two points at that distance in the image can just be seen apart.

TABLE I

RAYLEIGH LIMIT FOR SIMPLE SPHERICAL ABERRATION

$\frac{l'}{2Y}=f$-number.	$f/8$.	$f/16$.	$f/32$.
Permissible LA′ .	±·020″	±·082″	±·33″
$\tfrac{1}{2}$TA′ = diameter of geometrical circle of least confusion . .	·00063	·0013	·0026
Actual resolving power = f-number × wave-length .	·00016	·00032	·00064

The permissible residue of longitudinal spherical aberration is seen to be surprisingly large, especially for the slender image-forming cones (rarely wider than $f/16$) of microscope objectives. The geometrical circle of least confusion comes out at exactly four times the resolving power of the system, indicating the erroneous results obtained from the geometrical theory.

The realisation of the full resolving power stated in the last line of the table at the present time rests not only on direct observation and on actual experience in designing lens systems on the basis of the Rayleigh limit, but has also been verified by direct calculation of the light distribution in the plane of the best focus and in the neighbourhood of that plane.

It might at first sight appear that the "tolerance" for primary spherical aberration was of no interest in the discussion of highly corrected instruments because they are expected to be free from this defect. They, however, are so only if used in accordance with the intentions of the designer. In practice large liberties are taken by using microscope objectives at tube-lengths widely departing from that for which they were corrected, and in telescopes both by using eyepieces afflicted with considerable spherical aberration and by using instruments designed for distant objects for the observation of laboratory instruments only a few yards away. In all these cases primary spherical aberration makes its

appearance. Table I. explains why satisfactory results are usually obtained in spite of it.

(ii.) *The Rayleigh Limit for Zonal Aberration.*—The aperture of nearly all lens systems is so large that higher terms of the aberration series become sensible. In the case of low and medium power microscope objectives up to about ·35 NA these higher aberrations cannot be corrected, and it becomes important to limit the aperture to just that value at which the higher aberration does not sensibly lower the resolving power. This ideal can be closely realised by applying the Rayleigh limit.

The usual and, as it happens, the best possible method of designing such systems is so to proportion them that the paraxial and the extreme marginal geometrical rays are brought accurately to the same focus; the trigonometrically determined aberration of the marginal ray is therefore brought to zero. In accordance with equation (11) this means that $d(\mathrm{OPD}_p)/d\mathrm{Y}$ is also zero. As paraxial and marginal foci coincide, OPD_m and OPD_p are identical in this case, hence OPD_p can be directly determined by computing equation (10**) for all surfaces of the system and forming the algebraical sum. If higher aberration is present and predominantly of the Y^6 order, this sum will have a sensible value. A very low value would in any case indicate a high state of correction of the system, but not necessarily absence of higher aberration, which will have to be tested for as described in the following section if deep curvatures occur in the system.

Assuming that aberrations of higher than the sixth order are of unimportant magnitude, the equation of the distorted wave will be

$$\mathrm{OPD}_p = k_1\mathrm{Y}^4 + k_2\mathrm{Y}^6,$$

and its value for the full aperture Y_1 is known by the computation of (10**). But it is also known by (11) (on account of the geometrical spherical correction) that $d(\mathrm{OPD}_p)/d\mathrm{Y}_1$ is zero. Therefore there are two equations,

$$\mathrm{OPD}_{p_1} = k_1\mathrm{Y}_1^4 + k_2\mathrm{Y}_1^6,$$

and $$\frac{d(\mathrm{OPD}_{p_1})}{d\mathrm{Y}_1} = 4k\mathrm{Y}_1^3 + 6k_2\mathrm{Y}_1^5 = 0,$$

which can be solved for k_1 and k_2, and on putting the values found into the general equation for OPD_p, the latter becomes

$$\mathrm{OPD}_p = 3\mathrm{OPD}_{p_1}\left(\frac{\mathrm{Y}}{\mathrm{Y}_1}\right)^4 - 2\mathrm{OPD}_{p_1}\left(\frac{\mathrm{Y}}{\mathrm{Y}_1}\right)^6.$$

When plotted, the curve of the distorted wave takes the form shown in *Fig.* 8 if, as is invariably the case, the marginal OPD_{p1} is assumed to have a positive value. The distorted wave bends away from the ideal wave for the combined paraxial and marginal foci, reaches a maximum distance from it at the full aperture, and would cut the wave again some

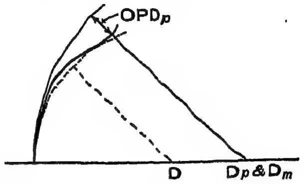

FIG. 8.

distance beyond the full utilised aperture. It is immediately evident that a point D nearer to the lens system must exist which is far more nearly equidistant from all parts of the distorted wave. The closest-fitting ideal wave is dotted in the diagram. It can be determined algebraically by noting that in accordance with equations (10) and (10*) a shift of focus away from D_p will introduce a term in Y^2 into the equation of the wave-curve. Strictly speaking, the terms in Y^4 and Y^6 would be slightly changed at the same time, but if the residual aberrations are as small as they must be if an instrument is to be of practical use, this small change may be safely neglected. A somewhat complicated investigation of the minimum problem involved leads to the result that the residual differences of optical paths become the smallest possible if the point D is so selected (which in the use of the instrument is done automatically and unconsciously simply by searching for the sharpest image) that for point D the residual wave distortion is of the form

$$\mathrm{OPD} = -1\tfrac{1}{8}\mathrm{OPD}_{p_1}\left(\frac{\mathrm{Y}}{\mathrm{Y}_1}\right)^2 + 3\mathrm{OPD}_{p_1}\left(\frac{\mathrm{Y}}{\mathrm{Y}_1}\right)^4 - 2\mathrm{OPD}_{p_1}\left(\frac{\mathrm{Y}}{\mathrm{Y}_1}\right)^6.$$

This gives the same highest value $= -\tfrac{1}{8}\mathrm{OPD}_{p1}$ for half and for full aperture and zero-value in the axis and at $\sqrt{\tfrac{3}{4}}$ of the full aperture. The residual phase-differences in the case of zonal aberration at the best focus are therefore only one-eighth of the amount found by (10**) for the marginal ray. As, in accordance with the Rayleigh limit, a difference of one-quarter wave-length may be allowed, it follows that in lens systems suffering from ordinary zonal aberration (that is Y^6 aberration in the absence of sensible amounts of still higher aberration) the OPD_m calculated by (10**) may be allowed to reach two whole wave-lengths. This result also has been tested and confirmed by a large number of successful lens designs based upon it and more recently by direct integration for the complete light distribution at the best focus.

In the more usual purely trigonometrical method of designing lens systems the zonal aberration is searched for by tracing a third ray through $\sqrt{\tfrac{1}{2}}$ of the full aperture in addition to the paraxial and extreme marginal rays. As is easily shown, the zonal longitudinal spherical aberration reaches a maximum at $Y = \cdot 7071\, Y_1$ if aberrations higher than the Y^6 term are absent. The amount of this zonal longitudinal aberration corresponding to the Rayleigh limit can be investigated in a manner similar to that employed above for ordinary spherical aberration. The result arrived at is that the longitudinal aberration for the ·7071 ray may reach 1½ times the amounts of the LA′ stated in Table I. The corresponding geometrical "circle of least confusion" measures about nine times the resolving power of the system, so that the geometrically estimated size of the image is even more misleading in this case than in that of ordinary spherical aberration.

The analytical method of removing the fourth order aberration completely leads to a wave-distortion of the simple form

$$OPD_p = k_2 Y^6,$$

k_2 having very nearly the same value as it would have if the trigonometrical method were adopted for the same system. A better focus can be found in this case at some distance beyond the paraxial one, but the residual differences of phase at this best possible focus are found to be 6·16 times as large as those existing at the best focus of a trigonometrically corrected system. As the zonal aberration grows with the 6th power of the aperture this means that a trigonometrically corrected lens system may be given $\sqrt[6]{6 \cdot 16} = 1 \cdot 35$ times the aperture possible with an analytically corrected system of the same type.

(iii.) *The Rayleigh Limit for Higher Zonal Aberration.*—In microscope objectives of NA exceeding about ·4 the Y^6 aberration can be controlled. Its negative value in objectives of low NA is due to the excessive marginal over-correction produced by the dispersive contact surfaces. This effect is always present, but when the NA is large and the usual plano-convex front lens is adopted, then very large angles of incidence accompanied by heavy spherical under-correction occur at the first plane surface of the system. The positive Y^6 aberration produced at this surface can then be played out against the negative Y^6 aberration of the corrective contacts, and by securing a suitable free working distance any desired balance may be struck. In the purely trigonometrical method of computing objectives it is usual to aim at union in one point of the rays passing through the paraxial, the marginal, and the ·7071 zone of the full aperture. It is, however, both simpler and leads to a closer knowledge of the residual aberrations to calculate a paraxial and a marginal ray and to bring these to a common focus and then to aim at making the OPD = zero for the computed marginal ray. If only Y^4 and Y^6 aberration were present the correction would then be perfect. In reality the higher aberrations come in in rapid succession. A balance can then be established between the Y^4 and Y^6 aberrations which are under control and the still higher aberrations which cannot be controlled. A full discussion is only possible by making the assumption that Y^8 aberration is the only one of sensible magnitude. This certainly is only a rough approximation, and for that reason the discussion must not be taken as absolutely trustworthy.

It is assumed that the wave-distortion is of the form $OPD_p = k_1 Y^4 + k_2 Y^6 + k_3 Y^8$. The correction stipulated is that the OPD_{p1} for the computed marginal ray shall be zero, and as the geometrical aberration is also removed for the same ray $d(OPD_{p1})/dY_1$ will also be zero in accordance with equation (11). This gives the two equations,

$$k_1 Y_1^4 + k_2 Y_1^6 + k_3 Y_1^8 = 0,$$

and

$$\frac{d(OPD_{p1})}{dY_1} = 4k_1 Y_1^3 + 6k_2 Y_1^5 + 8k_3 Y_1^7 = 0,$$

by which k_1 and k_2 can be expressed in terms of k_3, namely

$$k_1 = k_3 Y_1^4, \quad \text{and } k_2 = k_3 Y_1^2.$$

On putting this into the general expression for OPD_p it becomes

$$OPD_p = k_3 Y_1^4 Y^4 - 2k_3 Y_1^2 Y^6 + k_3 Y^8,$$

and this is zero for $Y = 0$ and for $Y = Y_1$, and has a maximum value for $Y = \cdot 7071\, Y_1$ and a minimum for $Y = Y_1$. For the latter the OPD is, of course, zero. For the maximum at $Y = \cdot 7071\, Y_1$ the value is

$$OPD_{p\,\text{maximum}} = \tfrac{1}{16} k_3 Y_1^8.$$

The residual greatest phase-difference at the computed focus is therefore $\tfrac{1}{16}$ of the total Y^8 aberration present in the system. The curve representing this wave is shown in *Fig.* 9.

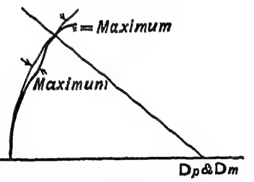

FIG. 9.

No improvement can be made in this case by a shift of focus. But as the zero-value of the OPD at the computed aperture is a minimum, the wave-curve bends again away from the ideal wave beyond the computed aperture, and the aperture may therefore be increased up to the point where the OPD reaches the same value as at ·7071 Y_1 without any increase in the maximum phase-differences at D_p. It is easily ascertained that the general expression for OPD_p reaches the value $\tfrac{1}{16} k_3 Y_1^8$, again at $Y = 1 \cdot 10\, Y_1$. Systems in which

this highest correction is aimed at should, the efore, have the "marginal" ray traced through $\frac{11}{10}$ of the intended *full* aperture. The advantage secured in this way is far greater than it would appear to be at first sight, for at $Y=1\cdot10\ Y_1$ the Y^8 aberration, which is the one beyond control by which the attainable NA is limited, will be $(1\cdot10)^8 = 2\cdot144$ times as large as at $Y=1\cdot00$. By establishing the stipulated corrections for $\frac{11}{10}$ of the intended full aperture, the fraction of the Y^8 aberration present in the real marginal zone which becomes effective at the focus therefore sinks to $1/(16\times2\cdot144)$ or to $\frac{1}{34}$ part. The Y^8 aberration at the extreme margin might therefore reach $\frac{1}{4}$ of 34 or $8\frac{1}{2}$ wave-lengths without transgression of the Rayleigh quarter-wave limit.

Whilst a highly favourable balance of the higher aberrations is sure to be established by the above method, no clue is afforded by it as to the amount of Y^8 aberration which may be present. This may, however, be closely estimated by noting that at aperture Y_1 the Y^4 aberration is exactly equal to the Y^8 aberration. The Y^4 aberration can be determined with sufficient approximation by reducing equation (10**) to first order terms by putting sines equal to angles and cosines equal to one. It then becomes

$$\text{Paraxial OPD}_m = \tfrac{1}{2}N'yi'(u'-u)(i-u'),$$

and if this is calculated with the nominal paraxial angles stipulated in the trigonometrical part of this article it will by summation over all the surfaces give the required indirect estimate of the Y^8 aberration of the computed ray. As $\frac{1}{16}$ of this appears as wave-distortion at the focus, this paraxial OPD_m sum may be allowed to reach 4 wave-lengths, but, on account of the uncertainties introduced by the presence of still higher aberrations and by the rough method of estimating the Y^8 aberration, it is highly advisable to restrict the paraxial OPD_m to a maximum value of only two wave-lengths. This would leave no reasonable doubt as to fulfilment of the Rayleigh condition.

There is no definite method for gaining control over aberrations higher than Y^6; if one were found, then it is an obvious deduction from the preceding paragraph that paraxial $\text{OPD}_m=0$ would be a convenient and effective additional condition to be fulfilled. It would still call for the tracing of only two rays through the system.

§ (11) Focal Range and Depth of Focus.—A very important application of the Rayleigh limit leads to the determination of the range within which the focal adjustment of an optical instrument may vary without sensible loss of definition and conversely to the fixing of the "depth of focus," that is the distance from the nearest to the farthest object which can be seen sharply at any one focal adjustment. All that is required is to discuss equation (11*)

$$\text{OPD} = \text{OPD}_p - \tfrac{1}{2}df\left(\frac{Y}{l'}\right)^2.$$

on the supposition that OPD_p has a fixed value, and that df is subjected to variation. The discussion is simplest for a perfectly corrected instrument in which OPD_p is zero. The Rayleigh limit of $\frac{1}{4}$ wave-length will then apply to OPD, hence

$$df = \tfrac{1}{2}\text{ wave-length}\left(\frac{l'}{Y}\right)^2.$$

By comparison with the permissible LA′ in the case of simple spherical aberration the value of df is seen to be $\frac{1}{8}$ of that found for LA′. But df may obviously be applied on either side of the geometrical sharp focus, hence for a perfectly corrected instrument

Focal Range $= \frac{1}{4}$ of the LA′ in Table I.

The testing of this result by direct integration brings out the same remarkable fact, which also appears in all the other tested cases of a phase-difference equal to the Rayleigh $\frac{1}{4}$ wave-length, namely, that the small deterioration of the image as compared with Airy's ideal spurious disc is limited to a loss of brightness in the central condensation (which nearly always is the only part appreciated by the eye) but does not affect its effective diameter. Within the Rayleigh limit there is thus no loss of resolving power, but only a moderate loss of brilliancy and contrast in the image. On the average (the figures vary sensibly for different cases) the loss of light from the central condensation at the Rayleigh limit is 20 per cent. This remarkable and most valuable peculiarity is maintained up to about twice the Rayleigh limit: the central condensation still maintains its small diameter, but at the doubled limit sinks to about 45 per cent of the ideal maximum brightness, all the light lost in the central condensation appearing in a faint halo and in the more or less distinct diffraction rings. For this reason all the tolerances deduced above may be doubled in case of extreme necessity, still without serious loss of resolving power on detail possessing sufficient contrast. The focal range becomes quite large at high f/numbers as it grows with their square. Thus in photomicrography the cones converging towards the sensitive plate are hardly ever wider than $f/128$, and $f/400$ may be taken as near the average. For $f/400$ the focal range within the Rayleigh limit is 625 times the figure given in Table I. for the LA′ limit at $f/8$, or 12·5 inches. It is therefore quite unnecessary to focus on ground glass in order to localise the image. Equally good results will be obtained, with a great saving of time and eyesight, by focussing "in the air" with a weak magnifier (strong reading-glass) held at about its focal length from the eye and adjusted by guess for focus in the plane to be occupied by the photo-

graphic plate. The image seen in this way will have many times the brightness of that seen on ground glass, and the detail will not be obscured by the grain of the focussing screen.

When there are sensible differences of phase due to spherical aberration at the best focus, then the focal range is necessarily correspondingly reduced, and this reduction is in fact the chief drawback attaching to residuals of aberration up to the Rayleigh limit. If the aberrational differences of phase can be restricted to half the Rayleigh limit the loss of focal range is unimportant, and if only one-quarter of the Rayleigh limit is used up to cover aberration the loss of focal range is quite insensible.

The comparison of the physically determined light distribution near a focus with that suggested by purely geometrical ray tracing yields remarkable diagrams. The upper part of *Fig.* 10 shows by the two inclined

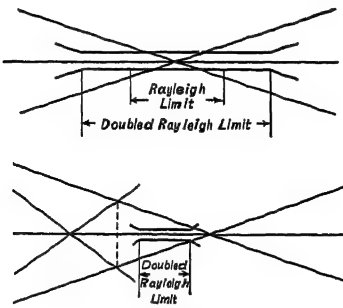

FIG. 10.

straight lines the limits of the geometrical cone of rays in the absence of all aberration. Integration of the interference effect leads to the concentration of all the normally appreciated light between the two parallel lines, which only begin to spread out at the doubled Rayleigh limit. The lower part represents the case of simple spherical aberration at the Rayleigh limit. The inclined lines represent the rays from half and full aperture respectively, the intersection of which determines the geometrical circle of least confusion. The physically determined light distribution is represented by the close parallel lines which lie entirely to the right of the geometrically determined supposed best image and enclose a cylinder of only one-quarter the diameter of the circle of least confusion.

It is noteworthy that Taylor, in his *System of Applied Optics*, called attention to this cylindrical constriction of the light near a focus as an observational fact worthy of theoretical investigation. Any keen observer can easily verify it.

The depth of focus in the object space may be deduced directly from the focal range in the image space by the well-known theorem that the magnification in depth (along the optical axis) is the square of the linear magnification. This, however, becomes inaccurate for high numerical apertures, and it is then desirable to determine df at the object directly by the strict formula from which the above deductions were derived:

$$\text{Difference of phase} = 2df \sin^2 \frac{DD_pD'}{2}.$$

On the side of the object the angle DD_pD' is $\sin^{-1}NA$ if the object is in air, or $\sin^{-1} NA/N$ if the object lies in a medium of index N. In the latter case the wave-length at the object will also be shortened in the proportion of 1 to N, hence the universally applicable equation for df will be

$$df = \frac{\text{Allowed difference of phase}}{2N \sin^2 (\frac{1}{2} \sin^{-1} (NA/N))},$$

in which the difference of phase (according to Rayleigh $= \frac{1}{4}$ wave-length) must be measured by the wave-length in air. The range df may be allowed on either side of the sharply focussed object, hence for the Rayleigh limit

$$\text{Depth of focus} = \frac{\cdot000005 \text{ inch}}{N \sin^2 (\frac{1}{2} \sin^{-1} (NA/N))}.$$

This gives for the numerical apertures stated in the first horizontal line the values in Table II. for wave-length ·00002 in. (bluish green):

TABLE II

Numerical Aperture.	Depth of Focus in Air.	Depth of Focus in Medium of 1·5 Index.
	inch.	inch.
·25	·000312	·000476
·50	·000075	·000117
·75	·000030	·000050
1·00	..	·000026
1·25	..	·000015

The small values of the depth of focus explain the necessity of a delicate, fine adjustment for the focussing of microscopes. The amounts given in the table are available even in the case of projection of the image upon a fixed screen or photographic plate. In visual observations there is an additional amount of depth of focus due to the range of accommodation of the human eye: this is dealt with in the introduction.

§ (12) THE OPTICAL SINE CONDITION.—Although most perfectly freed from spherical aberration, a microscope objective may be utterly useless on account of coma in the images of objects not lying exactly in the optical axis. In microscope objectives of high numerical aperture this defect can reach such extraordinary magnitude that the theoretical resolving power may only be realised if the two close points are placed symmetrically to either side of the optical axis. The removal of coma is therefore

absolutely indispensable. Until 1873 this called for laborious calculations or else for numerous empirical trials of experimental lenses. In that year Abbe and Helmholtz simultaneously but quite independently announced the remarkable theorem known as the optical sine condition, by which the detection of coma is reduced to an almost negligible amount of computation. The theorem states that when any centred lens system causes a ray starting under an angle U from an axial object-point B (*Fig.* 11) to

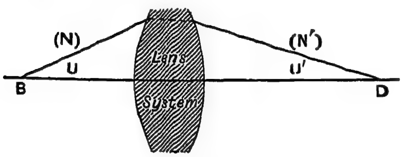

FIG. 11.

reach the trigonometrically determined image-point D under angle U′, then the ratio N sin U/N′ sin U′ will be the magnification of the image produced in the plane of D of a small object near B and in the plane passing through it at right angles with the optical axis. N represents the refractive index of the medium surrounding the object, and N′ the index of the medium in which the image is formed. It follows at once that if zones of the lens system of greater or smaller diameter are considered, they will give an image of the same size only if the ratio N sin U/N′ sin U′ is constant throughout the full aperture. All that is required in order to remove coma in the small field employed by microscope and telescope objectives is therefore to form the ratio N sin U/N′ sin U′ for every computed ray (usually the paraxial and the marginal one), and to modify the system until this ratio attains the same value for the several rays. This is in fact the universal practice of designers of telescope and microscope objectives, and it is very rarely the case that any suspicion of residual coma can be detected in systems thus corrected. When this happens it is due either to zonal variation of the sine ratio or to higher forms of coma which grow with the third power of the diameter of the field and are not included in the theorem. The latter covers all orders of simple coma growing in direct proportion with the diameter of the field.

Many proofs have been given of this remarkable theorem, but most of them are either incomplete or of a highly involved type. For a simple and yet valid proof reference is made to a paper by Conrady in Monthly Notices of *R.A.S.* for March 1905.

§ (13) THE CHROMATIC CORRECTION OF OBJECT GLASSES.—All the ray-tracing equations which have been given involve the refractive index of the lenses of which a lens system is built up. As the refractive index of any given glass varies for light of different colour and wave-length, the conclusion is obvious that the location of the final focal point, the magnification, and the spherical correction will also, as a rule, vary according to the colour of the light. Owing to the comparatively small change of N in the visually bright part of the spectrum (averaging less than 1 per cent of N between the C and F lines) and the pronounced maximum of intensity at the middle of this short range, the variations of magnification and spherical aberration are usually small and can be neglected in systems of low aperture, or treated by a lower approximation than that required for the spherical correction of the brightest rays in systems of high aperture.

The makers of optical glass supply with each melting a table giving the refractive index N_d for the D-line, the dispersion $N_f - N_c = dN$ between the C and F lines, $N_f - N_d$ between D and F, and under the symbol small Greek ν, the ratio of $(N_d - 1)$ to $(N_f - N_c)$. $N'_g - N_f$ for the blue end of the spectrum is also frequently given, G′ being the adopted symbol for the dark-blue hydrogen line close to the solar G-line. Other indices have to be found by interpolation. The best formula (Conrady, Monthly Notices, R.A.S., 1903) for this purpose is

$$N = N_0 + aw + bw^{3\frac{1}{2}},$$

in which N_0 represents the hypothetical index for infinite wave-length, w the reciprocal of the wave-length expressed in μ (·001 mm.), for which N is to be determined, and a and b constants for any one glass. By writing out this formula for the values of N usually given by the glassmakers (C, D, F, and G′), and introducing on the right the corresponding numerical values of w, N_0, a, and b can be solved for in terms of the usual data, and are found as

$$N_0 = N_d - [\cdot 84895](N_f - N_c) + [\cdot 92452](N'_g - N_f),$$

$$a = [\cdot 69108](N_f - N_c) - [\cdot 81775](N'_g - N_f),$$

$$b = -[9\cdot 29980 - 10](N_f - N_c) + [9\cdot 63529 - 10](N'_g - N_f).$$

The figures in square brackets are the logarithms of the numerical factors, which are more useful than the factors themselves.

For the whole range of ordinary optical glasses this interpolation formula gives indices agreeing with direct determinations within one or two units of the fifth decimal place throughout the visible spectrum. On the basis of the nature of the secondary spectrum,

the formula can be discussed so as to determine the wave-length for which a lens system has minimum focal length when the C and F rays are brought to a common focus in accordance with almost universal custom based on long experience. This wave-length of the visually most important rays is thus found as 5555 Ångström units, and the corresponding index can be determined accurately by

$$N_{5555} = N_d + \cdot 2157 (N_f - N_c) - \cdot 0474 (N'_g - N_f),$$

or with nearly always sufficient approximation by the extremely simple formula

$$N_{5555} = N_d + \cdot 188 (N_f - N_c),$$

which is obtained from the more accurate one by introducing ·585 as an average value of the ratio $(N'_g - N_f)/(N_f - N_c)$, from which the latter does not vary for practically useful glasses by more than about ±6 per cent. Decidedly better results are obtained by carrying out the main calculation of lens systems for fulfilment of the sine condition, and freedom from spherical aberration within the Rayleigh limit with this index for visually brightest light obtainable by a single slide-rule setting instead of the widely used N_d.

§ (14) Geometrical Correction of the Chromatic Aberration.—Ray-tracing methods for dealing with the chromatic aberration must be devised with due regard to the variation of spherical aberration in different colours, and to the existence of the secondary spectrum.

A first method consists in tracing a paraxial and a marginal ray in each of two colours near the limits of the spectrum, which is effective under the given conditions. C and F are generally best for visual purposes, D and G′ for systems intended for photography at the visually determined focus. It will nearly always be found that the four rays cannot be brought to a common focus: the best that can be done is to allow spherical over-correction for one (practically always the more refrangible) colour and spherical under-correction of nearly the same amount for the other (less refrangible) colour, and to bring the four intersection points within the smallest possible space along the axis, and to the most symmetrical distribution, which will be usually the sequence, counting in the direction away from the lens system: blue paraxial focus closely followed by the red marginal focus, after a fairly considerable interval the red paraxial focus, and closely beyond the latter the blue marginal focus. As the difference in the spherical aberration for the two colours is almost entirely of the primary order, this arrangement of the foci implies that the red and blue rays through the ·7071 zone would be found closely united at the midway point. The chief drawback of this method of carrying out the chromatic correction is, in the case of microscope objectives, that the criteria for the Rayleigh limit cannot be conveniently applied on account of the residual longitudinal spherical aberration in both colours. Its advantage is that the spherical variation of chromatic aberration is determined directly.

A better method consists in the tracing of a paraxial and a marginal ray in "brightest" light, as defined for visual purposes by the simple interpolation formula given above, and in establishing perfect correction of the longitudinal spherical aberration for these two rays. To correct the chromatic aberration two rays of different colour (C and F for visual purposes) are traced through the ·7071 zone and brought accurately to a common focus. On account of the secondary spectrum the latter will lie at some distance beyond the focus of the brightest light. In this case the criteria for the Rayleigh limit can be applied to the brightest light. The spherical variation of chromatic aberration is, however, not revealed.

A very convenient simplification of the preceding method results if the effect of the secondary spectrum is eliminated from the *calculation* (it of course remains in the actual lens system) by coupling with the calculation of the paraxial and marginal "brightest" rays one fictitious "violet" ray traced through the ·7071 zone, the N_v used being determined for each glass as the sum of its index for brightest light plus its dispersion between C and F. In this method the three computed rays can be brought accurately to one common focus. It can be confidently recommended for all ordinary purposes and for low-power microscope objectives if a purely ray-tracing method is preferred for any reason to the more expeditious and physically sound optical path method now to be given.

§ (15) Physical Treatment of the Chromatic Aberration.—Referring back to *Fig.* 2, but assuming that the object-point O send out white light composed of all colours of the spectrum, the different velocities of propagation of these colours in any one lens of the system, and along axial and marginal paths in it of different length, will in general cause emergence of waves of varying curvature corresponding to the separate colours. The aim of achromatisation is to reduce these variations of curvature to the least possible magnitude for the range of the spectrum which contributes most strongly to the final image. *Fig.* 12, an elaboration of *Fig.* 2, will make this quite clear. If the thick curve W′ in the image-space represents the emerging wave of brightest light, then in the case of chromatic under-correction the emerging more refrangible waves will have a greater curvature—and therefore a shorter intersection length of corresponding rays—and the less refrangible waves will have less curvature. By small adjustments of the relative power of crown and flint components

the marginal gap between corresponding waves of different colour can be modified, and as the differences of refractive index for the range of

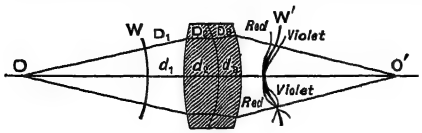

FIG. 12.

colours which calls for correction is always small, the *relative* distortion of the waves will be only affected to an unimportant extent by such a change. Under these conditions reasoning of the same kind as was applied above in the application of the Rayleigh limit to the problems of spherical aberration and the location of the best focus in those cases immediately leads to the conclusion that the best compromise (*i.e.* the least residual gaps between the different waves in the intermediate zones) will be attained if the waves of different colour are so adjusted that they intersect each other in the extreme margin of the effective aperture when they are tangent to each other in the axis. This leads immediately to a solution of the problem. By the definition of a wave surface the optical paths along the geometrical rays between conjugate points of two positions of a wave are absolutely equal. If the upper ray in *Fig.* 12 represents the trigonometrically traced marginal ray in brightest light, and d_1, d_2, etc., are successive parts of the axial path, D_1, D_2, etc., the corresponding parts of the marginal path, and if N_1, N_2, etc., are the respective refractive indices for brightest light, the relation therefore exists for the two paths between W and W′

$$\Sigma(d-D)N=0.$$

If the lower marginal ray in the diagram is similarly regarded as the trigonometrical tracing from W to the wave tangent to W′ in the axis, but of a different colour, and if D'_1, D'_2, etc., are the successive parts of the marginal path, and N_1+dN_1, N_2+dN_2, etc., the respective indices, then for this coloured wave the corresponding relation exists

$$\Sigma(d-D')(N+dN)=0.$$

The discussion of the two sums would still call for the trigonometrical tracing of the two rays of different colour on account of the difference between the corresponding D and D′. At this stage Fermat's "theorem of the minimum optical path," as it is loosely called, becomes available. According to this theorem, the optical path of light between two points as determined by the law of refraction, that is by exact trigonometrical ray-tracing, represents a maximum, minimum, or stationary value with reference to all alternative closely neighbouring paths. These neighbouring paths therefore can at most differ by small quantities of the second order if they are everywhere within small distances and at small angles of the first order compared to the computed path. It follows that if dN represents a very small increment of N, then the differences between the corresponding sums of D and D′ values are strictly negligible. But the same convenient simplification is found to hold for any finite value of dN which can occur in lens systems. When the difference between a trigonometrically determined path and a neighbouring path at small but finite distances and angles is evaluated it is easily proved that this difference will rarely amount to so much as $\frac{1}{10}$ wave-length for any thicknesses or any angles of incidence that can occur in practicable lens systems. The neglecting of the difference between each D and the corresponding D′ for each constituent lens or space is therefore always legitimate in actual lens systems.

For the ideal chromatic correction shown in the lower part of *Fig.* 12, when the coloured and the brightest wave intersect in the marginal zone this equality of D and D′ applies to all sections of the total path. There are then the two relations—

For the brightest light, $\Sigma(d-D)N \quad =0,$

For the coloured light, $\Sigma(d-D)(N+dN)=0,$

and the difference, $\Sigma(d-D)dN \quad =0,$

embodies the condition to be fulfilled by the lens system if the ideal chromatic correction is to be realised.

If the ideal correction shown in the lower part of *Fig.* 12 is not realised there will be a marginal gap between the brightest and the coloured wave, and for the last section of the respective marginal paths there will then be a corresponding difference between D and D′. If the sum of the $(d-D)dN$ is still calculated with the D-values for the brightest light, the sum will differ from zero by the exact amount of the marginal gap between the two waves. Therefore this sum is an unconditional measure of the residual chromatic aberration of any lens-system if put into the form

$$\Sigma(d-D)dN=\text{Chromatic aberration}, \quad (12)$$

the latter expressed as a difference of optical paths.

The sense of the difference $(d-D)$ has been chosen so as to give a positive value for a simple convex lens $(d>D)$ and for coloured light more refrangible than the brightest light $(dN>0)$ in accordance with the custom of counting chromatic "under-correction" as positive in this case.

The indices and dispersions supplied by the glassmakers are determined in air, and are therefore relative and not absolute values. This fact justifies to a large extent the universal custom in practical optics of computing lens-systems with a total disregard of the refractive properties of air. The air is always treated as if its refractive index were exactly *one* and its dispersion *zero*. In evaluating equation (12) this means that air-spaces contribute nothing at all to the value of the chromatic sum, and that the terms $(d-\mathrm{D})d\mathrm{N}$ have only to be calculated for the actual simple lenses of which the system is composed. When the space between the object or image and the nearest lens is filled with a medium other than air, as, for instance, with oil or water in the case of immersion objectives and condensers for the microscope, this space must of course be included in forming the sum.

The only quantity in (12) which calls for an addition to the computing formulae is D. By projecting the D of any one lens upon the optical axis it is easily verified that if X_0 is the depth of curvature calculated by (8) of the first surface, X that of the second surface, and U the angle of convergence of the marginal ray, then

$$\mathrm{D}=(d+\mathrm{X}-\mathrm{X}_0)\sec \mathrm{U}. \qquad (12^*)$$

This formula also covers the case of the space between the object-point and the first lens surface of an immersion-system, by looking upon this space as a lens consisting of immersion-medium and of a thickness equal to the distance from the object-point to the pole of the first actual lens surface. X_0 is then obviously zero and the formula becomes simplified to that extent.

A well-handled slide-rule is generally sufficient for the working out of the $(d-\mathrm{D})d\mathrm{N}$ sum, because the $d\mathrm{N}$ supplied with optical glass are neither determined with sufficient accuracy nor sufficiently constant for different plates of the same melting to be depended upon beyond about 1 part in 500. Unusually thick lenses will, however, call for closer calculation, as in their case the percentage uncertainty of $(d-\mathrm{D})$ will be much higher than that of D. Even then the slide-rule may be used, provided that U is reasonably small, by calculating directly

$$d-\mathrm{D}=(\mathrm{X}_0-\mathrm{X})\sec \mathrm{U}-d(\sec \mathrm{U}-1),$$

in which the great thickness appears with a very small factor and influences merely a small correction.

In practice the $(d-\mathrm{D})d\mathrm{N}$ is calculated for visual instruments with $d\mathrm{N}=\mathrm{N}_f-\mathrm{N}_c$ as given by the makers and for photographic systems with $d\mathrm{N}=\mathrm{N}'_g-\mathrm{N}_d$.

§ (16) The Rayleigh Limit for Chromatic Aberration.—As by (12) the $(d-\mathrm{D})d\mathrm{N}$ sum expresses directly the difference of marginal optical paths for the directly traced "brightest" ray and for the coloured ray of a different refractive index, it is at once apparent that the sum may be allowed to differ from zero-value by the Rayleigh quarter-wave provided that the $d\mathrm{N}$ used refers to the colour, most remote from the brightest, which still contributes a sensible amount to the total intensity of the image. In visual instruments the light corresponding to the C and F lines may be taken as representing this limit. But as the practice is to use the whole dispersion between C and F as the value of $d\mathrm{N}$, whilst the visually brightest light corresponds to the region about midway between C and F, a value of the $(d-\mathrm{D})(\mathrm{N}_f-\mathrm{N}_c)$ sum of half a wavelength will correspond to the Rayleigh limit for either C or F light at the focus of the brightest light. For visual instruments of moderate aperture, in which the spherical variation of chromatic aberration may be assumed to be unimportant, the Rayleigh limit therefore corresponds to

$$\Sigma(d-\mathrm{D})(\mathrm{N}_f-\mathrm{N}_c)=\pm\cdot 00001''=\pm\cdot 00025\text{ mm.}$$

As in the case of the spherical tolerances previously discussed, this apparently minute latitude in the value of the chromatic sum really amounts to an extremely generous allowance. When it has to be drawn upon in order to improve the correction of other aberrations in systems of few surfaces (and it should, of course, be taken advantage of only for some good and sufficient reason!) it is usually used up in *one* of the constituent lenses. Now $(d-\mathrm{D})$ may be taken roughly as of the order of ·1 inch for any one average lens and $(\mathrm{N}_f-\mathrm{N}_c)$ has an average value of ·01. The full amount of $(d-\mathrm{D})(\mathrm{N}_f-\mathrm{N}_c)$ for an average lens is therefore of the order of ·001 inch. The tolerance of $\pm\cdot 00001$ inch represents 1 per cent of this value, so that either the power of the lens—which is proportional to $(d-\mathrm{D})$—or the dispersion of the glass may be varied to the extent of ± 1 per cent without transgression of the Rayleigh limit, and therefore without sensible loss of defining or resolving power.

In systems of large aperture, which almost invariably contain surfaces of deep curvature, the spherical variation of the chromatic aberration represented by the separation of the different coloured waves in the lower part of *Fig.* 12 for zones between axis and margin must be estimated and restricted within safe limits.

Owing to the smallness of the variation of the refractive index for the range of colours which call for serious consideration in any one instance (C to F for visual instruments), the gap in question is almost entirely due to variation of *primary* spherical aberration for different colours and can be evaluated with reference to the "brightest" wave on the principles which were employed in the section on spherical aberration for the determination of the gap between a wave distorted by

spherical aberration and the closest-fitting ideal spherical wave.

As the brightest and the coloured wave intersect each other in the marginal zone, and as the gap between them is attributable (with sufficient approximation) to primary spherical aberration, the gap must correspond to an equation of the form

$$\text{Gap} = c\left(\frac{Y}{Y_1}\right)^4 - c\left(\frac{Y}{Y_1}\right)^2,$$

which gives a maximum value of $-\frac{1}{4}c$ at $Y = Y_1\sqrt{\frac{1}{2}}$, where Y_1 is used as a symbol for the full semi-aperture.

In the paraxial region only the second term will be sensible, as Y/Y_1 will be a very small fraction. Hence a determination of the $(d-D)dN$ sum for the paraxial region will determine the second term and thereby the value of c. This calls for the determination of the net thickness $(d-D)$ of each lens in the vicinity of the optical axis. This is easily derived from the equation already used,

$$d - D = (X_0 - X)\sec U - d(\sec U - 1).$$

$X_0 - X$ will be very small and the factor sec U in the *first* term is therefore to be neglected, as the term is clearly small of the second order. But in the second term d represents a constant finite quantity multiplied by (sec U − 1), which for small angles is small of the second order. Both terms of the equation, therefore, contribute terms of the second order. For the paraxial value of X equation (8*p*) gives

$$x = \tfrac{1}{2}y(u+i),$$

or, as by *Fig.* 1,

$$y = r(u+i),$$

$$\therefore\ x = \tfrac{1}{2}r(u+i)^2.$$

For small angles (sec U − 1) becomes $= \frac{1}{2}u^2$, hence the computing formula is

$$(d-D)_{\text{paraxial}} = \tfrac{1}{2}r_0(u_0+i_0)^2 - \tfrac{1}{2}r(u+i)^2 - \tfrac{1}{2}d\,.\,u^2. \qquad (12p)$$

If the zonal chromatic aberration is to be determined this equation has to be evaluated for each constituent lens, just like the marginal $(d-D)$, and the sum $(N_f - N_c)(d-D)_{\text{paraxial}}$ formed. The use in this calculation of the large fictitious values of the paraxial angles recommended in the first part of this article is equivalent to determining the Y^2 term of the equation for the gap at full aperture; hence the paraxial $(d-D)dN$ sum gives the value of c in the equation for the gap directly without any further reduction. As the maximum width of the gap has been determined above as equal to $\frac{1}{4}c$, one-quarter of the paraxial $(d-D)dN$ sum represents the maximum distance between the red and blue emergent waves, both of which will be at approximately half this distance from the "brightest" wave between them. In accordance with the Rayleigh limit the paraxial $(d-D)dN$ sum may therefore be allowed to reach $\frac{8}{4}$ or two entire wave-lengths. The rule to be followed in these cases of zonal variation of the chromatic correction is, therefore:

(*a*) Bring the $(d-D)dN$ sum to zero-value for the marginal ray by suitable changes of radii, thicknesses, or separations, or by selection of glass of appropriate dispersion.

(*b*) Calculate the $(d-D)dN$ sum for the paraxial region with the aid of (12*p*). If it does not exceed two wave-lengths (·00004 inch), the zonal chromatic aberration will be within the Rayleigh limit and practically insensible. Objectives which fulfil this or an equivalent geometrical condition are now usually described as semi-apochromatic.

§ (17) The Secondary Spectrum.—The $(d-D)dN$ method of dealing with the chromatic aberration supplies by far the simplest and clearest means of demonstrating and evaluating the so-called secondary spectrum of all lens systems made from the ordinary optical glasses.

As the $(d-D)$ value of the separate components of a system may by Fermat's theorem be treated as practically constant for the whole visible spectrum, it is at once seen that if $(d-D)dN$ has been made zero for two selected colours, it would also be zero for other colours if the dN-values for other colours of all the varieties of glass used in the system were in a fixed ratio to the respective values of dN for the originally selected colours. There are no glasses suitable for use in microscope objectives which fulfil this condition. As an example, two glasses largely used in microscope objectives may be taken from Chance's list—

No. 6493	$N_d = 1{\cdot}5160$		$N_f - N_c = {\cdot}00809,$
No. 337	$1{\cdot}6469$		${\cdot}01917,$
	$N_f - N_d = {\cdot}00567$		$N'_g - N_f = {\cdot}00454,$
	${\cdot}01376$		${\cdot}01170,$

or ratio of dispersions

2·37, 2·43, 2·58.

It is seen that the ratio of flint to crown dispersions increases greatly towards the violet end of the spectrum. To estimate the resulting confusion of phase for D and G′ when F and C have been brought to a common focus, it is best to calculate from the ratio in the F − C region what the dispersion of the crown-glass ought to be to establish proportionality. The result is that to remove the secondary spectrum the crown ought to have

$N_f - N_c = {\cdot}00809 \quad N_f - N_d = {\cdot}00581$
$N'_g - N_f = {\cdot}00494,$

or an increase of

·00000, ·00014, ·00040.

These differences, multiplied by the $(d-D)$ value of the crown, give directly the secondary spectrum effect as a difference of optical paths. Now it may be taken that the total of $(d-D)$ values for the crown components of an average microscope objective is about ·15 inch. Therefore the secondary spectrum effect in terms of optical path is, referred to the combined F and C focus, for the D-line $\cdot00014 \times \cdot15 = \cdot00002'' = 1$ wave-length, for the G′-line $\cdot00040 \times \cdot15 = \cdot00006'' = 3$ wave-lengths.

In reality one observes close to the focus of the brightest light which is nearly enough (for the present purpose) at D. Referred to this the F and C rays will arrive with a marginal difference of phase of one wave-length and the G′ rays with one of four wave-lengths or respectively four and sixteen times the Rayleigh limit. This demonstrates the extreme seriousness of the secondary spectrum in cases when a long range of colours comes into action and the difficulty of obtaining good photographs with "achromatic" microscope objectives. Practically no advantage results from substituting other ordinary optical glasses for the two selected above. But very different conditions are found when the mineral fluorite is substituted for the usual crown-glass and dense crown or very light flint-glass for the usual dense flint.

Fluorite :	$N_d = 1{\cdot}4338$	$N_f - N_c = \cdot00454$,
Telescope-flint :	$1{\cdot}5237$	$\cdot01003$,
	$N_f - N_d = \cdot00321$	$N'_g - N_f = \cdot00256$,
	$\cdot00708$	$\cdot00575$.

Ratio of dispersions : 2·21, 2·205, 2·245.

Calculating what the fluorite dispersions ought to be for perfect proportionality, the result is

$$N_f - N_c = \cdot00454 \quad N_f - N_d = \cdot00321 \quad \cdot00260,$$

or an increase of

$$\cdot00000, \quad \cdot00000, \quad \cdot00004.$$

The total $(d-D)$ value of fluorite in an apochromatic objective would, however, be larger than for an achromatic objective and may be put at ·25 inch, which leads to practically perfect achromatism for the entire C to F region and a secondary spectrum effect of $\cdot00004 \times \cdot25 = \cdot00001'' =$ half a wave-length for G′. Even G′ is therefore at the doubled Rayleigh limit which still gives a decidedly small and reasonably bright image of a point. This shows that a very great improvement can be effected by the proper use of fluorite in microscope objectives. But it must be borne in mind that the advantages will only be realised if the correction of the zonal spherical and chromatic aberrations is of a correspondingly high order. Clearly realising this, Abbe from the very first coupled removal of these zonal aberrations, which can reach astounding magnitude in microscope objectives, with the demand for removal of the secondary spectrum, and reserved the name Apochromat for systems which fulfil all three conditions. Objectives improperly called apochromatic are quite frequently met with, which when used with nearly their full aperture are easily beaten in visual observations and even in photographic work by carefully computed and made true semi-apochromatics of ordinary optical glass.

§ (18) THE CHROMATIC VARIATION OF MAGNIFICATION.—At the present time all microscope objectives of less than ⅛ inch equivalent focal length have an unachromatic simple front lens followed by chromatically over-corrected back-combinations. *Fig.* 13 represents the simplest possible (and for low powers quite a useful) representative of this type.

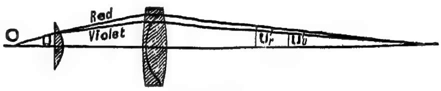

FIG. 13.

A white ray starting from the axial object-point O under angle U will evidently be spectrally decomposed by the unachromatic front lens, and as a consequence the more refrangible components will reach the chromatically over-corrected back lens at points closer to the optical axis than the points at which the less refrangible reach the back lens. If the system as a whole is achromatic for the image-point O′, all the component colours of the original white ray will be brought together at O′, but will necessarily reach it under angles steadily diminishing with the refrangibility of the colours. By the sine condition the magnification produced at O′ will be sin U/sin U′, and will be largest for the most refrangible, smallest for the least refrangible rays, with the obvious result that extra-axial object-points will be rendered not as white points but as short linear spectra with the violet end farthest from the optical axis. If the front lens consists of glass of high dispersion and is widely separated from the corrective back-combination, this chromatic difference of the magnification may reach several per cent of the mean amount and will emphatically call for correction if it approaches or exceeds 1 per cent. It *can* be corrected in the objective itself, as shown in *Fig.* 14, by the addition of a final widely separated uncorrected or chromatically under-corrected lens so calculated that by the action of a heavily over-corrected middle combination the dispersed colours are caused to meet in the final lens and leave it as a reconstituted white ray

proceeding towards O′. Abbe designed some experimental systems on this principle, but it is now invariably preferred to effect the

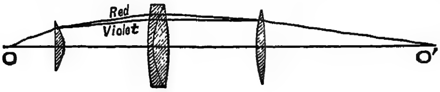

FIG. 14.

correction in the eyepiece by giving to the latter chromatic difference of magnification equal in magnitude but opposite in sign to that of objectives constructed according to *Fig*. 13.

When the chromatic difference of magnification of an objective is to be accurately determined, as it should be in the case of apochromatic systems, the best method consists in tracing a coloured ray right through at $\sqrt{\frac{1}{2}}$ of the full aperture used for the principal calculation.

§ (19) THE ABERRATIONS OF OBLIQUE PENCILS.—A microscope objective spherically and chromatically corrected in accordance with the preceding sections and fulfilling the sine condition will nearly always give satisfactory results throughout the field of small angular extent which is normally utilised. Nevertheless the outer part of the field of low-power eyepieces frequently shows unpleasant indications of the curvature of field and of the astigmatism, which are two defects of extra-axial image-points incapable of full correction in microscope objectives, and which are, partly for that reason, but chiefly on account of the heavy labour involved in their determination, usually left entirely unconsidered in the design of such objectives. Astigmatism causes extra-axial image-points to degenerate into an imperfect concentration of the rays which is characterised by the existence of two focal lines instead of one sharp focal point, one of these focal lines lying in a tangential direction with reference to the centre of the field, and being therefore called the tangential focal line, whilst the other lies at a distance from the first depending on the magnitude of the astigmatism, is directed towards the centre of the field, and is therefore called the sagittal focal line. If the astigmatism is "pure," then the focal lines are perfectly sharp straight lines, and all the rays pass through a small circular disc midway between the two focal lines, whilst at all other points the cross-section of the complete pencil of rays is elliptical. In many cases the astigmatism can be removed by suitable constructional modifications of the lens system. Another defect then remains (with rare exceptions), namely, curvature of the field. This curvature of the field in the absence of astigmatism is determined by the remarkable Petzval theorem. In its original, and hitherto the only generally recognised, form this theorem states that if a centred lens system is free from spherical aberration, coma, and astigmatism, then the residual curvature of the image of a radius $R'i$ is determined by

$$\frac{1}{R'_i}=\frac{1}{R_i}-\Sigma\frac{N-1}{N}\left(\frac{1}{r_1}-\frac{1}{r_2}\right)=\frac{1}{R_i}-\Sigma\frac{1}{N\,.f_0},$$

in which R_i stands for the radius of the surface on which the original object-points lie. The sums have to be taken for all the constituent simple lenses of which the system is built up, N being the refractive index, r_1 and r_2 the first and second radius of curvature, and f_0 the focal length of an infinitely thin lens having these radii. The remarkable feature of the theorem is that the curvature of the image is proved to be totally independent of the thickness and separation of the constituent lenses and also independent of the conjugate distances of object and image.

It has recently been pointed out (Conrady, *Monthly Notices, R.A.S.*, Nov. 1918, Nov. 1919, and Jan. 1920), as an almost obvious deduction from the usual equations for the oblique aberrations of centred lens systems, that the unsatisfactory "if" in the Petzval theorem may be avoided and the utility of the theorem may be greatly increased by incorporating in its statement the fact that in the presence of astigmatism the two focal lines always lie on the same side of the curved image surface defined by the original theorem, and that the tangential focal line of any one oblique pencil always lies at three times the distance of the corresponding sagittal focal line from the Petzval surface. This extended Petzval theorem takes the form

$$\frac{3}{R'_s}=\frac{1}{R'_t}+\frac{2}{R_i}-2\Sigma\frac{N-1}{N}\left(\frac{1}{r_1}-\frac{1}{r_2}\right),$$

in which R'_s signifies the radius of the surface on which all the sagittal focal lines lie, R'_t the corresponding tangential radius, whilst the remaining terms have the significance already referred to. An exact (first approximation) equation of unconditional validity thus takes the place of the widely misunderstood and misinterpreted Petzval theorem. The chief practical value of the extended theorem arises from the fact that it enables a designer to deduce a close value of R'_s as soon as the more easily determined R'_t and R'_i have been found.

In microscope objectives R'_t always has a value nearly equal to the equivalent focal length. If the astigmatism is corrected there will then be a severely curved field, whilst the attempt to reduce this curvature by over-corrected astigmatism (that is, by throwing the focal lines beyond the convex side of the

Petzval surface) leads to loss of definition in the outer part of the forcibly flattened field. The fact that a really satisfactory state of correction is thus impossible justifies to a large extent the universal neglect of a detailed study of the curvature of field and astigmatism in microscope objectives. It is, however, a fact that in the majority of cases, and especially in the spherically and chromatically most highly perfected apochromatic and semi-apochromatic objectives, the already great Petzval curvature is aggravated by under-corrected astigmatism which makes R'_s, and especially R'_t, shorter than R'_p.

The Lister type of low-power objective is decidedly favourable in this respect and can be easily rendered still better by closer approximation to the type of photographic portrait lenses, and this has been done repeatedly, especially for photomicrographic purposes, even to the extent of adopting the anastigmat type of photographic lens. In the higher powers the problem is far more difficult, because the distribution of curvatures of surfaces which favours a flat field is absolutely opposed to that which leads to low residuals of zonal spherical and chromatic aberration in the central part of the field. In the papers already quoted other extensions of the theory of oblique pencils are dealt with which open up new possibilities of reconciling these hitherto contradictory desiderata; but an addition of at least one rather widely separated component to the already complicated high-power objective will nearly always be required and will carry with it a reduction of the transmitted light by about 12 per cent.

Theoretically there is one more defect of lens systems not yet mentioned, namely, distortion: owing to the small angle of field of microscope objectives this defect never reaches appreciable magnitude (except perhaps in the case of very accurate measurements by screw-micrometers), and may therefore be passed over.

§ (20) The Calculation of Microscope Objectives.—It is always preferable to trace the light through a microscope objective in the reverse of the actual direction, that is, from what will eventually be the image to the object. One reason for this procedure is that the tube-length thus becomes a fixed initial datum and will remain unchanged in modifying the system so as to attain the correction of the aberrations. A second justification is supplied by the fact, of which a designer soon becomes aware, that it is far easier and simpler to reach perfect correction by modification of the front lens or lenses than by changes of the compounded back lenses.

All existing microscope objectives, with the possible exception of simple thin cemented achromatic lenses for low magnifications, may be taken to be the result of a succession of purely empirical trials either in actual glass and brass or by the trigonometrical computing method described in an earlier section. For the high powers this method is likely to remain the only one, for it is fairly obvious that in systems in which angles up to 60° or 70° occur no analytical approximation can be of the slightest use. But the lower powers of the Lister type can now be arrived at by a strictly systematic analytical solution recently developed at the Imperial College and based on the theory of oblique pencils given by Conrady in *Monthly Notices of the R.A.S.* of November 1918, November 1919, and January 1920. As an example of a system designed by this process, and also as an illustration of the practical use of the computing formulae given in this article, the following objective of Lister type is selected (*Fig.* 15). The problem set was to design such a system so that it should (in

Fig. 15.

the really employed reverse direction) produce a magnification of −4 times, that the image should be formed at 25 cm. from the back lens, that the separation of the two lenses should be 6·25 cm., and that $\frac{3}{5}$ of the total refraction effect or deviation of the marginal rays should be produced by the back lens. The glasses to be employed were

Chance No. 605	$N_d = 1{\cdot}5175$	$V = 60{\cdot}5.$
Chance No. 360	$1{\cdot}6225$	$36{\cdot}0.$

The analytical solution for freedom from spherical aberration and coma gave for infinitely thin lenses

$$r_1 = 10{\cdot}64 \qquad r_4 = 13{\cdot}51$$
$$(d_1' = {\cdot}4) \qquad (d_4' = {\cdot}3)$$
$$r_2 = 2{\cdot}088 \qquad r_5 = 1{\cdot}449$$
$$(d_2' = {\cdot}2) \qquad (d_5' = {\cdot}2)$$
$$r_3 = 5{\cdot}13 \qquad (r_6 = -3{\cdot}20)$$

Analytically the astigmatism was found to be zero.

This first solution was tested trigonometrically, after putting in the suitable thicknesses given in brackets, by tracing a paraxial and a marginal ray through with initial $l_1 = L_1 = -25$ cm. and $\log u_1 = \log \sin U_1 = 8{\cdot}50504_n$ $(U = -1° 50')$, and gave after passage through the back lens

$$L_3' = 12{\cdot}7020 \qquad U_3' = 3° 37' 0''$$
$$l_3' = 12{\cdot}5096 \qquad u_3' = {\cdot}064120,$$

and after passage through the whole system

$$L_6' = 3{\cdot}0449 \qquad U_6' = 7° 12' 34''$$
$$l_6' = 3{\cdot}0263 \qquad u_6' = {\cdot}125346.$$

As might have been expected, the system proved spherically over-corrected, to the extent of $l_6' - L_6' = -\cdot 0186$. This was corrected by shortening the last radius to $r_6 = -2\cdot 93$ by a few trigonometrical trials. The result then was

$$L_6' = 2\cdot 8696 \qquad U_6' = 7^\circ\ 38'\ 12''$$
$$l_6' = 2\cdot 8699 \qquad u_6' = \cdot 132183.$$

The sine condition then showed the coma correction to be also defective, the magnification produced by the marginal rays being

$$\frac{\sin U_6'}{\sin U_1} = -4\cdot 1539 \text{ times,}$$

that by paraxial rays

$$\frac{u_6'}{u_1} = -4\cdot 1317 \text{ times,}$$

showing an inadmissible difference of about ½ per cent. The analytical solution was therefore repeated by solving for those forms of the two components which would give the opposite of the coma defect found trigonometrically, and the new solution was

$$r_1 = \quad 17\cdot 24 \qquad r_4 = \quad 6\cdot 94$$
$$r_2 = -\ 1\cdot 942 \qquad r_5 = -1\cdot 613$$
$$r_3 = -\ 4\cdot 33 \qquad (r_6 = -4\cdot 13),$$

changed empirically to $-3\cdot 00$.

With the same thicknesses of the individual lenses as before, and the same initial data, this gave

$$L_6' = 2\cdot 9877 \qquad U_6' = 7^\circ\ 14'\ 6''$$
$$l_6' = 2\cdot 9682 \qquad u_6' = \cdot 126509,$$

or, again, spherical over-correction. By two trials the last radius was brought to $r_6 = -3\cdot 60$, and this gave

$$L_6' = 2\cdot 7847 \qquad U_6' = 7^\circ - 44' - 52''$$
$$l_6' = 2\cdot 7840 \qquad u_6' = \cdot 134885.$$

The slight spherical over-correction may safely be ignored as it amounts to only a small fraction of the "tolerance" deduced in an earlier section.

The sine condition is fulfilled by this objective within one part in 3500, so that the coma correction is practically perfect. The analytically determined astigmatism of the second solution is in the over-corrected sense just about to the right extent to yield the most favourable approximation to a flat field. In all these respects the objective is therefore an exceptionally good one, although it departs to a startling extent from the stereotyped Lister type, which would have $r_3 = r_6 = \infty$, and very short radii of the first and fourth surfaces.

The achromatism next calls for investigation. Using the $\Sigma(d-D)dN$ method, the X of the six surfaces have first to be computed; by the equation $X = (PA)^2/2r$ they are found as

$$X_1 = \quad \cdot 01861 \qquad X_4 = \quad \cdot 01188$$
$$X_2 = -\cdot 17330 \qquad X_5 = -\cdot 04814$$
$$X_3 = -\cdot 07682 \qquad X_6 = -\cdot 02029$$

$$X_2 - X_1 = -\cdot 19191 \qquad X_5 - X_4 = -\cdot 06002$$
$$X_3 - X_2 = +\cdot 09648 \qquad X_6 - X_5 = +\cdot 02785.$$

As $D = (d + X - X_0)\sec U$, and as the values of d_1 in proper order were ·4, ·2, ·3, and ·2, the calculation proceeds

	$d+X-X_0$.	U.	$D=(d+X-X_0)\sec U$.	$d-D$.
First lens	·20809	−0° 17′ 44″	·20809	+·19191
Second lens	·29648	−1 57 55	·29669	−·09669
Third lens	·23998	8 38 32	·24044	+·05956
Fourth lens	·22785	2 22 18	·22804	−·02804

The sum $\Sigma(d-D)dN$ can now be worked out for any available glasses of the assumed refractive indices. For the glasses used in the analytical solution Chance's list gives $N_f - N_c$ for the crown as ·00856, for the flint as ·01729. Using these with the above values of $d-D$ for the several lenses it is found that

$\Sigma(d-D)dN = -\cdot 000004$ cm. $= -\cdot 08$ wave-length.

As the tolerance is ·5 wave-length, this minute over-correction may be allowed to pass. If the residual had proved larger it would have been necessary to search the glass lists for a crown with slightly higher or for a flint with slightly lower dispersion. The great advantage of the $(d-D)$ method is that it is nearly always easy to establish sufficiently exact achromatism by merely ringing the changes on available meltings, provided of course that the rough design was arrived at with due regard to approximate fulfilment of the chromatic condition.

The test for zonal chromatic aberration by the paraxial form of the $(d-D)$ equation is next carried out by the formula given above. It was found to give the paraxial residual $= +\cdot 000048$ cm., or under-correction amounting very nearly to one wave-length. As the "tolerance" was fixed at two wave-lengths the objective is found to be satisfactory.

Zonal spherical aberration must then be determined by the trigonometrical OPD_m equation (10**). Employing 20,000, the approximate number of wave-lengths in one centimetre, as an additional factor so as to obtain the OPD directly in approximate wave-lengths, the results are

$$OPD_1 = -\ \ \cdot 35 \qquad OPD_4 = +\ \cdot 005$$
$$OPD_2 = +14\cdot 84 \qquad OPD_5 = +3\cdot 32$$
$$OPD_3 = -11\cdot 04 \qquad OPD_6 = -6\cdot 12,$$

and their algebraical sum $= +\cdot 66$ wave-length represents the lead with which the

marginal ray meets the axial ray at the final focus. As the present system includes no very large angles or curvatures this residual may safely be interpreted as indicating simple zonal aberration, for which a tolerance of two wave-lengths was established. The result is therefore highly satisfactory.

It may be of interest to add that the whole of the analytical and trigonometrical work involved in arriving at this final design was carried out in less than ten hours The objective would be described as a $2\frac{1}{2}$ inch of NA. 135, for English tube-length. If made to two-third scale it would be suitable for a $1\frac{1}{2}$ inch for Continental tube-length.

In the higher powers of three or more separated components the attainment of the desired correction depends almost entirely on empirical trials guided by experience and instinct, the latter being most easily acquired by progressive studies beginning with simple achromatic lenses and gradually advancing to more complex forms. The calculation of the OPD values should never be omitted, for experience has shown that if the differences of optical paths arising at any one surface exceed 30 or at most 50 wave-lengths the fulfilment of the Rayleigh condition for the whole aperture is rendered almost impossible. Similarly the sum of all the positive OPD amounts should not exceed 100 or at most 200 wave-lengths for any one complete system.

In systems with the usual thick plano-convex front lens the form of the latter which leads to correction of the longitudinal spherical aberration and of the coma for the computed marginal ray can always be determined by a practically direct solution. Refraction at the final plane surface does not change the ratio of sin U′ to u', as both are derived from their values before refraction by multiplication with the relative refractive index. Therefore the sine condition must be fulfilled by the U′ and u' of the first, spherical face of the front lens, and the requisite radius can be quickly found by a few trials based on this criterion. Provided that this radius leads to spherical over-correction of the refracted pencil (if it does not, then spherical correction will be impossible) the necessary thickness of the front lens can be found by a direct solution. Let the intersection lengths of the rays issuing from the convex surface be l' and $L' \equiv l' + (L' - l')$, and let d be the sought thickness. The intersection lengths of the rays arriving at the plane face will be $l' - d$ and $l' - d + (L' - l')$ respectively. The corresponding intersection lengths after refraction are to be equal (so as to remove the spherical aberration) and are determined by $Pl(3p)^*$ and $Pl(3)^*$ respectively. Hence the condition

$$\frac{(l'-d)N'}{N} = [(l'-d)+(L'-l')]\frac{N'\cos U'}{N\cos U},$$

in which U represents the obliquity of the marginal ray arriving at the plane and U′ its value after refraction as obtained from the equation by $\sin U' = \sin U . N/N'$. This equation immediately gives the solution

$$d = l' - \frac{(L'-l')}{(\cos U/\cos U') - 1}.$$

With this convenient solution any number of front lenses can be found for given back combinations and the best one picked out by the criterion of zonal aberrations. This represents the strongest argument in favour of calculation of microscope objectives in the reverse direction.

In objectives of a numerical aperture exceeding about ·25 the spherical aberration of the cover-glass usually employed in microscopy has to be allowed for. As objectives of these higher powers always have a plano-convex front lens this allowance is easily made without any laborious calculation by diminishing the thickness of the front lens calculated by the last equation by the thickness of the cover-glass. This simple procedure is legitimate even when the refractive index of the front lens differs very considerably from that of the cover-glass, for it is found by direct calculation that the aberration of a thin plano-parallel plate is almost independent of its refractive index in the region of usual glass indices.

§ (21) Eyepieces.[1]—The image produced by a microscope objective is usually further magnified by an eyepiece inserted in the upper end of the tube.

The cones of rays issuing from the objective towards the primary image have a common base at or near the back lens of the objective; it is convenient and usual to assume that this common base of all the image-forming pencils coincides with the second focal plane of the objective. Any one of these pencils is refracted by the lenses of the eyepiece as indicated in *Fig.* 16, and should, for a normal eye with

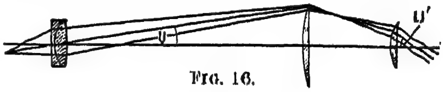

Fig. 16.

relaxed accommodation, emerge as an inclined bundle of parallel rays. The angular magnification of the eyepiece is then defined as the ratio tan U′/tan U, U being the angle at which the central or principal ray of the oblique pencil leaves the second focal point of the objective, and U′ the corresponding angle after passage through the eyepiece. The angular magnification so defined represents the number engraved on many eyepieces—more especially on compensating ones—and is the most convenient one for the designer. From the general theory of lenses it follows that if D represents the

[1] See also "Eyepieces."

distance from the upper focal plane of the objective to the lower focal plane of the eyepiece (=the so-called optical tube-length of the microscope), f the equivalent focal length of the eyepiece, and MA the angular magnification as defined above, then

$$\text{MA}=\frac{-\text{D}}{f}.$$

The values of D used by Abbe for the compensating eyepieces have been widely adopted; they are D=180 mm. for the "Continental" and D=270 mm. for the "English" standard tube-length. English makers, however, more usually adopt 10 inches as the value of D on which their magnification numbers are based.

The order of importance of the various aberrations is quite different for eyepieces from that for objectives. The reason is that the individual image-forming pencils passing through the eyepiece are very slender, their convergence ratio as they leave the objective rarely reaching even $f/16$. Consequently the longitudinal spherical and chromatic aberration of the individual pencils is unimportant and may usually be ignored altogether. On the other hand pencils like the one shown in *Fig.* 16 aiming at image-points near the margin of the field of view pass the eyepiece lenses at large angles of incidence (frequently exceeding 30°, and at the contact surface of achromatised eye-lenses even 50°), and these large angles may lead to very serious amounts of chromatic difference of magnification, of distortion, of astigmatism, and even of coma. These are the aberrations which call for the attention of the designer.

The chromatic difference of magnification is most easily dealt with. It arises from the dispersion of a white principal ray into its constituent colours by the prismatic effect of the extra-axial parts of the eyepiece lenses. Such a ray will be dispersed by the first or field-lens (a) as indicated in *Fig.* 17, and if a

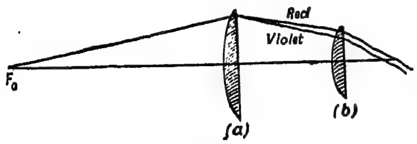

FIG. 17.

single lens were used as an eyepiece the violet and red images would be seen in the reverse direction of the corresponding emerging rays and would not coincide: the red image would appear decidedly smaller than the violet one. This defect is most usually corrected by placing a second lens, the eye-lens (b), at a considerable distance from (a). The violet ray then traverses this second lens closer to its centre than the red ray and suffers less deviation, and a means is provided to secure parallel emergence of the different coloured rays. As was pointed out in discussing the objective, the latter may itself supply primary images with a chromatic difference of size, the violet primary image being larger than the red one. The eyepiece then must compensate this difference in addition to correcting its own. The following paraxial solution is usually sufficient to determine the data of an eyepiece consisting of two thin lenses so as to establish equal magnification in all colours:

Let C be the compensation constant of the objective with which the eyepiece is to be used, calculated as C=1 − (size of red primary image)/(size of blue primary image), the red image corresponding to the C-line of the spectrum, the blue image to the F-line. For most of the apochromatic objectives C=·012. In the case of eyepieces for general use with ordinary objectives it would be advisable to introduce C=·004 or ·005 as a compromise.

Let f be the desired equivalent focal length of the eyepiece, f_a the focal length of the field-lens, f_b that of the eye-lens, $k=f_b/f_a$ the adopted ratio of the two separate focal lengths, a usually suitable numerical value being $k=\cdot 5$.

Further let ν_a be the glass-maker's ν-value for the material of the field-lens, ν_b the corresponding value of the eye-lens, MA the required angular magnification, always a negative number, and d the separation (air-space) between the two thin lenses. Then the problem will be solved by calculating

$$f_b=f[\text{P}\pm\sqrt{\text{P}^2-\text{Q}}],$$

in which

$$\text{P}=1+\tfrac{1}{2}\text{MA}\,.\,k\left(\frac{\nu_a+\nu_b}{\nu_b}+\text{C}\,.\,\nu_a\right),$$

$$\text{Q}=(1+\text{MA}\,.\,k)\left(1+k\frac{\nu_a}{\nu_b}\right),$$

and then

$$f_a=\frac{f_b}{k},\quad\text{and } d=f_a+f_b-\frac{f_a f_b}{f}.$$

For eyepieces without compensation (C=0) two plano-convex lenses of ordinary crown-glass will usually give fairly satisfactory results. If the Huygenian type is to be adhered to for compensating eyepieces, good results are only obtainable by making the field-lens of dense flint-glass (Nd=1·62 or better 1·65) and the eye-lens of light crown-glass, or better still by using an achromatised eye-lens ($\nu_b=\infty$). For compensating eyepieces for high values of NA Abbe introduced chromatically over-corrected close combinations on account of the greater distance of the eye-point obtainable with this type. With Huygenian eyepieces of high magnification the eye has to be brought very close to the eye-lens

in order to see the whole field, and this proves irritating, especially to observers with long and stiff eyelashes.

The modification of an eyepiece design with a view to reducing the other aberrations mentioned involves the whole theory of pencils of finite obliquity and aperture and cannot be usefully dealt with in the available space.

§ (22) THE ILLUMINATION OF MICROSCOPIC OBJECTS.—From the point of view of geometrical optics it ought to make very little difference how the illumination of an object is effected, provided it is of suitable intensity for comfortable observation. If aberrations are absent the instrument should yield a perfectly sharp image of every point in the object regardless of whether the whole aperture of the object-glass is filled with light or whether only a part of the aperture transmits light. Moreover, such an absolutely sharp image should bear unlimited magnification. This was in fact the view taken until about 100 years ago; if the instrument failed to give sharp images when a certain magnification was exceeded, the explanation was sought in uncorrected aberrations. Certain observational experiences which demonstrated that with the same instrument and the same magnification sharper images and higher resolving power could be obtained sometimes merely by changing the direction from which the object was illuminated were explained as shadow-effects of the type which renders visible under oblique illumination countless small craters on the moon of which not a trace can be seen in the full moon. The improbability of any appreciable shadow being produced by the usually frail and highly transparent microscopic objects was ignored.

The undulatory theory of light supplied the means of explaining this obvious breakdown of the purely geometrical explanation of optical images. Airy's determination of the form and size of the spurious disc produced by interference of the light arriving at the geometrical focus of a perfect instrument solved the problem to a considerable extent. Although his result was obtained nominally for the telescope it is equally applicable to any other perfectly corrected optical instrument, for the diameter of the spurious disc is found to depend only on the wave-length of the light (to which the diameter of the disc is proportional) and on the aperture of the object-glass, if the diameter of the disc is measured in angle, or on the ratio of aperture to focal length if the diameter of the disc is measured in linear measure; the diameter of the disc in either case is inversely proportional to the aperture. As two discs will cease to be separated by a dark space when their distance apart is equal to their diameters it follows that the least distance at which two points in the image can be resolved is equal to the diameter of the spurious disc, no matter in what unit the latter is measured, and also that this distance is inversely proportional to the effective aperture of the object-glass and directly proportional to the wave-length of the light employed.

When applied to the microscope, Airy's theory of the spurious disc explains some of the observed phenomena fairly satisfactorily. As the smallness of the image depends on the effective aperture, *i.e.* that part of the lenses which is really filled with light, there should be a maximum of resolving power when the object-glass is completely filled with light and a reduced resolving power if only a part of the full aperture is utilised. This is qualitatively in accordance with experience, but not quantitatively, for it is found that a microscope objective retains one-half of its maximum resolving power if only a very small axial illuminating pencil is employed; by the theory the resolving power should be reduced to a very small fraction of its maximum value. Light scattered by the structure of the object and thus slightly utilising the space not filled with direct light was naturally adduced in explanation; but it is impossible thus to account for the fact that—with all kinds of objects—the resolving power is just half that obtainable from the lens when completely and uniformly filled with light.

Another and even graver objection to the application of the Airy theory in the case of the microscope arises from the fact that the theory is only valid, firstly, if all the light arriving at any one image-point is coherent, that is, derived from one original point-source and, moreover, if this light approaches the image-point as a truly spherical wave train; secondly, if other image-points in the immediate neighbourhood of the one first considered receive no light from the source illuminating the first, otherwise there would be secondary interferences between adjacent image-points and the form of the individual images would be profoundly modified. These fundamental conditions could only be fulfilled if the objects under observation were rendered self-luminous, say by making them white hot, which is manifestly out of the question in all but most exceptional cases. It used to be thought (Helmholtz was the last responsible scientist upholding this view) that the objection could be met by projecting upon the object under examination the sharp image of a self luminous source by means of a highly corrected condenser. But no condenser yet made has the requisite freedom from aberrations, and even if one were produced it would still depict each point of the source as a tiny spurious disc with attendant interference-rings, all consisting of coherent light covering an appreciable area

of the object and so defeating the theoretical requirements.

Finally the Airy theory can give no reasonable explanation of any kind of the results obtained by lighting objects with light of such obliquity that the direct illumination cannot enter the objective of the microscope, that is, the theory fails entirely for dark-ground illumination.

§ (23) ABBE THEORY.—Abbe was the first physicist who clearly realised these shortcomings of the Airy theory when applied to the microscope. He overcame the difficulty in the way which is rendered obvious the moment its nature is recognised, by studying the nature of the image produced when the object is illuminated by a single point-source so that all the light falling upon the object is necessarily coherent and capable of interference. If an extended self-luminous source is subsequently substituted, each point of it will produce an image of the type determined, and as the vibrations of different points of a self-luminous source are independent and incapable of permanent interference the final image will everywhere have the simple sum of the intensities of the elementary images without any complications due to secondary interferences.

If a minute hole measuring only a small fraction of a wave-length in diameter is produced in an opaque film and illuminated from a distant point-source, then there will be no scope for sensible interference effects, and the hole will send out light in all directions on the principle of Huygens and will behave exactly as if it were itself self-luminous. This is the only case in which the theories of Airy and of Abbe lead to the same result. It is approximately realised in the "ultra-microscope," by which minute particles are seen exactly like stars in a telescope; in fact, if the instrument is well corrected the spurious disc with its surrounding diffraction rings is clearly seen.

But if the light-transmitting aperture attains a size of the order of a wave-length or if there are a number of apertures within small distances of each other, then there will be interference effects between the light from different points of the aperture or apertures, resulting in the producing of some type of diffraction spectra. In the vast majority of cases the result is hopelessly complicated and, moreover, inaccessible to theoretical discussion, inasmuch as the latter would require the minute structure of the object to be known with absolute certainty. In the case of delicately structured natural objects only known by microscopical observation an obvious vicious circle would be involved in using such objects to test a theory. This also was clearly realised by Abbe and avoided by devising a large number of highly ingenious experiments on artificial simple objects such as finely-drawn-out glass threads, and especially on gratings ruled in a silver or carbon film and used either singly or two crossed so as to produce dot-patterns. By observing such objects of accurately known structure Abbe proved experimentally his theoretical conclusions that refraction or reflection of light by the object could not explain the image, but that the image could be fully accounted for by the diffraction spectra produced by the object, and that the verisimilitude of the image depended on the extent to which the diffracted light was admitted by the objective of the microscope. For a fuller account of this Abbe theory reference must be made to Dippel's handbook of microscopy, and for a more detailed study of the application of the theory to the conditions usually prevailing in the actual use of the microscope to two papers by Conrady.[1]

All that is required to establish the theory of illumination is to consider the distribution of the diffraction spectra in the case of a simple grating of straight and equidistant slits. If such a grating is illuminated by parallel light from a distant point-source a number of diffracted beams are produced, and as the angles at which these proceed obey a sine law whilst a microscope objective also must satisfy the optical sine condition, it easily follows that, no matter in what direction the source of light may be placed, the diffracted beams are depicted in the upper focal plane of the objective focussed on the grating as a series of equidistant points if the light is monochromatic, the distance from point to point being inversely proportional to the spacing of the grating and to the wave-length of the light, and the line formed by all the diffracted light-points being at right angles to the direction of the grating-slits. If at least two consecutive diffracted beams are transmitted by the objective, then their interference in the final image plane (usually on the retina of the observer's eye) will produce an alternation of bright and dark lines coinciding with the image of the grating which would be deduced by geometrical optics. With an objective of limited aperture only a part of the complete set of diffraction spectra will be admitted. Referring to *Fig.* 18, in which the direct light is distinguished by a small circle, the flanking diffraction spectra by crosses, it is easily seen that if the source of light were placed upon the optical axis, an objective of small aperture (A) might admit only the direct light and no resolution would be obtained. It would require an aperture B to admit the direct light and the two nearest diffraction

[1] *Journ. R. Micr. Soc*, 1904, pp. 610-633, and 1905, pp. 541-553.

spectra with axial illumination and to secure resolution. But if the source of light were moved to one side of the optical axis—thus

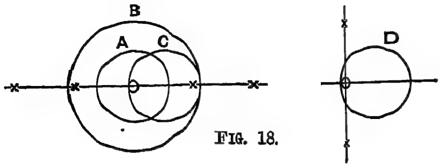

FIG. 18.

producing oblique illumination—then the aperture A would just be capable of admitting the direct light and the nearest diffraction spectrum (C) and resolution of the grating would result. The increased resolving power with oblique illumination is thus explained; also the two-to-one ratio of resolving power with extremely oblique and with axial illumination, respectively.

But a very grave objection to simple oblique illumination is also easily deduced. As a rule the observer will be ignorant of the direction of the lines of the structure under observation or there may be in the same field specimens having lines in various directions. Now with oblique light arranged according to case C and a structure producing a row of diffraction spectra of the same, or even a closer, spacing, but on a line nearly at right angles to that first considered, only the direct light would be admitted (D) and no resolution would result. To avoid this pitfall it is therefore absolutely necessary when employing simple oblique illumination to try it in all azimuths, either by rotating the object by means of a mechanical stage or by producing a corresponding change in the illuminating pencil by a rotating eccentric diaphragm of the substage-condenser. But a method which nearly always deserves preference is to produce oblique light in all azimuths simultaneously by means of a condenser opened to a suitable aperture to secure the desired degree of obliquity with a large "solid cone" of illumination, or to accentuate the higher resolving power of oblique light by adding a central stop below or above the condenser-iris which cuts out the central part of the illuminating cone and so produces "annular illumination." Evidently the essential requirement is that the illumination should be perfectly symmetrical with regard to the optical axis, that is, strictly concentric with the latter. Looking down the tube of the microscope the observer should see either a uniformly bright and nicely centred disc of light or a ring of light of uniform brightness and bounded by circles concentric with the axis of the microscope. These are the conditions which are both necessary and sufficient to secure truthful and reliable images of microscopic objects no matter what their structure may be. The realisation of these conditions is not difficult if a uniformly bright source of light of large area, such as the sky or a large flame, is available, and excellent results are then obtainable with condensers of the simplest type. But when the source is small and especially when it is almost linear like an incandescent lamp filament, then the conditions can only be adequately satisfied with a condenser carefully designed so as to be fairly free from spherical and chromatic aberration and accurately focussed so as to project a sharp image of the source of light upon the object under observation. Condensers of this kind closely resemble microscope objectives of corresponding numerical aperture and are designed by the methods described in earlier sections: the tolerances, however, may be safely extended to two or three times the amounts stipulated for objectives.

The Abbe theory also leads directly to a formulation of the proper conditions to be fulfilled in dark-ground illumination. If a regular structure is illuminated by light of such obliquity that the direct light cannot enter the microscope objective, then the image will be produced entirely by diffracted light and at least two diffraction spectra must be admitted in order to secure an image of the structure. *Fig.* 19 shows at once that the maximum of resolving power will be secured if the first and second diffraction spectra can just enter at opposite margins of the aperture. Evidently the direct light will then be three times as far from the axis as either diffraction spectrum, and this maximum can therefore only be realised if a condenser is available which has three times the numerical aperture of the objective to which it supplies dark-ground illumination. As the numerical aperture of a condenser cannot exceed 1·5, it follows that the full resolving power of objectives over ·5 NA cannot be realised by dark-ground illumination; the latter therefore implies a disadvantage in the case of all objectives of high NA. On the other hand, there may be present in the same field coarse structures which give closely spaced diffraction spectra. In order that the latter may be admitted, it is necessary that the ring of dark-ground illumination should extend inwards as nearly as possible to the aperture of the objective in use. Hence a second important rule: that the dark-ground stop should be only just large enough to secure a dark field. This rule cannot usually be satisfactorily fulfilled if a high-power condenser has to be used

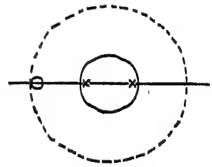

FIG. 19.

in order to secure illuminating cones of great obliquity. The reason is that in practically all existing condensers of high N.A. the diaphragm and dark-ground stop are placed far below the anterior focal plane, with the result that a real image of both is formed close above the object under observation (*Fig.* 20). If this

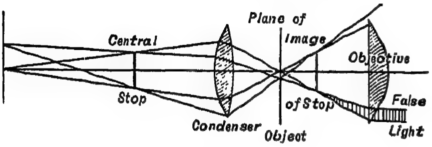

FIG. 20.

image of the dark-ground stop is only just large enough (as it ought to be) to stop direct light from the axial object-point from entering the microscope objective, then it will stop out an *oblique* cone of similar angle from extra-axial object-points, with the result that from the latter direct light will be admitted on the side of least obliquity of the inclined hollow illuminating cone. The field thus is dark only in and near its centre, with rapidly growing illumination towards its margin, and the effect is totally spoilt. This grave drawback can only be removed by placing the diaphragm and central stop close to the anterior focal plane of the condenser: unfortunately the present design of microscope stages and substages renders the fulfilment of this important condition very difficult. The various types of reflecting condensers (paraboloids, etc.) are attempts to overcome this difficulty: it would be decidedly preferable to have oil-immersion condensers with correctly placed diaphragms, and it is therefore to be hoped that designers will give earnest attention to this desideratum.

MICROSCOPY WITH ULTRA-VIOLET LIGHT

§ (1) INTRODUCTION.—The evolution of the modern microscope has been a process in which improvements of importance have alternated with long periods of apparent inactivity. It has in general followed the same lines as other optical instruments, that is, so far as methods of correcting for spherical and chromatic aberration are concerned (see "Microscope"). The introduction of immersion lenses by Amici in 1855 marks one of the great optical improvements that has had a profound influence on its development, although it was at a much later date that full advantage was taken of the method. Not until the latter part of the last century, largely owing to the researches of Abbe,[1] were the factors governing resolving power recognised and understood. It was realised as the result of those researches that there exists a limit beyond which resolving power cannot be increased. The practical result therefrom was the computation and production of apochromatic objectives, in which colour correction was of a higher order than had at that time been achieved in any optical instrument. Since that period there has been no real advance in microscopic optics.

There are two distinct methods of investigation in modern microscopy, one in which enhanced visibility is the main purpose in view, no information as to the form or structure of minute objects being secured, and the other the more usual one of the resolution of structural details. In the former case objects are rendered self-luminous, appearing as bright bodies on a dull ground. The method is known as "dark-ground illumination" when bodies within the resolution limits are being observed, as "ultra-microscopy" when small particles beyond these limits are made visible.[2] Considerable confusion has arisen owing to the use of the term "ultra-microscopy" in describing both modes of observation. In their fundamental physical aspects the method of dark-ground illumination and observation with the ultra-microscope are identical, as both serve to enhance the visibility of an object. The practical difference is in the type of object under observation and the manner in which it is observed, rather than in the difference between the character of the appliances used for the purpose. When objects seen in a dark field show structural details or well-defined contours we are dealing with simple dark-ground illumination. When, on the other hand, the field is seen to contain particles in which there is no trace of detail or evidence of structure, and which appear as mere points of light, the case is one of ultra-microscopic observation. It is obvious that both types of image may be seen at the same time; the fundamental difference is therefore dependent on the size

[2] Siedentopf, *Journ. Roy. Micr. Soc.*, 1903, p. 573; *Ann. d. Phys.*, 1903, pp. 1-39; *Berl. klin. Wchnschr.*, 1904; *Zs. f. wiss. Mikros.*, 1907, p. 382; Faraday, *Proc. Roy. Inst.*, 1854, p. 310.

of the object, whether it is above or below the resolution limits, and on the distance between neighbouring visible units. It is in the direction of obtaining increased resolution that the greatest need is felt in practical microscopy.

§ (2) Resolving Power.—It is well known that the smallest distance separating two points in an object—such as a grating—is given by the relation

$$d=\frac{\frac{1}{2}\lambda}{\sin a},$$

where λ is the wave-length of the light used in the medium surrounding the object, and a is the angle subtended at any point in the object by half the effective angular aperture of the objective.[1] This is usually written

$$d=\frac{\frac{1}{2}\lambda_0}{\mu \sin a},$$

when λ_0 is the wave-length in air, and μ the refractive index of the medium. It follows that the value of d, the distance between any two elements of recurring structure, is dependent on the wave-length of the light used and on the product of $\mu \sin a$, which is known as the numerical aperture (N.A.) of the illuminating and observing optical system. This relation is applicable in the case of a grating illuminated by a beam of the greatest possible obliquity, ensuring that the essential diffraction spectra are within the limits of the objective aperture. It is reduced to

$$d=\frac{\lambda_0}{\mu \sin a},$$

when axial illumination is resorted to, a condition that applies to most observational work. It is in this connection important to remember the well-founded view of Abbe that "the diffracted light emanating from the object may utilise the whole aperture of the system, although the incident cone of light, if it were simply transmitted in the absence of an object, would fill only a very small portion of the aperture." It follows that greater resolution can be obtained either by reducing the wave-length of the light used as the illuminant or by increasing the N.A. of the objective. With dry lenses the greatest attainable N.A. is ·95. This can be increased by using immersion lenses, the resulting N.A. in the case of water being approximately 1·25, cedar-wood oil 1·50, or monobromide of naphthaline 1·60, the latter being used only in metallurgy, or in cases where flint cover-glasses of the necessary refractive index can be utilised. The actual resolution obtained with white light with a mean wave-length of 550 $\mu\mu$, when a grating is illuminated by oblique rays and with N.A. 1, is therefore about 92,000 lines per inch. The use of oblique light is necessary to obtain the utmost resolution with such an object, as otherwise the diffraction spectra which are essential to the formation of the image cannot be embraced by the objective. It has to be recognised that such an image is not of necessity a true representation of the object; it is in most cases no more than an indication of the periodicity of the structure. The so-called resolution of diatoms may be cited as an example, in which the structure may give rise to an image consisting of parallel lines or bars. Such lines are known to be merely an indication of a regular sequence of depressions, perforations, or excrescences of the same periodicity, and this constitutes the only point of similarity between the object and the image. To obtain a real image the object must be illuminated with a solid axial cone of light, and under these conditions resolution falls to one-half of the value stated. It would therefore be of the order of 46,000 lines per inch in white light. Johnstone Stoney[2] states that with an immersion objective of N.A. 1·35, and an immersion condenser of N.A. 1·30, using a suitable stop to secure oblique illumination in a direction at right angles to the direction of the lines of the grating and with blue light of 450 mm. wave-length, the practical limit of separation is about 0·20 μ. He has also demonstrated that a pair of objects may be resolved when they are separated by about five-sixths of the interval between the elements of a row of such objects or points; in other words, that resolution is increased appreciably when only two neighbouring elements of structure are being observed. The computation by Abbe[3] of apochromatic objectives has resulted in the production of systems for visual work with the highest attainable N.A., and in which spherical and chromatic correction are of a high order. Their chief characteristic is that they are perfectly corrected for three colours in the spectrum, and approximately for all colours in white light. Their superiority over any achromatic system is dependent on their computation and not on the use of any particular material, such as fluorite, in their construction, although this material has optical constants which are essential in the computation of such objectives, no suitable optical glass yet being available. By using light of short wave-length in the spectroscopic region of the green, blue-green, or blue-

[3] Abbe, *Journ. Roy. Micr. Soc.*, 1879, p. 377.

violet, the greatest attainable visual resolution is secured. The most useful illuminant for this purpose is the mercury-vapour lamp, as it is possible by using suitable colour screens to utilise the bright lines in the orange, green-blue, or violet. Even when used without a screen this illuminant has the advantage possessed by no other, that the mean wave-length is reduced, as no red radiations enter into its composition. It is obvious that even under these conditions resolution is strictly limited. The only practical method of obtaining increased resolution that has been evolved since the researches of Abbe, with proportionately increased magnification, which constitutes a definite advance, is in the use of ultra-violet light, a method which opens up a wide field for investigation. The shortest wave-length that has sufficient luminosity in the visual spectrum for direct observation may be regarded as being in the region of wave-length 475 $\mu\mu$, but if it is possible to utilise ultra-violet radiations of a wave-length as short as 220 $\mu\mu$, resolution will, other things being equal, thereby be doubled. There is the self-evident objection to such a method, that the image can no longer be a visual one, and, further, that the optical system must be composed of materials which are transparent to ultra-violet light.

§ (3) Quartz Optical Systems. — The transparency of any optical glass is not sufficient for work with the more refrangible portion of the spectrum, even a borosilicate crown-glass transmits but a small percentage of light of wave-length 300 $\mu\mu$. Schott of Jena has made optical glass particularly transparent to the ultra-violet light, but at wave-length 280 $\mu\mu$ a specimen 1 mm. thick only transmits 50 per cent of the incident light, and with shorter wave-lengths it is practically opaque. The only materials available therefore are quartz, either crystalline or fused, and fluorite. Fused quartz is rather less transparent than crystalline, but in carefully selected pieces which are free from impurities the difference for the purpose in view is not important. Fluorite was first used in the construction of microscope objectives by Spencer in America as long ago as 1860, while Boys in England, in or about 1885, suggested the suitability of fused quartz for this purpose. It was not until 1900 that M. von Rohr [1] of Jena succeeded in constructing a quartz-fluorite objective of about 4 mm., equivalent focus N.A. 0·30. This may be regarded as experimental, as it was supplanted in 1904 by a series made entirely of fused quartz. These objectives were termed "monochromats," as they are computed for a wave-length of 275 $\mu\mu$, although they can be used satisfactorily over a considerable range in the ultra-violet region, provided that the light is monochromatic. The equivalent focal lengths are as follows:

6 mm. dry lens N.A. in white light 0·35.
2·5 mm. glycerine immersion N.A. white light 0·85.
1·7 mm. glycerine immersion N.A. white light 1·25.

The effective N.A. of these lenses when used with ultra-violet light may be regarded as double the values indicated, being respectively 0·70, 1·70, and 2·50, this being the approximate relation of the mean wave-length of white light to that of ultra-violet (275 $\mu\mu$). The immersion fluid is glycerine and water with a refractive index 1·447/D. The immersion fluid must be sufficiently transparent to ultra-violet light, and in this respect glycerine fulfils the purpose, but precautions must be taken in practice to ensure that its refractive index remains constant, a short exposure to atmospheric influence causing appreciable alteration.

Five oculars for projecting the image on to the photographic plate have been computed, and these are made from crystalline quartz. Their initial magnifications are 5, 7, 10, 14, and 20 when used at a mechanical tube-length of 160 mm. The maximum magnifications obtainable are set out in the following table:

Objective.	Eyepieces . . .	5	7	10	14	20
6 mm. N.A. 0·70	Optical camera length . Magnification . .	30 cm. 250	34 cm. 400	30 cm. 500	34 cm. 800	30 cm. 1000
2·5 mm. N.A. 1·70	Optical camera length . Magnification . .	30 cm. 600	30 cm. 800	31·5 cm. 1200	30 cm. 1600	31·5 cm. 2400
1·7 mm. N.A. 2·50	Optical camera length . Magnification . .	31 cm. 900	32 cm. 1300	31 cm. 1800	31 cm. 2500	31 cm. 3600

The term "optical camera length" is the distance of the sensitive plate from the upper focal point of the microscope, this being for all practical purposes the cap of the eyepiece. The substage condenser is of quartz and is made with two interchangeable top lenses,

[1] Kohler and von Rohr, *Zeitschrift f. Instrumen.*, 1904.

so that the illuminating beam may be of such N.A. as is desirable with each objective.

FIG. 1.—Microscope and Camera ready for Photographing.

A, Fluorescent searcher eyepiece. B, Fluorescent uranium glass disc. C, Right-angled quartz prism.

Without either top lens the condenser is a dry one suitable for use with the 6 mm. objective. The complete condenser is used with the immersion lenses, and is itself also immersed with glycerine. An iris diaphragm is provided as in all substage illuminators. The illuminating beam is deflected in the direction of the optic axis of the microscope by means of a right-angled quartz prism which replaces the mirror on an ordinary microscope. The essential parts on the microscope are therefore the same as for visual work, except that they are all of quartz.

Figs. 1, 1A, and 2 show the microscope and camera and the arrangements for illuminating the object respectively.

§ (4) OBJECTS.—The object to be photographed must be mounted on a quartz slide and covered with a quartz cover-glass. The object-slides are of crystalline quartz, ground at right angles to the optical axis, and are 0·5 mm. thick.

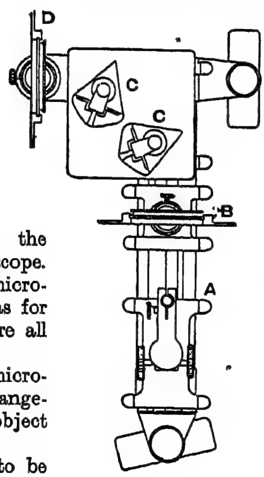

FIG. 2.

The use of optically worked slides and cover-glasses of definite and constant thickness is essential, as otherwise the difficulty of adjusting the apparatus would be greatly increased. In visual work the adjustment of tube-length to correct for spherical aberration introduced by cover-glasses of varying thickness is essential, but this would be a matter of considerable difficulty

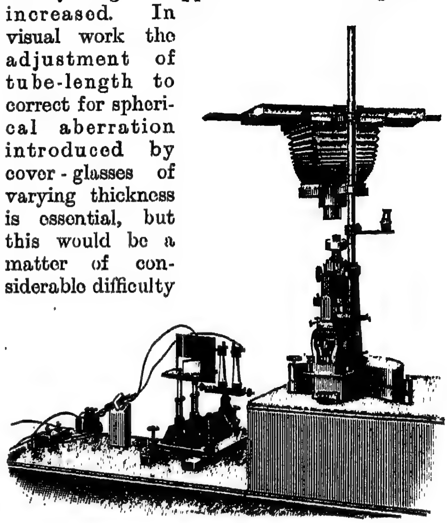

FIG. 1A.—Showing the whole Apparatus in Action.

when using ultra-violet light. For the same reason it is essential that the object should be immersed in as thin a layer of mounting medium as possible, otherwise the effect on the performance of the objective is the same as that resulting from the use of a thicker cover-glass.

The object, or element of structure under examination, must in fact be nearly, if not quite, in contact with the under surface of the cover-glass. There are certain limitations as to the type of the object that can be dealt with by this method—limitations which are determined in large part by the transparency of the object to ultra-violet light. The term "transparency" used in this sense is a relative one, as many substances that in thicker layers are completely opaque become very translucent when in thin microscopic layers. Some micro-organisms, for instance, which in the direction of their breadth are beyond the limits of microscopic resolution, have entirely baffled all efforts to photograph them by means of ultra-violet light. The radiations pass

completely through, and no image is formed on the photographic plate. This, however, is probably a question of wave-length. Radiations of shorter wave-length, when they can be utilised for the purpose, will probably do all that is required, and these very small organisms can then be dealt with. The objects best suited for this method are bacteria, yeasts, or any cellular structure which can be observed as separate units or in thin layers. Apart from the difference obtained in the image as the result of differences of thickness, there is a differentiation of structure due to differences of organic constitution which is shown in the resulting photograph. Spore-forming organisms, for instance, result in a somewhat striking picture; the organism itself may be somewhat translucent, but the spores are almost invariably quite opaque to ultra-violet light, although they are of similar dimensions. The same applies to granular contents in yeast cells and other cellular structures of a similar character.

The method therefore acts as a staining reaction without the necessity of carrying out any processes which might result in alteration in the appearance of the structural elements. Objects must in all cases be unstained. They must not be treated by any of the well-known methods used in bacteriology or cytology, in which fixation, hardening, or drying takes place. These processes probably cause some change in organic tissues, and in most cases they result, in the method under discussion, in the tissues becoming opaque to the radiations used. It is obvious therefore that the results are a representation of the tissues or micro-organism under actual living conditions.

In practice the preparation of the object presents no difficulty. The only point is that it must be mounted between its cover-glass and slide in some fluid which is transparent to ultra-violet light. Such fluids are not numerous; but distilled water, glycerine, or glycerine and water, Ringer's solution, normal saline, or castor-oil are among the substances available. To inhibit motion in living organisms a ½ per cent solution of agar may be used, or a dilute solution of gelatine. This procedure is, however, to be avoided if possible, and it is preferable to rely on thin layers of material so that motion is inhibited by the short distance, and consequent small free path, between slide and cover-glass. The ordinary nutritive media, as used by bacteriologists, are in some cases suitable, but they may be diluted to about one-fifth or one-sixth their ordinary strength. Sections may be passed from xylol to vaseline oil or castor-oil, but it is necessary to see that the xylol is completely removed, as that substance is opaque. In general, scrupulous cleanliness is essential, as otherwise the dust particles which occur in nearly all preparations become all too evident. The quartz slides and cover-glasses must be boiled in bichromate of potash and sulphuric acid to ensure perfect cleanliness, and should then be heated in a Bunsen flame before they are put into use.

§ (5) Light Sources.—The source of light is a high-tension spark discharge between metallic electrodes, usually magnesium or cadmium. The necessary characteristics of the light are, that it should emit ultra-violet radiations in sufficient quantity, and that its spectrum should mainly consist of a few intense bright lines, or groups of lines. The lines must not be too close together, so that any individual line may be isolated by spectroscopic methods, and utilised as the source of light.

Few metals conform to the necessary conditions. Iron, for instance, is quite unsuitable, although it emits ultra-violet rays freely; but the large number of lines in its spectrum, and their closeness together, make it impossible to utilise it. Cadmium and magnesium are the most suitable, their spectra consisting of a few intense well-separated lines. Recent experiments indicate that silver and beryllium may prove of value where intervening wave-lengths are required. The length of spark required is about 5 mm., but it must be what is usually referred to as a "fat" type of spark of high intrinsic brilliancy. It appears that there is a definite limit to the amount of energy that can be used in this direction. The conditions are comparable to that of an arc, in which increase of current results in a greater volume of light owing to the increased size of the luminous crater, but does not materially alter the intrinsic brilliancy. The coil used is therefore one that gives a heavy discharge at a relatively low voltage. An oil-immersed condenser, which has been found superior to a Leyden jar, is connected in parallel with the spark, with the result that a rapidly alternating discharge takes place between the metal points. Either an electrolytic or a mercury break may be used as an interrupter; but it has been found in practice that the latter gives better results, as it runs for a long period with greater regularity.

§ (6) Methods of Observation.—The spectroscopic arrangements for projecting the necessary monochromatic light into the microscope follow the lines in general of an ordinary spectroscope, with the exception that there is no slit. In front of the spark, and at a suitable distance from it, a quartz lens of about 18 cm. focal length is placed, so that an image of the spark is projected at the

plane of the iris diaphragm in the microscope substage. A pair of crystalline quartz prisms of opposite rotation are arranged so that the light is decomposed, and are set at minimum deviation for the particular wave-length it is desired to use. The light passes from the prisms to the right-angled quartz reflecting prism underneath the microscope, and is, by means of that prism, deflected in the direction of the optic axis of the instrument. In the plane of the iris diaphragm on the microscope a disc of uranium glass, on which is engraved a small circle, is placed. A fluorescent image of the spark can be observed within this circle, and must be sharply focussed and accurately centred so that the ultra-violet rays pass into the substage condenser when the uranium glass is removed. When this is secured, the first condition essential for satisfactory adjustment is satisfied.

The accurate focussing of the image is the most difficult part of the process, and until considerable experience has been gained cannot be performed with certainty. There are two methods available: in one, reliance is placed on the fluorescent screen already described, but it must be admitted that this is uncertain. The difficulty is increased when lines in the spectrum are being used which are not of great brilliancy; and, in any case, the appearance of the image varies with each object.

The object must be examined beforehand by visible light, so that its appearance under these circumstances is known; then small elements of structure that are fairly easily seen must be selected for focussing purposes. If these are in the same plane as unknown structural elements the result is satisfactory, but the element of chance is too great for the process to be regarded as a reliable one.

In the second method the image is observed by means of a quartz objective and ocular, the illuminant being one of the lines, either in the region of the blue or the violet, emitted by a mercury vapour lamp. Thus by using suitable screens, which are commercially obtainable, any desired wave-length is transmitted and the image at once observed and accurately focussed on any desired plane. The illumination is then changed to the particular ultra-violet line that it is proposed to use for photographic purposes. Either by calculation or by trial and error, the difference between the focal planes of the wave-length which is used for observation and that which is to be used for photographing is determined. The fine adjustment of the microscope is then moved by this predetermined amount, and the photograph at once taken. In practice it is found that this method is quite satisfactory and yields almost invariably good results. Its accuracy is mainly dependent on the mechanical perfection of the fine adjustment on the microscope, but the ability of the observer to focus an object illuminated by light of short wave-length is also a factor. It is found advisable to use a dark slide of repeating type, so that three photographs can be taken successively on one plate without any readjustment of the apparatus. A slight adjustment of the microscope fine adjustment above and below the required focus is then made for each photograph, so that, if there is any slight lack of adjustment, either one or the other of the photographs will be satisfactory. The photographic plates used must be of fine grain and with the smallest possible quantity of gelatine on its surface. Experiments have been made with plates of the Schumann type, that is, as used for photographing the far ultra-violet; but they have not proved so satisfactory as a slow photographic plate with a minimum of gelatine and the maximum quantity of silver that the gelatine will hold. Development is carried out to obtain the greatest amount of contrast, and a developer used which will give as fine a grain as possible. No printing process does full justice to the negatives, as the images are of necessity somewhat thin and the elements of structure often result in but small differences of density. To fully appreciate the advantage of the method the original negatives must be seen.

It has to be admitted that the whole process is one of considerable difficulty; it involves considerable acquaintance with spectroscopic methods as well as those incidental to ordinary microscopy. At the same time the results that have been secured are an advance on anything that can be done by any other method. In the present state of knowledge there is no indication of any optical improvement being effected which will be a substantial advance in microscopic method, but if radiations of sufficiently short wave-length can be utilised, it is difficult to see what limits can be placed on the microscope. The illustrations chosen are of simple, well-known objects, so that the differences in appearance can be appreciated. *Figs.* 3, 5, and 7 are photographs of living organisms illuminated under the best possible conditions by means of a dark-ground illuminator. *Figs.* 4, 6, and 8 are the same organisms photographed in ultra-violet light. In each case there is a suggestion of structure in the dark-ground image, but there is no comparison when careful examination is made between the two images. On theoretical as well as practical grounds the dark-ground method is useful enough for the observation of somewhat gross structures, but it utterly fails when resolution of a high order is needed.

§ (7) Visual Methods.—As a means of microscope research, the method so far described suffers from the disadvantage that it is purely a photographic process. The visual image obtained upon the fluorescent observing screen, which is used for the location of the image and approximate focussing, affords no indication of the ultimate value of the results. There is only one method by which a visual image can be obtained, which is indicative of structure, and that is by observing the fluorescence that occurs in certain animal tissues and other substances when they are illuminated by means of ultra-violet light. It is well known that fluorescence is brought about principally by the ultra-violet rays; the rays of the visible spectrum being much less active. The microscopic observation of the fluorescence of animal and vegetable tissues differs in practice from that hitherto described. There are two sources of light available, either an electric arc or a quartz mercury vapour lamp. The electric arc is preferable, and can be used either with ordinary carbons or with one or both carbons provided with a core of copper, iron, or nickel. Carbons impregnated with carbonate of iron also form a satisfactory light source, as the resulting radiations consist in large part of light in the ultra-violet region. The necessity for a spectroscopic arrangement to decompose the light does not arise, as the particular wave-length of the radiations employed is not of moment. In addition, the loss of light resulting from the use of a pair of quartz prisms to isolate the ultra-violet region of the spectrum is so great as to render the observation of some fluorescent images difficult, if not impossible. The fluorescence that occurs is characteristic of the fluorescing body, and is practically independent of the wave-length of the exciting light. It follows therefore that, if ultra-violet only can be used as an illuminant and all visible light excluded, a satisfactory light source is at once obtained. This isolation of the ultra-violet portion of the spectrum was not practicable until R. W. Wood of Baltimore [1] found that nitrosodimethylaniline in aqueous solution of one in five thousand to ten thousand would transmit a considerable portion of the ultra-violet spectrum while cutting out part of the visible spectrum. A quartz or uviol glass cell can therefore be filled with this solution of a thickness of about 1 cm., and this acts as an absorbing screen.[2] In addition, a piece of blue uviol glass, together with a cell containing a 20 per cent solution of copper sulphate, is used. The purpose of the sulphate of copper is to cut out the extreme red, which is otherwise transmitted, and it also absorbs invisible heat waves. A quartz lens of suitable focal length is placed in front of the arc, so that a parallel beam is projected on to a right-angled prism of quartz which takes the place of the ordinary mirror on the microscope. A quartz condenser similar to that used in the case of ultra-violet light photography is placed in the substage. The object itself, which must be in thin section, is mounted on a quartz slide in any suitable fluid which is transparent to ultra-violet light; but it may be covered with an ordinary cover-glass, as the fluorescent light emitted by the object is in the region of the visible spectrum. The only precaution necessary is to ascertain that the particular glass used does not itself fluoresce. Recently Messrs. Chance Brothers have introduced a new kind of glass which is transparent to ultra-violet light while transmitting but little visible light. If used in conjunction with a sulphate of copper screen, as already described, it forms a very efficient means of obtaining ultra-violet light, the region transmitted being between 300 and 400 micromillimetres wave-lengths. The effects obtained when unstained microscopic objects are illuminated in this way are very beautiful, and in many cases a range of colour is produced which extends over a considerable portion of the visible spectrum. In view of the subtle differences of tint that occur in the fluorescent image, the value of the result is largely dependent upon the power of the observer to detect colour differences; the colour sensitiveness of the eye is in fact the determining factor. As all solid bodies which fluoresce in ultra-violet light also have a definite phosphorescent period, it is probable that an application of Becquerel's phosphoroscope might be found to be of considerable value in these observations. Tissues are best observed in as fresh a condition as possible, and sections are preferably cut frozen to avoid the necessity of employing embedding processes, which may cause structural changes. The section itself must be thin, because if there are superimposed elements of structure the underlying ones which fluoresce cause a considerable amount of light diffusion. All animal cells and tissues, except those which are pigmented, have the power of fluorescing in ultra-violet light. Haemoglobin, or its derivatives, does not fluoresce. The following are a few typical examples of the colours which certain animal tissues exhibit as the result of fluorescence:

Unpigmented hair: intense light yellow.

Pigmented hair, such as black: no fluorescence.

Skin: intense light blue, the blood-vessels appearing dark and non-fluorescent.

Teeth: intense white, somewhat bluish in tint.

Mucous membrane of small intestine: light green.

Spleen: dark brown.

Liver: dark brown, somewhat greenish.

Kidney: dark yellow green.

Section of lung: dark brown, somewhat greenish; transverse sections of the larger vessels of bronchi fluoresce light blue.

Aorta: intense light yellow.

Muscles: intense light green.

Fat: light green.

Bones: light blue.

Cornea and lens of the eye: intense light blue.

NAVIGATION AND NAVIGATIONAL INSTRUMENTS

I. Introduction

§ (1) Methods employed.—The principal demand that the navigator of a ship makes upon physical science is for instruments that will enable him to determine his position upon the surface of the earth, and for instruments that will enable him to determine the direction in which his ship is moving.

Until a recent date methods of navigation could be classified either under the heading of "dead reckoning" or else of nautical astronomy. In addition, methods of determining position from the bearings of recognisable landmarks, and of identification of position from a series of soundings, occupy a subsidiary place in the science of navigation. Recently an entirely new method of position fixing has been developed, namely directional wireless telegraphy, a method which has such great possibilities that it is conceivable that in time it will entirely displace astronomical methods.

§ (2) Leading Marks.—The simplest of all methods of position fixing is by leading marks when in sight of a coast. A shoal can be marked and avoided by beacons set up on shore or by natural landmarks noted as being in line when just clear of the danger. By watching the relative changes of bearing of these marks the navigator keeps his ship in safe waters. An extension of this method (which requires the use of four shore objects) is to utilise three only and the angles they subtend at the ship. If three points, A, B, and C, can be identified on the chart and if the angular distance from A to B is α and the distance from B to C is β there is a unique position determined by the point of intersection of two circles. The instruments required for such position fixing are a sextant to measure the two angles α and β and, to avoid the trouble of geometrical construction, a station pointer to lay off the position on the chart.

Another method is to take the bearings of two known objects by means of the azimuth compass. Lines of bearing in the reversed directions from those observed are then drawn through the objects upon the chart and their point of intersection gives the position of the ship. With one object only the fix can only be made by taking two bearings at different times and laying down upon the chart the "run" of the ship in the interval. For such a fix the navigator must have means of determining the direction and speed of the ship through the water, and these data, combined with the observed leeway and the set and drift of the tides as given by tide tables, enable him to complete the fixing of his position. Speed is measured by log line, which in its primitive form was simply a log of wood dropped over the stern and line paid out as fast as it would run, speed being measured by the number of knots of the line that ran out in a specified time, usually fourteen or twenty-eight seconds. The modern form of log indicates continuously the distance a ship has run. For rough purposes the rapidity of revolution of the propeller is also a measure of the speed.

§ (3) Astronomical Methods.—Such methods as have been described above are applicable only when the ship is in sight of land. For cross-seas navigation the position is known provided the course, *i.e.* the direction, and speed are continuously and accurately known. But an error in the determination of the course or an error in the estimation of the speed will have a cumulative effect upon the ship's position, so that it is clear that dead-reckoning methods cannot be relied on to give accurate information to the navigator for any length of time. Besides the inaccuracies of the log and the inaccuracies of steering or of the compass itself, there are also unknown effects from wind and from ocean currents. From time to time, therefore, it becomes necessary to have recourse to astronomical methods in order to fix the position and so obtain a new and accurate point of departure from which a new dead reckoning can be made. Ordinarily the navigator likes to have an astronomical fix at least once a day; in a ship running at high speed sights are taken more often still when the weather permits. With an overcast sky nothing, until the advent of directional wireless telegraphy, was available to the navigator but dead-reckoning methods.

Every astronomical observation for position is a measurement of the angular altitude of a heavenly body above the horizon at a noted time. The altitude is measured by a sextant and the time obtained from a chronometer whose error on Greenwich Mean Time is known with sufficient accuracy. Formerly this error used to be obtained from the known error when the ship was last in port, and from the rate determined from a previous error. Nowadays a ship with wireless can obtain

the error of her chronometers by time signal in almost all parts of the world.

§ (4) THE SUMNER LINE.—A sight having been taken, the observed altitude and time give the navigator a means of drawing upon his chart a certain line of position or "Sumner Line." The position of this line can be realised from *Fig.* 1. Let X be the subsolar (substellar

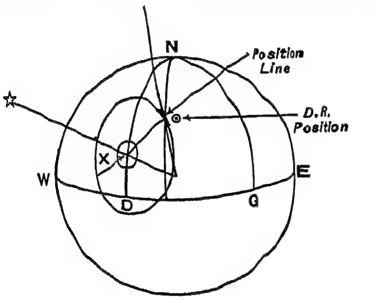

FIG. 1.

or sublunar) point, that is, the one point upon the earth's surface at which the sun's centre is at the zenith at the time the sight is taken. The earth being treated as spherical, the subsolar point is that place at which a line drawn from the earth's centre to the sun's centre will cut the earth's surface. Such a line being a radius of the earth is a vertical line at this point, and the sun, at that point and at that time, has an altitude of 90° above the horizon. The latitude, XD, of the subsolar point is the sun's declination and the longitude, GD, is the Greenwich apparent time converted into angle. For the case of a star the latitude is the declination and the longitude the star's Greenwich hour angle at the time.

If a circle of 60 sea miles radius be described round the subsolar point, its circumference contains all those points on the surface of the earth whose verticals are inclined at an angle of one degree with the vertical of X. Hence at the instant in question this circle is the locus of all points for which the altitude of the sun is 89°. If the circle has 120 sea miles radius it becomes the locus of points for which the altitude is 88° and so on. The curves of constant altitude are in fact a series of small circles drawn round the subsolar point as pole and spaced in exactly the same way as the parallels of latitude round the pole of the earth. The deductions that can therefore be made from an ordinary navigational "sight" are simply that the ship's position is somewhere on a certain small circle that can be drawn, if need be, for its pole and its radius are known.

As the navigator always knows the position of his ship with approximate accuracy, he is concerned with a small portion only of this small circle, namely that part of its circumference which is in the neighbourhood of his dead-reckoning position. For such length of the circumference as he usually has to consider it is sufficient for him to treat the curve when projected on to the Mercator chart as being straight, and such a line is called a position line or Sumner line, after Captain Sumner, an American merchant-service captain who first called attention to the use of them.

The methods by which the position of the Sumner line can be determined are various, but the method of false positions devised by Marc St. Hilaire is the one now most commonly practised. A position is adopted which is known to be not far different from the ship's actual position, and the altitude of the sun or other heavenly body is calculated for that spot and for the instant at which the sight was actually taken. A comparison is made between this calculated altitude and that measured by the sextant, and the difference between the two, measured in minutes of arc, represents the distance, measured in sea miles, separating the assumed position from the Sumner line. If the observed altitude is the greater, then the Sumner line is nearer to the subsolar point than the assumed position and *vice versa.* The Sumner line is always drawn at right angles to the true bearing or azimuth of the heavenly body observed, so that the distance of the assumed position from the Sumner line is always measured in the direction of the true bearing.

§ (5) SOURCES OF ERROR. REFRACTION.—As in all instruments for precise measurement, one of the main considerations in the design is the errors that are likely to arise and to be present in the measured values. The effect of an error in the measurement is very apparent, as each minute of error moves the Sumner line one sea mile parallel to itself. The accuracy with which the position line can be laid down upon the chart is precisely the accuracy (apart from errors of drawing) with which the sun's altitude can be measured. Errors enter into the final result either from errors of the sextant or inaccuracies due to external causes, of which the only one which needs consideration is the variable atmospheric refraction.[1] This will affect both the position of the sun in the sky and the apparent position of the horizon, and it is obvious that the latter will be the more displaced of the two. The depression of the visible horizon in minutes of arc, if the atmosphere had no refractive effect, is $1 \cdot 063 \sqrt{h}$, where h is the height of the observer's eye in feet. Atmospheric refraction reduces this amount by approximately 8 per cent, and the tables for dip, as the depression of the horizon is also called, are calculated

[1] See "Trigonometrical Heights," etc., Vol. III.

from the formula $0{\cdot}98\sqrt{h}$. For abnormal states of the barometer and temperature correcting tables are given, and in the majority of cases the results are sufficiently close for the ship's navigator. Circumstances may, however, arise in which these dip tables are widely erroneous. The most likely conditions for error are a calm clear day with a warm air and a colder sea. There will then be an inversion of temperature in the lower layers of the atmosphere, and the refraction factor in the dip being based on the supposition that the atmosphere is in a state of equilibrium in which the temperature falls uniformly at the rate of 1° C. per 600 feet is in these circumstances quite false. In special cases errors in the dip tables have been known to be so great that the sea horizon is refracted above the true horizontal and the sea as seen from the deck of the ship appears saucer shaped. Errors of four or five minutes under the conditions quoted above appear to be common; several reliable reports have been made of the dip being as much as twenty minutes in error.

When, as in cable laying or in marine surveying, accurate position fixing is needed, it is customary to combat errors of refraction by taking sights in a series of azimuths and determining the position from the Sumner lines so obtained. Sometimes subsidiary instruments are used to measure the dip at the time of the observation. These are described later.

Errors in refraction do not affect the heavenly body observed to the same extent unless its altitude is very low. Usually if the altitude is not less than 20° any inversion of temperature in the lower levels of the atmosphere will hardly affect the apparent position of the body in the sky, and the tabulated values of the refraction in altitude will be good enough.

§ (6) Other Sources of Error.—Other errors which affect the accuracy of the position line are those of the sextant itself, namely the first order zero error and the second order perpendicular error, side error, and collimation error. These are explained in the description of the sextant.

The possibility of the navigators being able to take any sights at all depends upon the sea horizon being visible. Frequently it is obscured by low-lying banks of mist. At night-time it is always difficult to distinguish it except in bright moonlight. When a telescope is used with the sextant the difficulty is greater still. Only a portion of the exit pupil of the telescope is occupied by light from the horizon, and there is always loss by internal reflection at the various glass air surfaces of the telescope. Taking both these into consideration, it is found that the intrinsic brightness of the horizon is less than half when viewed through the telescope of what it is when viewed by the unobstructed naked eye. Through such reasons as these it has become a very common practice of navigators to limit their star observations to morning and evening twilight during the half-hour or so when the horizon is still reasonably clear and the brighter stars can be picked up without difficulty. One direction in which many attempts to solve these difficulties of the navigator have been made is the provision of something which will replace the sea horizon as a basis of measurement of altitude. All these attempts have been made with the idea of providing some sort of level or vertical controlled by gravity. The reason for their failure is referred to in the description of the sextant.

§ (7) Fixing Position.—From what has been stated it will be seen that observations of two heavenly bodies, or two observations of the same body separated by a distinct lapse of time, are necessary for the determination of a fix. During the daytime the second course has to be adopted. It is true that occasionally the moon can be used, but for some reason, possibly because the corrections are troublesome, few navigators make use of it. The planet Venus, when at her greatest distance from the sun, can also be used at times, but it needs a very skilled navigator to pick the star up in broad daylight and to measure her altitude.

Attempts have also been made to obtain a bearing of the sun with sufficient accuracy to enable the position of the ship on the Sumner circle to be identified. If the bearing can be taken with the certainty that the error does not exceed a quarter of a degree, then the ship's position on the Sumner circle can be limited to a length of a few miles, the amount depending upon the altitude. But it is difficult to get a magnetic or gyro compass to maintain such accuracy, and the error cannot be measured to that precision at sea except by Polaris, the only star whose bearing can be sufficiently accurately calculated when the ship's position is only roughly known.

Another direction in which improved aids to navigation are likely to be forthcoming is from the extensive experiments in sound ranging that have been carried out in the recent war. These experiments have covered a very wide field and have achieved many valuable successes. Among these may be instanced directional hydrophones, by means of which distant submarine signals can be located in direction at ranges up to fifty miles. For approaching a coast in foggy weather the peace time uses of such devices are obvious. Again, the experience of war has shown that it is possible, by exploding a charge under water, to time the echo reflected back from

another ship with such a nice degree of accuracy that her range can be calculated from it. It is likely that such research will make it possible to take deep-sea soundings with infinitely less trouble than was attendant upon the old methods.

II. Instruments used in Navigation

§ (8) Methods of Dead Reckoning.—When the navigator has determined his position (latitude and longitude) at a certain instant, and subsequently knows his courses, speeds, and lengths of time running on those courses, he has sufficient information to supply him with the position at any time afterwards. The new position can be determined either by plotting the track upon the chart or by working out a "traverse," which means that each element of the distance run must be resolved into its north-south and east-west components. The algebraic sum of the former gives the "diff. lat." from his previous position, the latter his "departure" from the same spot. The "departure" being found, the difference in longitude is deduced from the relation

Diff. long. = Departure × secant mid latitude.

The whole of the resolution of the different elements of the run into components can be done by the traverse table.

The accuracy of the final estimation of position depends upon the accuracy of the arguments—course and distance—with which the traverse table is entered. "Course" is rendered inaccurate by unsteady steering, and by erroneous estimation of the leeway made. "Speed" has errors due to inaccuracies of the log.

The two instruments concerned with dead-reckoning estimation of position are the Compass (magnetic or gyrostatic) and the Log line.

§ (9) The Magnetic Compass. (i.) *Description.*—The magnetic compass is undoubtedly the most important instrument of navigation in use in the ship. It consists of a circular card, divided into degrees and "points," to which is attached a series of magnetic needles. The whole, balanced upon a central pivot and kept in a horizontal position through the weight being below the point of support, turns under the earth's magnetic force so that the needles lie in the magnetic meridian. The reading of the card against a "lubber-line" in the bowl then indicates the direction of the ship's head.

Compasses are either of the liquid type or else of the dry-card type. In the former case the whole bowl is filled with a mixture of alcohol and water, the formula for naval compasses being ordinarily 67 per cent distilled water and 33 per cent pure alcohol. For air purposes, where much lower temperatures are encountered, pure alcohol is used. The object of the liquid is to increase the damping effect and cause the compass to settle down more quickly if by any chance it is disturbed.

The support of the card is usually in the form of a sapphire cap resting on an agate point.

The needles in most cases are disposed symmetrically in two parallel bundles on either side of the centre and at such distances as will give the whole equal moments of inertia about any diameter of the card. Unless this equality exists the principal moments of inertia will lie, from considerations of symmetry, in the north-south and east-west lines. If such a compass is subject on board to a forced oscillation about any other diameter of the card than a cardinal one, an oscillation of the card in its own plane will be set up with a period which increases as the difference between the two principal moments of inertia is lessened. As forced oscillations of this description are very likely to result from the vibrations of the main engines or of other machinery, the equality of the two principal moments of inertia is of considerable importance. With two single needles the distance apart should be equal to the length of the needles divided by $\sqrt{3}$.

The relative values of the strength of the horizontal component of the earth's magnetic field, the viscosity of the liquid, friction of the pivot, etc., and the moment of inertia about the axis determine the period at which the card will oscillate about its equilibrium position and the rate of decay of the amplitude of this oscillation. Usually with a liquid compass the period for the latitude of Greenwich is from 10 to 18 seconds from rest to rest and the decay factor, *i.e.* the ratio of a half-swing from rest to rest to the one preceding it, about one-half for each successive half-swing.

In certain compasses used in aircraft the damping has been increased and the moment of inertia reduced to such an extent that the compass is aperiodic and goes directly back to the meridian without oscillation.

The direction of the ship's head, as shown by the compass, requires correction for variation and deviation. The former term denotes the angle between the magnetic and the geographical meridians and is obtainable always from the Admiralty charts, in which the amount at the date of publication and the annual change are indicated. The deviation of the compass is the angular deflection of the needle from the magnetic meridian due to the influence of the permanent and induced magnetism of the iron and steel used in the construction of the ship.

(ii.) *Historical.*—The origin of the magnetic compass is lost in obscurity. It is apparently referred to in Chinese and Siamese manuscripts

of the fourth century. Possibly it antedates the Christian era. Unquestionably it remained a very crude instrument indeed until the fourteenth century, when the Neapolitan Flavio Gioia made very considerable improvements in it, but even then it was so very approximate in its indication of the north point that it was always believed to indicate the true north, and it was not until 1555, when Martin Cortez of Seville published a book on navigation, that any mention is made of magnetic variation. Twenty years later magnetic dip was discovered by Norman, and from data supplied by seamen curves of magnetic variation and dip were gradually constructed. Towards the end of the seventeenth century differences in the variation as supplied by different ships began to be manifest. Denis in 1666, and Dampier in 1691, instanced anomalies of a similar kind, and Wales, who was astronomer to Cook's expedition to the South Seas, first asserted that the direction of the ship's head affected the compass. In 1794 Mr. Downie, master of H.M.S. *Glory*, observed that "the quantity and vicinity of iron in most ships has an effect in attracting the needle." In 1801 Captain Flinders, whose name is still preserved in connection with the "Flinders bar," found that a change in the position of the binnacle affected the compass, and as a result of his representations to the Admiralty a series of experiments was made at Sheerness on several of H.M. ships, but the scope of the work was too limited to permit of really general deductions being drawn. Professor Barlow, after an extensive course of experiments, proposed in 1819 to counteract the effect of large masses of iron used in the construction of the ship by a circular plate suitably placed in proximity to the compass, and in 1835 Captain Johnson, the Admiralty Superintendent of Compasses, found during an investigation into the applicability of Barlow's plate to the compasses of the iron ship *Garryowen*, that the ship herself was permanently magnetic and that the plate failed to correct the resulting compass error. As a result of Johnson's experiments the Admiralty commissioned Airy, then Astronomer-Royal, to make further experiments on board the iron vessels *Rainbow* and *Ironsides*, and his conclusions from these experiments were that the permanent magnetism of the ship could be counteracted by the location near the compass of suitably placed permanent magnets.

While these investigations were being made in England, Poisson was also engaged in similar work in France. His work, which was of a more academic character, was presented to the Academie des Sciences in 1824. This celebrated memoir on the Theory of Magnetism is generally recognised as forming the foundation of the Theory of the Deviations of the Compass. In 1838 he contributed a second memoir in which, although recognising the possibility of permanent magnetism being present, he yet presumed that it was of very small amount, and omitted it in his solutions.

Unlike Poisson, Airy started with the recognised necessity of dealing with the permanent magnetism, but the deductions he made from the *Ironsides* experiments were not fully justified, and subsequently a serious divergence of opinion arose between Airy and Scoresby respecting the validity of the former's conclusions. The main point at issue was whether the rules devised by Airy for the correction of the compass applied only in the place at which the corrections were made or whether they could also be considered reasonably accurate for changes of latitude. Scoresby also affirmed that the so-called permanent magnetism of the ship, produced by hammering, etc., during construction, was only sub-permanent; that a large part of it disappeared during the early voyages; and that it might be very largely changed by the buffeting that a ship might receive if she continued on the same course for any length of time in heavy weather. The loss of an important ship, the *Taylor*, on her first voyage, in 1854, a loss which was in some quarters attributed to the defects of Airy's conclusions, led to the formation of the very important Liverpool Compass Committee, which issued three reports on the Deviations of the Compass —in 1856, 1857, and 1861. Following these reports the Admiralty ordered further investigation, and a mathematical examination of the subject was carried out by Archibald Smith, very largely based on Poisson's original work. Subsequently, under the direction of Captain F. J. Evans, R.N., Superintendent of the Admiralty Compass Department, and of Archibald Smith, the *Admiralty Manual of the Deviations of the Compass* was published in 1862, and passed through successive editions in 1863, 1869, 1874, 1882, 1893, 1901, and 1912.

The Admiralty Manual, with its investigation and rules for correction, is now looked upon as the standard work on the subject, and has been adopted as the basis of similar publications in other countries.

Very few changes were necessary in the first five editions, but in the sixth, brought out in 1893, certain modifications of detail had to be introduced on account of the greater use of steel in ship construction; but in principle there is little change since the work first appeared, and the only controversial points that have aroused any discussion have been such matters as the comparative merits of the liquid as against the "dry-card"

compass, the construction of the cap and pivot, and the most suitable period of oscillation.

With the advent of aeroplanes and airships the need of compasses for their special use became apparent, and experimental work is still in progress for the purpose of evolving the best type. One of the principal difficulties in this connection lies in the fact that an aeroplane in turning is subject to very large horizontal acceleration, and the compass card "banks" in consequence at angles of possibly 60° or 70° with the horizontal. Under such circumstances the vertical component of the earth's magnetism may have as much or even more effect on the needle than the horizontal. In particular it is quite possible, when turning away from north, for the compass to go off in the wrong direction. When in sight of the ground this is comparatively unimportant, but when flying in cloud the unreliability of the compass in indicating turn can easily result in the pilot's getting his machine into a "spinning nose dive." It appears impossible to provide a compass that will fulfil all the requirements of the air pilot, and up to the present the "aperiodic" previously referred to seems to be the best compromise.

§ (10) MATHEMATICAL THEORY OF THE COMPASS. (i.) *Deviation Error.* — The mathematical theory of the deviations of the compass has to take account of the permanent magnetism of the ship, of the induced magnetism of soft iron changing with each change of course, of the varying values of the earth's magnetic field in different latitudes, and to include the effects that are due to the rolling, pitching, and yawing that the ship may be subject to in a seaway. Of these three types of motion that of rolling is the most important. In the days of sailing ships the vessel would be heeled over to leeward for long periods, and the "heeling error" was of primary importance. In a steamship rolling takes place about the upright position, and consequent deviations due to heeling are of alternate sign, so that their relative importance is less than it was in sailing-ship days. As the whole of the investigation of heeling error has been made on a statical basis, it is quite probable that the formulae obtained are not true for a ship with a considerable degree of roll when dynamical considerations enter into the question.

For the purpose of considering the quantitative values of the deviation, take as axes of reference Ox in the fore and aft line (ahead) through the compass, Oy in a horizontal athwartship direction (to starboard), and Oz in a vertical direction downwards, the assumption being that the ship is for the present on an even keel (see *Fig.* 2).

Let X, Y, and Z be the components of the earth's field at the origin, and P, Q, and R the components of the ship's field (permanent magnetism).

Then the total field will have components

$$X' = X + aX + bY + cZ + P,$$

$$Y' = Y + dX + eY + fZ + Q,$$

$$Z' = Z + gX + hY + kZ + R,$$

where $a, b, c, d, e, f, g, h, k$ are parameters dependent upon the distribution of soft iron in the ship. These equations are due to Poisson.

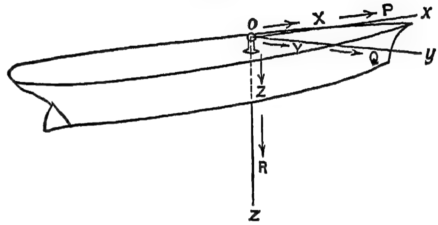

FIG. 2.

If H and H′ are the horizontal force of the earth and the horizontal force of the earth and ship respectively, θ the dip, ζ the magnetic course, ζ'

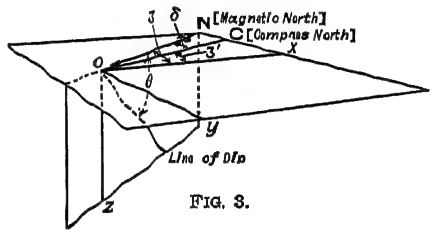

FIG. 3.

the compass course, and $\delta\ (=\zeta-\zeta')$ the deviation, we have (see *Fig.* 3)

$$X = H\cos\zeta, \quad Y = -H\sin\zeta, \quad Z = H\tan\theta,$$

$$X' = H'\cos\zeta', \quad Y' = -H'\sin\zeta';$$

by substitution and reduction we obtain

$$\frac{H'}{H}\sin\delta = \frac{d-b}{2} + \left(c\tan\theta + \frac{P}{H}\right)\sin\zeta$$

$$+ \left(f\tan\theta + \frac{Q}{H}\right)\cos\zeta + \frac{a-e}{2}\sin 2\zeta + \frac{d+b}{2}\cos 2\zeta,$$

and

$$\frac{H'}{H}\cos\delta = 1 + \frac{a+e}{2} + \left(c\tan\theta + \frac{P}{H}\right)\cos\zeta$$

$$-\left(f\tan\theta + \frac{Q}{H}\right)\sin\zeta + \frac{a-e}{2}\cos 2\zeta - \frac{d+b}{2}\sin 2\zeta.$$

The former of these equations gives the strength of the couple tending to turn the compass needle eastwards, the latter the strength of the couple tending to turn to north. The mean value of the former is $(d-b)/2$, which is usually, but not necessarily, zero; the mean value of the other is $1+(a+e)/2$. This we denote by λ. In iron vessels λ is nearly always less than unity. The quantity λH, which

is the mean value of $H' \cos \delta$, or of the component of the earth and ship directed to magnetic north, is usually known as "mean force to north."

If we write

$$\frac{1}{\lambda}\frac{d-b}{2}=\mathfrak{A},\quad \frac{1}{\lambda}\frac{a-e}{2}=\mathfrak{D},\quad \frac{1}{\lambda}\frac{d+b}{2}=\mathfrak{E},$$

$$\frac{1}{\lambda}\left(c\tan\theta+\frac{P}{H}\right)=\mathfrak{B},\quad \frac{1}{\lambda}\left(f\tan\theta+\frac{Q}{H}\right)=\mathfrak{C},$$

we obtain

$$\tan\delta=\frac{\mathfrak{A}+\mathfrak{B}\sin\zeta+\mathfrak{C}\cos\zeta+\mathfrak{D}\sin 2\zeta+\mathfrak{E}\cos 2\zeta}{1+\mathfrak{B}\cos\zeta-\mathfrak{C}\sin\zeta+\mathfrak{D}\cos 2\zeta-\mathfrak{E}\sin 2\zeta},$$

which gives the deviation on any magnetic course when the coefficients $\mathfrak{A}$, etc., are known.

In terms of the compass course the expression for the deviation is more complicated, but can be written in the form

$$\begin{aligned}\delta=&A+B\sin\zeta'+C\cos\zeta'+D\sin 2\zeta'+E\cos 2\zeta'\\&+F\sin 3\zeta'+G\cos 3\zeta'+H\sin 4\zeta'+K\cos 4\zeta'\\&+L\sin 5\zeta'+M\cos 5\zeta'+N\sin 6\zeta'+\ldots\end{aligned}$$

in which A, B, C ... are derivable from $\mathfrak{A}$, $\mathfrak{B}$ ... In view of the fact that $\mathfrak{B}$, $\mathfrak{C}$, $\mathfrak{D}$ are small quantities of the first order, $\mathfrak{A}$ and $\mathfrak{E}$ small quantities of the second order, and if we go to terms of the third order, we find

$$A=\mathfrak{A}$$

$$B=\mathfrak{B}\left(1-\frac{\mathfrak{D}}{2}+\frac{\mathfrak{B}^2}{8}+\frac{\mathfrak{C}^2}{8}+\frac{\mathfrak{D}^2}{4}\right)-\frac{\mathfrak{E}\mathfrak{C}}{2},$$

$$C=\mathfrak{C}\left(1+\frac{\mathfrak{D}}{2}+\frac{\mathfrak{B}^2}{8}+\frac{\mathfrak{C}^2}{8}+\frac{\mathfrak{D}^2}{4}\right)-\frac{\mathfrak{E}\mathfrak{B}}{2},$$

$$D=\mathfrak{D},$$

$$E=\mathfrak{E}+\mathfrak{A}\mathfrak{D},$$

$$F=\frac{\mathfrak{B}\mathfrak{D}-\mathfrak{C}\mathfrak{E}}{2}-\frac{\mathfrak{B}^3}{24}+\frac{\mathfrak{B}\mathfrak{C}^2}{8}-\frac{3\mathfrak{B}\mathfrak{D}^2}{8},$$

$$G=\frac{\mathfrak{C}\mathfrak{D}+\mathfrak{B}\mathfrak{E}}{2}+\frac{\mathfrak{C}^3}{24}-\frac{\mathfrak{C}\mathfrak{B}^2}{8}+\frac{3\mathfrak{C}\mathfrak{D}^2}{8},$$

$$H=\frac{\mathfrak{D}^2}{2},$$

$$K=\mathfrak{D}\mathfrak{E},$$

$$L=\frac{3\mathfrak{B}\mathfrak{D}^2}{8},$$

$$M=\frac{3\mathfrak{C}\mathfrak{D}^2}{8},$$

$$N=\tfrac{1}{3}\mathfrak{D}^3.$$

Succeeding coefficients would all be of fourth or higher orders. Similar expressions for A_1, B_1, C_1, etc., when the expansion is made in terms of the *magnetic* course can also be obtained.

In actual practice it is not necessary to go further in the expansion than the first five terms, and provided the value of δ does not exceed about 20° we can write

$$\delta=A+B\sin\zeta'+C\cos\zeta'+D\sin 2\zeta'+E\cos 2\zeta'.$$

The deviation then consists of a constant part A, a semicircular part $B\sin\zeta'+C\cos\zeta'$, and a quadrantal part $D\sin 2\zeta'+E\cos 2\zeta'$. The constant part A is always small for a compass placed on the fore and aft line of the ship provided the masses of soft iron are symmetrically placed, as most usually happens. The semicircular deviation is due partly to the permanent magnetism of the ship and partly due to induced magnetism; the quadrantal deviation to induced magnetism only. The correction of the former is made by suitably placed permanent magnets and by the "Flinders Bar"; of the latter by suitably placed masses of soft iron, usually two spheres placed one on each side of the binnacle. The next term of the expansion, the sextantal deviation, represents the effect of magnetism induced in the soft iron (in effect, in the correcting spheres) by the magnets of the compass itself. In the particular case of spheres symmetrically disposed, the sextantal term becomes zero provided the distance between the two needles is equal to the length divided by $\sqrt{3}$, a condition which fortunately is satisfied owing to the need of the card to have equal moments of inertia.

It appears, then, that after the compass has been approximately corrected by permanent magnets and spheres the approximate value for the outstanding deviation is that given just above.

(ii.) *Heeling Error.*—When the ship is inclined from her normal position, modifications in the formula for the deviation have to be made. If i be the angle of heel to starboard (see *Fig.* 4) the new deviation δ_i can be shown

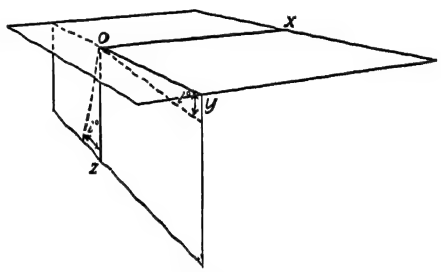

FIG. 4.

to exceed the deviation δ in the upright position by a quantity consisting of a constant part, a semicircular part, and a quadrantal part. When i is small, and when the soft iron of the ship is symmetrically placed, this relationship becomes

$$\delta_i=\delta+\frac{c-g}{2\lambda}i+Ji\cos\zeta'-\frac{c+g}{2\lambda}i\cos 2\zeta',$$

where $$J=\frac{1}{\lambda}\left(e-k-\frac{R}{Z}\right)\tan\theta.$$

The constant part $i(c-g)/2\lambda$, and the quadrantal part $-i(c+g)\cos 2\zeta'/2\lambda$, when taken together are equivalent to

$$\frac{c}{\lambda}i\sin^2\zeta' - \frac{g}{\lambda}i\cos^2\zeta',$$

which will only be zero for all courses provided $c=o$ and $g=o$. These conditions are not usually obtained, but the values of c/λ and g/λ are ordinarily small, and the error represented by these two terms may be safely neglected.

The semicircular heeling error cannot be so neglected, and the error represented by this term has to be specially dealt with in correcting the compass.

The quantity $-J$ is usually spoken of as heeling coefficient, $-Ji$ as heeling error. The correction is made by vertical magnets placed directly below the compass bowl.

(iii.) *The Six Coefficients.*—Owing to the symmetrical disposition of soft iron relative to the compass, four of the Poisson parameters, viz. b, d, f, and h, become zero, and hence A and E are zero. The coefficients B and C of semicircular deviation then depend on $\mathfrak{B}$, $\mathfrak{C}$, and $\mathfrak{D}$. The value of the last term $\mathfrak{D}$ is in all ordinary cases positive, and can be diminished by soft iron correctors placed on either side of the compass. In a perfectly corrected compass D, and therefore $\mathfrak{D}$, must be zero to eliminate quadrantal deviation, and the semicircular will then only disappear provided $\mathfrak{B}=o$ and $\mathfrak{C}=o$. Both these coefficients are compounded of permanent and induced magnetism effects, as is seen from the equations

$$\mathfrak{B}=\frac{(c\tan\theta+P/H)}{\lambda},$$

$$\mathfrak{C}=\frac{(f\tan\theta+Q/H)}{\lambda},$$

and if perfect correction is required in all parts of the world, it is necessary that c and f should be zero and P and Q should be zero. The parameter f is zero from symmetry and c is made zero by means of the Flinders bar, a vertical bar of soft iron placed before or abaft the compass according to whether the coefficient is negative or positive. The remaining parts of $\mathfrak{B}$ and $\mathfrak{C}$ are corrected by permanent magnets placed respectively fore and aft and athwartships for the purpose of reducing both P and Q to zero.

The heeling coefficient $-J$, which can be written

$$\left(D+\frac{\mu}{\lambda}-1\right)\tan\theta,$$

where $$\mu=1+k+\frac{R}{Z},$$

is zero in a ship for which the quadrantal deviation is corrected provided $\mu=\lambda$. Now $\mu=1+k+R/z$, $\lambda=1+\frac{1}{2}(a+e)$, and since $a=e$ is the condition for correction of quadrantal deviation the above equations reduce to

$$\kappa+\frac{R}{Z}=e,$$

a condition that cannot be universally satisfied unless $\kappa=e$ and $R=o$. A correction is, however, possible in any particular magnetic latitude by vertical magnets placed below the compass.

§ (11) Determination of the Errors of a Compass.—By "swinging" a ship it is possible to determine in several ways the amount of the deviation. One of the simplest of those ways is to turn the ship while making repeated bearing observations of a distant point of land. The ship's head is steadied on each point of the compass while the observation is made and a curve of errors subsequently constructed. The diameter of the turning circle of the ship must be small in comparison with the distance of the landmark observed in order to avoid parallactic errors, and the exact magnetic bearing must be obtained by measurement from the chart, or otherwise, in order to discover any constant error (A) of the compass.

If the ship is swung at sea out of sight of land corresponding observations can be made of the sun, but in this case it is simpler to determine the deviations by noting the time of each observation and thence calculating the true azimuth.

An alternative method when close to land is to set up an azimuth compass on shore at a place free from magnetic disturbance and take reciprocal bearings between the landing compass and the ship's instrument on each point. Differences of bearing then represent the deviations.

If the ship is swung in an upright position no indication is obtained of the value of the heeling error when rolling, but sufficient information is forthcoming if the values of λ and μ can be obtained. The former of these, λ, is the ratio of the mean horizontal directive force to north at the compass to the horizontal directive force on shore. It is determined from the times of oscillation of a horizontal magnet set to vibrate first on shore and then on board in the binnacle after the compass bowl has been removed. If the horizontal force on board were the same in all azimuths, we should have $\lambda=H'/H$, but since H' changes with the line of the ship's head it is necessary to use a correcting factor, giving rise to the general expression

$$\lambda=\frac{H'}{H}\cdot\frac{\cos\delta}{1+\mathfrak{B}\cos\zeta-\mathfrak{C}\sin\zeta+\mathfrak{D}\cos 2\zeta-\mathfrak{E}\sin 2\zeta}.$$

The values of $\mathfrak{B}$, $\mathfrak{C}$, $\mathfrak{D}$, and $\mathfrak{E}$ are obtained from the analysis of the curve of deviations.

The second constant μ is obtained from measurements of the vertical component of magnetism. It is the ratio of the mean value of the vertical force on board to the vertical force on shore. The measurement is made by means of a dip circle, which is a magnet mounted so as to turn about a horizontal axis. By turning the whole instrument in azimuth the needle can be made to hang vertically, and the ratio of the squares of the times of oscillations about its equilibrium position on board and on shore leads to the value of Z'/Z. As in the previous case, the value of Z' changes with the direction of the ship's head, and for precise determination of its value it is necessary to make the observations on a number of different directions. A second method of evaluating μ is by means of the heeling error instrument, in which a magnet can also rotate about a horizontal axis. This magnet is exactly balanced before being magnetised and is gravitationally in neutral equilibrium. Hence, when placed so that the needle is free to move in the plane of the magnetic meridian, it would set itself in the line of the dip. A small aluminium weight can be attached to the needle and adjusted so that the needle takes up a horizontal position. The moment of the weight about the axis thus balances the moment of the vertical force. By adjusting the weight for the instrument firstly on shore and secondly on board in the compass bowl the ratio of Z' to Z can be obtained. The angle of dip can also be determined for this instrument.

Having obtained the values of λ, μ, and θ, and knowing also $\mathfrak{D}$ from the deviation curve, the coefficient of heeling error $(\mathfrak{D} - 1 + \mu/\lambda) \tan \theta$ is found.

§ (12) CORRECTIONS OF THE DEVIATION.—In practice it is desirable that a ship's compass should be as nearly as possible corrected on all courses and in all latitudes. It is not possible to obtain this state of affairs with absolute exactitude, partly from the inherent difficulties of the problem and partly from the fact that the so-called permanent magnetism is only subpermanent, and it is therefore essential that the navigator should make frequent azimuth observations of the sun or a star for the purpose of determining the deviation for the course he is actually steering. The order in which the corrections are carried out is

(i.) Quadrantal deviation.
(ii.) Heeling error.
(iii.) Semicircular deviation.

(i.) *The Quadrantal Deviation.*—This consists almost entirely of the term D sin 2ζ, and the coefficient D in an uncorrected compass (*a*) does not change with change of latitude, (*b*) is always positive, and (*c*) remains constant for a great length of time. The correction of D is performed by means of soft iron spheres placed on the port and starboard sides of the binnacles, experience of previous ships of a similar design suggesting the size of the spheres and their position. The ship is then swung with the spheres in position and the new D determined from the table of deviations so obtained.

If this new D has a positive sign the spheres must be moved inwards or smaller spheres provided; if negative the opposite must be done. The necessary data are supplied in Table IV. of the *Admiralty Manual.*

For compasses out of the fore and aft line or between decks in the neighbourhood of unsymmetrically placed masses of iron, a coefficient E may exist. This can be corrected by moving one sphere ahead and the other astern of the athwartship line.

Before touching the heeling error corrections it is usually desirable to take out all or as much as possible of the soft iron semicircular deviation by means of the Flinders bar. This consists of a portion of $\mathfrak{B}$, viz. $(c/\lambda) \tan \theta$, and a portion of $\mathfrak{C}$, $(f/\lambda) \tan \theta$, the latter being zero through the symmetrical disposition of soft iron. The Flinders bar therefore corrects the coefficient *c*, and the magnitude of *c* in an uncorrected ship is known from previous experience. Should it not be so known it can only be determined from value of the semicircular deviations in widely separated latitudes.

(ii.) *Heeling Error.*—The next error needing correction is the semicircular heeling error, consisting of a part due to soft iron and a part due to permanent magnetism. The latter part is much the more important, and no separate means are usually provided for elimination of the soft iron part. The correction is made by means of vertical magnets below the binnacle adjusted up or down until the vertical force in the binnacle is the same as the vertical force on shore. The ratio $\mu : \lambda$ is thus made unity, and since $-\mathrm{J} = (\mathfrak{D} + \mu/\lambda - 1) \tan \theta$ the heeling error is thereby corrected, but will require a new adjustment of the vertical magnets if the ship makes a big change of latitude.

(iii.) *Semicircular Error.*—Except for constant deviation A, there remains only the permanent magnetism part of the semicircular error. This is neutralised by means of permanent magnets, some fore and aft and some athwartship placed below the binnacle, the numbers and sizes being adjusted until the deviation is zero on each of the four cardinal points.

The constant A $(= (d - b)/2\lambda)$ ought to be zero since by symmetry *d* and *b* are both zero. In actual fact there is usually a small A in an uncorrected ship, and this can be most

easily eliminated by a small displacement of the lubber line.

Having made the above corrections as far as can be done, the ship has to be swung and the values of the deviation (now small) used to compile a deviation table, which is checked from time to time, and the compass readjusted, a thing which is particularly necessary after large change of latitude or after heavy weather while steering for a considerable time on the same course.

§ (13) THE GYRO COMPASS. (i.) *General Principles.*—Gyro compasses in a practical form first appeared some two or three years before the European War when they were put on the market by Anschütz of Germany, and by Sperry in the United States. The underlying principles were the same in both compasses and were the practical development of ideas which had been suggested many years previously by Foucault and by Lord Kelvin. The latter described to the British Association in 1884 a gyroscopic model of a spring balance, which contained gyros instead of springs, and a gyroscopic model of the mariner's compass, in which a gyro took the place of the magnetic needle.

The chief points to notice in the behaviour of a spinning flywheel or gyroscope mounted freely so as to be capable of turning in any direction are: (i.) that it offers considerable resistance to any force tending to deflect the axis of spin from its original direction, and (ii.) that in the case of a force at right angles to the axis, when the axis does yield it moves, not in the direction of the force but at right angles to it. Thus, if the spinning axis is initially horizontal, a vertical force will only result in a change of azimuth; but any couple in the horizontal plane will produce a change of tilt and no horizontal motion. It has been suggested that the first-named property of a gyro, its power of resisting disturbing forces, might be used to produce a compass, or at least a direction indicator: the gyro being set with its axle in some given direction at the start, and maintaining that direction throughout the trip. Unfortunately it has, so far, been impossible to provide a mounting so free from friction that the gyro will not slowly drift away from its original direction. Except for certain aeronautical purposes where accuracy within a couple of degrees is required for periods of only half an hour or so, this type of "compass" has therefore never been of any practical use.

Every gyro compass which has met with any success up to now has been definitely north-seeking, and, if forcibly deflected from the meridian, works its way back by a series of damped oscillations like a magnetic compass, but much more slowly. This is accomplished by taking advantage of the earth's diurnal rotation and causing the gyro to be affected by it. This rotation has an influence on the gyro compass which is analogous to the effect of terrestrial magnetism on a magnetic compass. The earth's rotation may be regarded as an angular movement of the vertical in space, and is made use of by causing the gyro to be sensitive to any change in the position of its axis of spin relatively to the local vertical. The obvious method of doing this is to mount the gyro with its axis horizontal in a pendulous frame. The gyro tends to maintain its direction in space while the vertical shifts; its axis thus in general acquires a tilt from the horizontal position, and the pendulousness of the frame then supplies a couple which causes the gyro to "precess" or move in azimuth. If the axis points north and south, the shift of the vertical does not alter the angle between it and the axis, which still remains horizontal; thus no couple is produced and the axis continues to point north and south. This is the principle of Foucault and of Kelvin, applied by Anschütz, Sperry, and others. It is the only principle on which a successful gyro compass has yet been constructed.

(ii.) *Early Forms of Compass.*—Trials of Anschütz and Sperry compasses were carried out by the British Admiralty about 1910, but it was found that although otherwise fairly satisfactory they both showed large deviations when the ship was rolling, unless at the same time the ship's head was towards one of the four cardinal points. This "Inter-Cardinal Rolling Error," as it is called, was overcome in about a year by both makers. Anschütz redesigned his compass entirely and added two more gyros of the same size as the primary gyro, making three in all; at the same time he adopted an entirely new method of damping invented by Schuler, a German. Sperry, however, adhered to the original form of his compass, but added one small subsidiary gyro called the "Floating Ballistic Gyro" to overcome the deviation formerly caused by rolling.

The increasing use of large masses of iron and of electrical machinery in modern ships—particularly in submarines—had by this time greatly impaired the reliability of the magnetic compass, so that the advent of a gyro compass which would not be affected by stray magnetic fields, and which promised to indicate the true north at all times, was particularly timely. After experience with both Anschütz and Sperry compasses under service conditions, the British Admiralty decided to adopt the latter in the Navy. All submarines and first class ships were accordingly fitted with Sperry compasses between 1911 and the end of the war.

The Patent Office records show that the gyro compass problem attracted the attention of many other inventors, but only three need

be specially mentioned here. In 1917 Professor Perry and S. G. Brown produced a compass for sea trials which contained some novel and useful features. A great advance in eliminating undesirable friction was attained by causing the gyro frame to oscillate in its bearings by an intermittent flow of oil. It was claimed that the rolling error was eliminated by making the gyro and its casing strictly non-pendulous, while producing the required couple by mechanically transferring oil from the low side to the high side whenever the compass was tilted. This transfer was accomplished by an air-blast relay controlled by a pendulum. The damping was effected by the same relay and was similar in principle to that proposed by Schuler for the Anschutz compass. This compass was installed in a British light cruiser, with the result that an order for a further number was placed by the Admiralty. Before these could be delivered the Armistice was declared and, owing to the consequent stoppage of new construction, they have not yet been put into service.

A somewhat similar fate befell a compass with two gyros invented by H. L. Tanner in New York and made by the Sperry Gyroscope Co. It was a radical departure from previous models and was noteworthy for the merit of its electrical equipment. The Armistice spoilt the chance of this compass also, so far as the British Navy was concerned, as it had only been installed in two warships. Both the Perry-Brown and the Tanner compasses have, however, met with considerable success in the mercantile marine. As the Sperry compass, more or less modified as will be described later, is almost universal in the British, American, French, and Italian warships, and has a performance which is fairly representative of gyro compasses in general, the following pages refer more particularly to this apparatus.

§ (14) The Sperry Compass.—The main features of the Sperry compass may be understood from *Fig.* 5.

The gyro is simply a flywheel 12 in. diameter weighing 50 lbs., and spun electrically by 3-phase current at a rate of 8600 r.p.m. It is enclosed in an airtight aluminium case *b*, which is exhausted to a good vacuum to prevent air friction and consequent heating. This case is supported in a vertical ring *d* in which it is free to tilt about the horizontal axis *c*. The ring can turn about its vertical axis ff_1, in an outer vertical ring *g*, and carries the gyro case with it. The bearings *f* and f_1 are merely guide bearings and do not support the weight which is borne by a stranded wire attached to the outer ring. This outer ring, called the Phantom Ring, is power-driven by a small electric motor *m*, controlled by contacts on the inner vertical ring. The arrangements are such that the plane of the phantom ring follows faithfully the plane of the inner vertical ring. The wire *e* therefore never gets twisted, and there is no movement of the bearings *f* and f_1, except for a small oscillatory motion of the phantom. The contacts have no "off" position; the motor is always running in one direction or the other, so the plane of the ring *g* is constantly hunting about a mean position coplanar with the ring *d*, with an amplitude of about a quarter of a degree. This allows the ring *d* to turn about its vertical axis ff_1, almost without friction. One may blow once on the side of the gyro case and cause it to

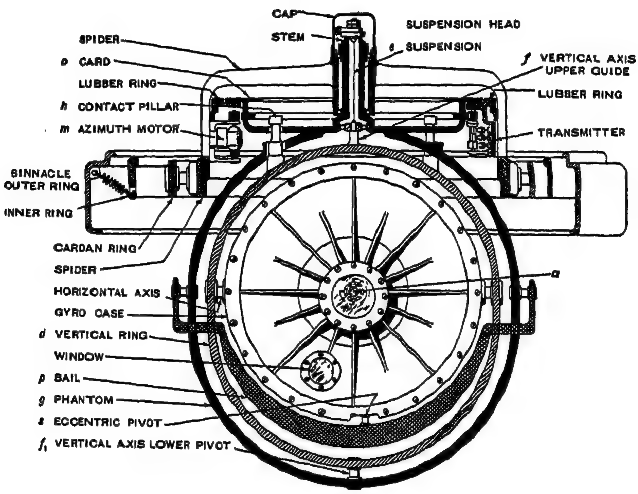

Fig. 5.

make several revolutions if the wheel is not spinning.

The gyro case is as nearly as possible in neutral equilibrium and the necessary pendulous moment is given to it by the separate mass p called the bail, which is hung independently on the phantom ring, and connected to the bottom of the gyro case at the point s. In order to avoid inter-cardinal rolling error, it is arranged that this point shall always be in the same position relative to the true vertical line through the centre of the gyro, even when the gyro case and its supporting rings are being swung east and west by the motion of the ship. The connection at s is therefore made by two rollers on one stem, the upper one sliding in a groove in the case and the lower one sliding in a similar groove in the bail. The roller stem is hung at the bottom of a short pendulum suspended from a. This pendulum, having a quick period, would itself be set swinging by the ship's motion if it were not stabilised by the small auxiliary gyro attached to it and known as the "floating ballistic gyro." The compass card o is carried by the phantom ring, and below it are arranged an automatic device for correcting the speed and damping errors, and an electrical transmitter for transmitting the corrected indications to a number of subsidiary dials in various parts of the ship.

§ (15) Theory of the Sperry Gyro.—The theory of the gyro compass,[1] written by H. Crabtree for Messrs. Elliott Bros.' handbook of the Anschütz compass, has been reprinted in that author's *Spinning Tops and Gyroscopic Motion*. The matter is also dealt with by Klein and Sommerfeld in *Theorie des Kreisels*. Sir George Greenhill devotes a chapter to the Gyro Compass in his *Report on Gyroscopic Theory*. All these writers, however, deal with the original single-gyro Anschütz compass, which is now obsolete. So far as is known, no similar mathematical explanation of the Sperry compass has yet been published, although it is in use to-day in all the principal navies of the world. A brief outline of the mathematics of the Sperry compass is therefore given here.

(i.) *General Equations.*—Let the axis of the gyro make an angle α with the meridian and β with the horizontal. Then if β is small the earth's diurnal rotation of ω radians per second has components in latitude λ.

$\omega \cos\lambda \cos\alpha$ about the gyro axle, . (1)

$\omega \cos\lambda \sin\alpha$ about the gyro tilt axis c, (2)

$\omega \sin\lambda$ about the local vertical. . (3)

The component (1) has no visible effect on the gyro, but if it maintains its direction in space, the axle has apparent motions equal to (2) and (3) relatively to the earth which increase β and α respectively.

As the gyro casing is not in perfectly neutral equilibrium, let C be its pendulous moment; to this is added B the pendulous moment of the bail. These two parts tilt together, so that the torque about the horizontal axis c of the gyro case is $\beta(B+C)$. From the fundamental gyroscopic law[2] this produces a precession in the horizontal plane at the rate $\beta(B+C)/H$, where H is the angular momentum of the flywheel. The apparent precession relative to the meridian is, however,

$$\beta\frac{B+C}{H} - \omega\sin\lambda = -\frac{d\alpha}{dt}. \quad . \quad . \quad (4)$$

Therefore, when the gyro remains at rest in azimuth it must have a tilt whose steady value is $H\omega\sin\lambda/(B+C)$.

In practice it is desirable for the gyro to settle with its axis perfectly horizontal as shown by spirit levels attached to the case. This is arranged by a latitude adjustment which sets the gyro and bail tilt axes out of alignment so that when the gyro axis is level and $\beta=0$, the bail has a tilt $\beta_0 = H\omega\sin\lambda/B$.

The torques about the horizontal axis c are now $C\beta$ due to the case and $B(\beta+\beta_0)$ due to the bail.

Equation (4) may then be written

$$C\beta + B(\beta+\beta_0) - H\omega\sin\lambda = -H\frac{d\alpha}{dt},$$

or since the terms $B\beta_0$ and $H\omega\sin\lambda$ cancel,

$$-H\frac{d\alpha}{dt} = \beta(B+C). \quad . \quad . \quad . \quad (4a)$$

Then
$$-H\frac{d^2\alpha}{dt^2} = (B+C)\frac{d\beta}{dt}. \quad . \quad . \quad (5)$$

If the gyro has a deviation angle α,

$$\frac{d\beta}{dt} = \omega\cos\lambda\sin\alpha \text{ from (2)}. \quad . \quad (6)$$

Substituting in (5), treating α henceforward as a small angle, and writing α for $\sin\alpha$,

$$H\frac{d^2\alpha}{dt^2} + (B+C)\omega\alpha\cos\lambda = 0. \quad . \quad (7)$$

Equation (7) shows that the compass swings in azimuth with an oscillatory motion of period

$$T = 2\pi\sqrt{\frac{H}{(B+C)\omega\cos\lambda}}. \quad . \quad . \quad (8)$$

(ii.) *Damping of the Oscillations.*—No account has yet been taken of the damping arrangement, without which the compass (being only very slightly damped by bearing friction) would oscillate perpetually about the meridian. To prevent this, the point s is set slightly to the east of the vertical line through a. Let r = the angle $f_1 as$, a small

[1] For a general account of the theory of a gyrostat see article "Gyroscope," Vol. I.

[2] See article "Gyroscope," § (6), Vol. I.

angle of about 1°. Then the couple due to the bail may be resolved into components approximately

$B(\beta+\beta_0)$ about the horizontal tilt axis c,
$rB(\beta+\beta_0)$ about the vertical axis ff_1

The latter affects the rate of change of β, so that while equation (5) remains unaltered, (6) becomes

$$\frac{d\beta}{dt}=\omega\cos\lambda\,.\,\alpha-rB\frac{(\beta+\beta_0)}{H},$$

and instead of (7) we have

$$H\frac{d^2\alpha}{dt^2}+r\frac{Bd\alpha}{dt}+(B+C)\omega\cos\lambda\,.\,\alpha=(B+C)r\omega\sin\lambda. \quad (9)$$

Thus in the steady state, when $d^2\alpha/dt^2$ and $d\alpha/dt$ are each zero, the compass has a deviation

$$\alpha_0=r\tan\lambda.$$

This deviation is due to the method of damping, and is therefore known as the "Damping Error" or sometimes as the "Latitude Error," because it varies as the tangent of the latitude angle. It is corrected in the readings shown by the compass, by shifting the lubber's mark out of the fore-and-aft line by an appropriate amount.

Since in equation (9) r^2B^2 is numerically less than $4H\omega\cos\lambda\,(B+C)$, the solution is

$$\alpha-\alpha_0=Ae^{-rBt/2H}\sin\left(\frac{B+C}{H}\omega\cos\lambda-\frac{r^2B^2}{4H^2}\right)^{\frac{1}{2}}t,$$

the equation of a damped harmonic oscillation with period

$$T_d=\frac{4\pi H}{\{4(B+C)H\omega\cos\lambda-r^2B^2\}^{\frac{1}{2}}}.$$

The ratio of successive swings is given by

$$f=e^{\frac{-rB}{4H}T_d}.$$

The value of f is normally about $\frac{1}{2}$ to $\frac{1}{3}$.

(iii.) *Speed Error.*—The above applies to a compass stationary ashore. In a ship moving over the earth's curved surface with a northerly velocity v miles per second at the equator, the apparent axis of the earth's rotation is shifted by an angle δ whose tangent is $v/R\omega$, where R is the earth's radius in miles. If the ship's speed is V on a course K degrees from north and the ship is at latitude λ, we may write (since δ is a small angle)

$$\delta=\frac{V\cos K}{R\omega\cos\lambda}. \quad . \quad . \quad . \quad (10)$$

If V is given in knots and δ is required in degrees,

$$\delta=\frac{1}{5\pi}\frac{V\cos K}{\cos\lambda}=0{\cdot}064\frac{V\cos K}{\cos\lambda}.$$

This "Speed Error" deflects the compass to the west on northerly courses and to the east on southerly courses. Its amount is about 1° for each 10 knots in British latitudes. It will be noticed that this error is entirely independent of the design of the compass. Speed or course error is inherent in any north-seeking gyro compass, although mechanical means may be arranged to correct it. Such an arrangement has been embodied in the Sperry compass, which has a latitude dial and a dial to be set by hand to the ship's speed. An ingenious mechanism then automatically corrects the readings by shifting the lubber's mark by the amount required for the course the ship is steering.

While the ship is actually changing its northerly velocity, the acceleration dv/dt produces a shift of the apparent vertical, as shown, for instance, by a plumb-line, through a small angle whose circular measure is $(dv/dt)/g$, where g is the acceleration of gravity in miles per sec.^{2}. As the case and bail do not alter their tilt relative to the horizon, this is equivalent to a change in the value of β, the tilt relative to the vertical. The pendulous moments of the bail and case then cause the compass to deviate in azimuth at the rate

$$\frac{d\alpha}{dt}=\frac{1}{g}\frac{dv}{dt}\cdot\frac{(B+C)}{H},$$

which must be multiplied by the cosine of the course if the acceleration is not along the meridian. By integrating over the period during which the acceleration persists (which is supposed short)

$$\alpha=\frac{V(B+C)}{gH}\cos K. \quad . \quad . \quad . \quad (11)$$

This is the "*ballistic deflection*," and for a northerly acceleration it is to the westward, and therefore of the same sign as northerly speed error. By making the amount of this deflection equal to the change of speed error the acceleration will move the compass dead-beat to its new resting position without any oscillation. Thus with the co-operation of the correction mechanism referred to above the compass will indicate true north before, during, and at the end of the acceleration. To secure this desirable result, δ in (10) must have the same value as α in (11), then

$$B+C=\frac{gH}{R\omega\cos\lambda}. \quad . \quad . \quad . \quad (12)$$

By substituting this value of B+C in equation (8) the periodic time of the undamped compass must be $T=2\pi\sqrt{R/g}$, or about 85 minutes.

The damping—for $f=\frac{1}{3}$—increases this period to about 90 minutes, and practically all gyro compasses are now constructed to oscillate in this time.

It will be noticed that the value of B+C in (12) is dependent on the latitude. Previous to 1918 compasses were designed to be correct in latitudes of about 40° to 50°, leaving a residual error outside those limits which grew to be rather serious in high latitudes. A modification of the Sperry compass patented by Commander G. B. Harrison and A. L. Rawlings of the Admiralty Compass Department, and

which will be described below, contains a means of altering the value of B to make the ballistic deflection approximately correct in any latitude.

(iv.) *Further Effects of Change of Course.*—Owing to the eccentric connection between the bail and gyro case (s in *Fig.* 5) the couple produced by the acceleration is not confined to the vertical plane. The component in the horizontal plane deflects the gyro axle slightly from the level position, and this causes the compass to wander slightly back from the correct azimuth after it has been placed there by the ballistic deflection. This disturbance has been named "*ballistic tilt*," and the resulting temporary deviation, which attains its maximum value about a quarter of an hour after the acceleration which produced it, is about 2° for 40 knots change of northerly speed. It may be reduced by making the eccentricity less, *i.e.* by reducing the angle r. This of course reduces the damping also. Sperry compasses, in which each swing was one-third the amplitude of the preceding one, have been altered to make this ratio one-half with marked success. The ballistic tilt effect was halved and no noticeable disadvantage was found with the lighter damping.

In compasses damped by other means, such as those of Anschütz and Brown, a precisely similar deviation has been found due to disturbance of the damping oil. Brown has introduced an automatic cut-out to get over this difficulty.

In the case of the Sperry, the deviation is slightly greater if a turn from north to south or south to north is made through west, and rather less if made through east. This is due to the eccentric connection being swung over as the turn is made in spite of the ballistic gyro. A similar effect, but exchanging east for west, has been observed with the Harrison-Rawlings modification.

(v.) *Recent Improvements.*—The sensitiveness of the ballistic gyro to east-west accelerations is occasionally the cause of serious deviations. If the ship rolls badly on a meridional course, the ballistic gyro may swing quite clear of the grooves in the bail and case and put the compass out of action. This was overcome to some extent by adding a weight to the ballistic gyro frame above its point of suspension so as to increase its natural period and make it more stable, but the Admiralty and the Sperry Co. have now adopted the Harrison-Rawlings modification, which does away with the ballistic arrangement entirely.

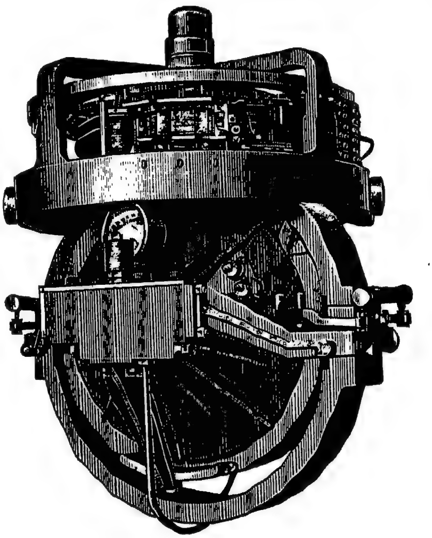

FIG. 6.

In this device the Sperry bail is replaced by a large U-tube containing mercury and opening at the ends into cast-iron boxes (see *Fig.* 6). When this is tilted by the gyro, an excess of mercury accumulates in the lower box and applies a couple which is opposite in sign to that of the pendulous bail. By reversing the spin of the gyro, however, the precession is made in the right direction, and the compass functions as usual. The inertia of the long column of liquid in the U-tube keeps it comparatively steady while the ship rolls and so eliminates rolling error. The above equations for the Sperry compass can be applied to the Harrison-Rawlings modification by making H and B both negative and neglecting C, the pendulousness of the case, which is zero in this arrangement. The quantity denoted by B, which is the "pendulous moment" of this form of bail, depends on the area of the free surface of the mercury to the boxes. A simple device is fitted which makes this area adjustable by turning the knob seen at the right-hand side of the box, and the compass can thus be set to give a correct ballistic deflection in any navigable latitude. With this arrangement the compass has been found proof against any weather, provided that the rolling is not so severe as to swing the gyro against the gimbal rings.

(vi.) *Accuracy.*—In conclusion, some idea may be given of the accuracy to be expected of a gyro compass under average conditions, and the probable causes of any deviations which may be met with. Either the original Sperry compass, or its modification just described, are liable to change of settling-point with a minute change in the balance of the gyro case. An increase of temperature causes the case to expand unequally, making it generally North heavy; change of atmospheric pressure with varying barometric height has a similar effect, as also has any variation of the vacuum maintained in the case. Wear of the bearings on which the wheel spins or on which the case tilts is a further cause of change of balance. The effect of any of these is small, and it would be very unusual for their combined action to change the settling-point more than 2° if the balance was not otherwise disturbed. As the

master-compass is kept below at a fairly constant temperature, no rapid changes of balance are likely to occur. Hence, if no correction by true bearings were available for periods of a week at a time, the compass might be relied on to keep within 1° of its settling position during the interval. Large deviations may be caused by wrong adjustment of the suspension wire by which the vertical ring is supported. This should be installed quite free from twist and checked from time to time to see that it remains so. The deviation due to a twisted suspension is, however, practically constant and does not introduce any uncertainty. The electrical arrangements of the master-compass and the transmission to the repeaters, when entrusted to an intelligent electrician, have proved very reliable, and the gyro compass equipment as an aid to navigation has justified its inclusion in the equipment of modern warships.

§ (16) THE LOG LINE.—In its old form the log line consisted of a wooden board of approximately triangular section, weighted on one side so that it would float upright and present the greatest possible resistance to being dragged through the water. The log line is made fast to the centre of the board and runs out from a reel. The determination of speed is made by noting how many "knots" of the line run out in a definite interval, usually 14 or 28 seconds.

Steamships, in which the course remains constant for great lengths of time, always now use some form of patent log, an instrument which measures distance run rather than speed. A log of this type is made of approximately cylindrical shape with spiral vanes fixed to the curved surface. It is towed astern of the ship, and as it travels through the water the vanes cause it to rotate on its axis. The rotation twists the tow-line and the latter turns a counting mechanism fixed to the taffrail, so that the distance run can be read off. In some patterns the log is practically upon the surface, in others it sinks to some distance below.

If there is a surface current both types show, in general, inaccuracies. A log towing at considerable depth may be completely below the current, and will thus indicate the speed of the ship over the ground; a log towing on the surface would show the speed of the ship relatively to the water, provided the current extended to a depth well below the keel of the ship. In still water both types are equally reliable.

§ (17) METHODS OF POSITION FIXING. (i.) *The Station Pointer.*—One of the commonest methods of fixing position when off a coast is by the measurement by a sextant of the two angles between three recognisable marks on shore.

If A, B, and C (*Fig.* 7) are these points and P the position of the ship, the angles APB (a) and BPC (β) are measured. The position can then be graphically constructed upon the chart by drawing the circle APB to contain the angle a, and the circle CBP to contain the angle β. Since the two circles must have the point B in common, their other point of intersection P is uniquely determined.

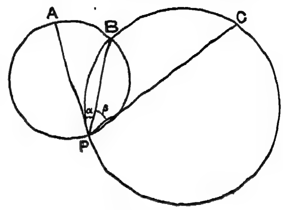

FIG. 7.

The construction of these circles being laborious and difficult when their curvatures are flat, the station pointer is used to achieve the same end. The instrument consists of a graduated circle with three arms, of which the chamfered edges are radii of the circle. One of the arms is fixed and the other two can be rotated, one to the right and the other to the left. The scale of graduations has the zero on the edge of the fixed arm, and the graduations extend from 0° to 180° on either side. The measured angles are set on the instrument by means of the two movable arms, a vernier being available for accurate setting. The instrument is placed upon the chart and moved about until the edges of the legs pass accurately through A, B, and C. The centre of the circle must then be the point P, which can be marked down upon the chart as the ship's position.

Accuracy in the determination of a position by this method is very largely a question of proper choice of the three shore marks.

If it should happen that the angle BCA, as in *Fig.* 8, is equal to the observed angle a, then a circle can be drawn through the *four* points A, B, C, and P and the ship's position becomes completely indeterminate; it may be anywhere on this circle. The two circles of *Fig.* 7 coalesce, and any point on the circumference fulfils the conditions as regards the magnitudes of the angles APB and BPC.

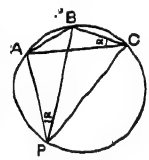

FIG. 8.

The criterion of the suitability of the three marks depends upon the relative positions of A, B, C, and P. In particular, the "fix" is a good one if the middle object is on the nearer side of the line joining the two outside ones. The errors of position obtained by this method are dependent upon the errors of measurement of the two angles, errors of setting the two arms, and errors of locating the station pointer on the chart. Probable values for each of these errors could be obtained and combined

so as to give a probable error of position of each of the two position lines, in this case a small part near P of the circumferences of the circles PBA and PBC. The most probable position is then the point P. The probability of position, per unit area of the chart, diminishes as we move away from P, but diminishes at different rates for different directions. This probability of position per unit area is constant around the circumference of an ellipse whose centre is P and of which the tangent lines at P to the two circles are conjugate diameters (see *Fig.* 9). One of these ellipses is such that the probability of the position lying within it or outside it is one-half. An ellipse of three or four times the linear dimensions gives something closely approximating to certainty of position.

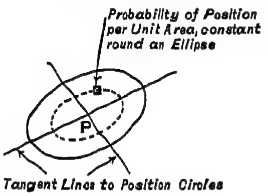

FIG. 9.

It should be noted that similar results hold in all cases where a position is fixed by means of two position lines, each of which has a definite probable error of lateral displacement.

When three or more position lines are found for the purpose of determining a "fix," and they do not pass through a point, the most probable position must be determined by the method of least squares, but it is not possible to make any simple statement as regards the way in which the rate of decrease of the probability of position per unit area varies with variation in direction.

This method of position fixing is almost always used for fixing soundings when making a survey. The sextant used in such case is of special construction, and is called a sounding sextant. (For description see under "Sextants," § (20).)

(ii.) *The Bearing Plate or Pelorus.*—Owing to the impossibility in many cases of obtaining an all-round view from the standard compass, it is necessary at times to employ subsidiary means for taking bearings when the standard compass cannot be used. The bearing plate used for this purpose consists of a circular brass circle, divided into degrees, slung in gimbals so as to remain horizontal when the ship rolls. A concentric circle fits inside the brass one, and is also graduated. This is used like a compass card, and is set so as to show the course by standard compass against the zero of the brass circle, used as a lubber line. The ship's head must of course be kept steady while an observation is being made. A sight vane fits over the brass circle and is used in the same way as the azimuth circle of the standard compass. When a bearing is taken it can be read relatively to the ship's head on the outer circle or relatively to the standard compass on the inner one.

(iii.) *Sounding Machines.*—When soundings are required in water too deep for the ordinary hand lead a sounding machine is used. It consists of a framework supporting a drum round which is wound about 300 fathoms of 7-strand wire. The drum can revolve freely on its axle, can be braked, or can be wound up either by hand or by electric motor. The wire is led from the drum through a block at the end of a spar 30 to 40 feet long, projecting beyond the ship's side, and at the end of the wire is a short length of hemp rope to which a 24-lb. lead is fixed and also a brass guard tube, the latter being about 6 feet above the lead. A dial indicator on the machine shows how much the wire has run out. When sounding from a ship at rest the length of wire run out gives the depth immediately, but when the ship is under way the lead does not sink straight down but trails away aft. In such case the depth is determined by the "chemical tube"—a glass tube open at one end and sealed at the other. The inside of this tube is lined with chloride of silver, coloured red. The tube is placed inside the guard tube open end downwards, and the sea-water has access to it through holes in the guard tube. As the lead sinks water enters the tube compressing the air, and the length of the tube thus filled is connected with the pressure, and therefore with the depth, by a simple extension of Boyle's law. This length is immediately visible when the lead is hauled up, as the part of the chloride of silver that has been in contact with sea-water is turned white and can be measured. As a check upon the accuracy of the sounding, as found by the chemical tube, the amount of wire run out, which is a function of the depth and the speed, can be used.

In very deep water great advances have recently been made by sounding by acoustical methods. If a small charge be exploded near the ship's side the reflected sound wave from the bottom of the sea can be easily detected. With suitable means for accurate measurement of the time between the explosion and the echo it is possible to determine the depth with a very close degree of accuracy.

Another and somewhat similar method is to drop overboard an explosive charge which sinks at a uniform speed which is known. The charge explodes on striking the bottom, and the elapsed time before the explosion is heard leads to a determination of the depth.

§ (18) METHODS OF NAUTICAL ASTRONOMY.—When out of sight of land the navigator has from time to time to obtain his position

by means of observations of the sun or stars. A measurement is made by a sextant of the angular altitude of the heavenly body above the sea horizon, while the time is noted by a chronometer whose error on G.M.T. is known.

Astronomical observations are also necessary to check from time to time the error of the compass. To this end an azimuth mirror is fitted to the standard compass for the purpose of taking the bearing. The time being noted when the bearing is observed, and the latitude and longitude of the ship's position being known with sufficient accuracy, the true bearing of the sun can be calculated and the compass error determined.

Occasionally special instruments are used for the purpose of measuring the depression of the visible horizon below the true horizontal. Tabulated values of this depression are available, but are sometimes inaccurate owing to abnormalities of the refraction.

§ (19) THE SEXTANT. (i.) *Description.*—After the mariner's compass the next most important instrument that the navigator uses is the sextant. With it he measures the angular altitudes of the sun and of the stars above the visible horizon. From these observations his position on the earth's surface is determined. With the sextant also he measures horizontal angles between visible terrestrial objects from which his position when near land can be plotted upon the chart.

Simple in principle and simple in construction as the sextant is, it was not invented until nearly the middle of the eighteenth century, and earlier navigators had to measure altitudes by the cross-staff, a wooden apparatus resembling a T-square with three sliding crosses of unequal lengths. The instrument was held with the long arm of the T horizontal, and the observer looked along this and maintained it so as to be in the direction of the horizon. One of the crosses was then moved until its upper edge was in line with the sun's centre and the altitude read off from a scale of tangents. A modified form was the back staff, in which the observer turned his back upon the sun and held his instrument so that light from the sun passing through one slit fell upon another. If at any time the observer could through this second slit see the sea horizon his sight was correctly made; if not, the slit nearest to the sun needed setting up or down. The cross-staff, or fore staff, and the back staff were the principal measuring instruments in use by all the great navigators of the Middle Ages. Cabot, Columbus, Hawkins, Drake, Raleigh made their great voyages by no other aid than theirs. Chronometers, as we know them, that will keep a fairly steady rate for months on end, had not been designed. The lunar distances of stars were not then tabulated, so that they could make no observations for longitude, and their "sights" consisted merely of the determination of the latitude at noon. About 1664 a reflecting form of backsight was invented by Hooke, but a cursory examination of its design shows that it was not properly a sextant, inasmuch as a small tilt of the instrument in the vertical plane would throw the images of the sun and the horizon out of contact. Presumably for this reason it was never used, and although reinvented by Grandjean in 1732 (*Fig.* 10), and approved

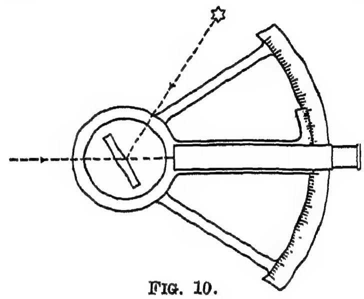

FIG. 10.

by the Académie Royale des Sciences de Paris, it was not until a double-mirror instrument was designed a few years later that the navigator possessed anything corresponding to the sextant as we now know it, an instrument that can be tilted in the vertical plane and yet maintains contact between the image of the sun and the image of the horizon. This condition can only be realised provided both images are formed after an even number, or both after an odd number of reflections. Customarily the sun is reflected twice and the horizon not at all; but several designs have been produced in which each is reflected once, or in which one is reflected once and the other three times. As to who was the first designer of the sextant is not known with certainty. Popularly it is ascribed to Hadley in 1731; but Newton certainly designed one independently about the same time, and there are claims of one designed by an American merchant captain of an even earlier date.

In all these earlier forms of sextant the main principle is shown in *Fig.* 11. It consists of a framework or limb A to which is attached a fixed mirror H, the horizon glass. The limb is in the form of a sector of a circle, and a movable arm R, the index arm, can rotate round the centre of this circle. Fixed to the index arm and rotating with it is the index glass I. The horizon glass is usually silvered over half its area, so that the observer looking horizontally into the horizon glass can see the twice-reflected image of the sun in the silvered portion and then also see the

horizon directly through the unsilvered portion. By using a small telescope T attached to the limb these two images become superposed, and, the telescope being usually of the inverting type, the field of view is as

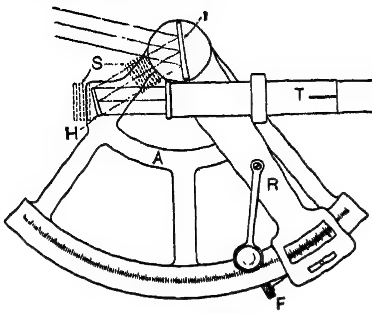

FIG. 11.

shown in *Fig.* 12. When exact contact is made the measure of the sun's altitude is twice the angle between the two mirrors, and can be read off from a scale engraved on the arc of the instrument. By cutting this scale in "sextant degrees"—*i.e.* 720° to the complete circle—the altitude measured can be read direct.

The use of the instrument requires considerable practice before the observer can become proficient. The sun is first of all "brought down" to the horizon. To do this the index arm is set somewhere near zero and the sextant held in a vertical plane, but with the sight line directed towards the sun instead of horizontal. Two images of the sun will then be seen—one in the silvered and one in the unsilvered portion of the horizon glass. The sextant is now brought slowly down to its normal position, moving the index arm all the time while this is being done in order to keep the reflected sun in the horizon glass, until ultimately the horizon appears through the unsilvered portion. "Bringing the sun down" is usually carried out with the telescope removed so as to give the observer a greater angular field of view.

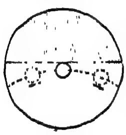

FIG. 12.

When the sun and horizon are both visible in and through the horizon glass the index arm is clamped to the limb and the telescope shipped, the final adjustment necessary to make contact being done by means of the fine-motion screw or "tangent screw" F attached to the arm. The final adjustment in itself requires care. If the sextant is "rocked"—*i.e.* given a small angular rotation round the axis of the telescope—the sun will move relatively to the horizon as shown in *Fig.* 12, and the adjustment is only correctly made provided that in its motion across the field of view the sun swings just to touch the horizon and just does not dip into it. To keep the sun in the field of view while this rocking motion is being made, the whole instrument has to be suitably turned in azimuth. By acting as described above, the navigator makes a measurement of the apparent altitude of the sun's lower limb above the visible horizon with an accuracy of observation normally of about 30″.

The sextant has, in addition to the parts described, other fittings that need to be referred to. Shades S are placed between the two mirrors in order to reduce the brightness of the sun. They consist of pieces of dark glass with parallel faces and of different densities. If not made with their two faces exactly parallel they will refract the light passing through them, and a consequent error in the measurement results. With a shade that is prismatic this deviation will be greatest if the edge of the prism—*i.e.* the line of intersection of the two plane faces—is at right angles to the limb, and will be zero if the edge is parallel to the limb. As the shades need to be mounted loosely in their frames on account of the variation in temperature that a sextant has to withstand, and as the circular form is the most convenient to make, the shades have ordinarily to be made of glass so nearly parallel that light passing through it is not deviated by more than 5″. The shades are usually four in number and of densities such that the transmission ratios are 1 in 40, 1 in 400, 1 in 7000, and 1 in 35,000, but such figures are very approximate.

Three shades and sometimes four are also placed behind the horizon glass. The sextant has at times to be used with a second image of the sun reflected in a mercury trough, instead of with the sea horizon. There is also frequently a good deal of reflected light from the surface of the sea, and a special light shade is included to cut off some of this glare. Sometimes also a Nicol prism is placed behind the horizon glass to cut out the polarised light reflected from the water.

(ii.) *Errors.*—The sextant in use is always subject to errors of varying amounts. The mirrors are not rigidly held, and change their position; and an examination of the value of the zero error, which is the most important of the first-order errors, is necessary from day to day. The determination is made by the sea horizon, or by the measurement of the sun's diameter "on and off the arc." Another first-order error is that of centring, the scale being cut from a point which is not the working centre. Sextants are tested in this respect at the National Physical Laboratory. The amount of decentration which is allowable in order to comply with the N.P.L.

test, that the error must not exceed 40 seconds of reading, lies between about one-thousandth of an inch in the direction of the middle reading and about three-thousandths in the direction at right angles, with a sextant of 7-inch radius. Whether the value of the centring error as given in the N.P.L. certificate is permanent is a very doubtful point. The sextant in use is exposed to hot sunlight on one edge of the limb while the rest is in shadow. Some sort of deformation of the limb must take place, and it is quite possible that an additional minute or two of centring error is introduced every time the sextant is used in the tropics. Makers of sextants have frequently contributed to the risk of this trouble by finishing the limb a dull black, but of late there has been a tendency to make sextants in which the metal work is much less absorbent of heat.

First-order errors also arise from the shades and mirror being made from non-parallel glass. The worst effect on the reading occurs when the "edge" of the prism is perpendicular to the plane of the limb, no error being caused when this edge is parallel to the limb. If shades were mounted so as to be non-rotatable the prismatic error would always be of the same magnitude and might be included in the zero error, although it would involve a separate correction for each shade.

A prismatic horizon mirror gives rise also to a constant error, but with a prismatic index mirror the resulting correction is different for each reading and increases rapidly towards the higher angles. As a consequence it is necessary that mirrors should be made with a high order of accuracy in parallelism. In addition to absolute error there is also trouble in the duplication of an image if the mirror is of non-parallel glass, one image being formed by light reflected from the first surface of the mirror, the other by light reflected at the back. A simple practical test for parallelism of the mirrors is obtained by observing through the highest-power telescope the image of a star seen after reflection at the two mirrors, the index mirror being set to the top end of the arc. If under these conditions no duplication of the image is noticeable the mirrors are quite good enough for the purpose.

The second-order errors of a sextant are due to three principal causes, viz. want of perpendicularity of the two mirrors to the plane of the limb and want of parallelism of the line of sight to the same plane. When all these three defects occur together the resulting error in the reading can be shown to be

$$\begin{aligned}\epsilon = 2\operatorname{cosec} R\{&\alpha^2\cos(d+\tfrac{1}{2}R)\cos(d-\tfrac{1}{2}R)\\ &+\beta^2\cos d\cos(d-\tfrac{1}{2}R)-\gamma^2\sin^2\tfrac{1}{2}R\\ &-2\beta\gamma\sin\tfrac{1}{2}R\sin(d-\tfrac{1}{2}R)+2\gamma\alpha\sin d\sin\tfrac{1}{2}R\\ &-2\alpha\beta\cos d\cos(d-\tfrac{1}{2}R)\},\end{aligned}$$

where R is the value of the reading, d the "sextant angle," viz. the angle between the normal to the horizon mirror and the axis of the telescope, and α, β, γ are the errors of the index mirror, horizon mirror, and line of sight respectively. If R is zero the value of ϵ is not zero unless $\alpha=\beta$. This fact is clearly obvious, as, without this condition, the two mirrors cannot be moved so as to be parallel to one another, and the two images of the same point cannot be made to pass over one another.

All sextants are provided with means to adjust the second-order errors. The procedure is, usually, to set the index mirror so that its plane approximately bisects the arc. One end of the arc can then be seen directly and the other by reflection in the index mirror. The latter is then adjusted until the two views of the arc are coincident. When carefully done the value of α should not exceed two or three minutes. Having set up the index mirror, the horizon mirror is then adjusted so that the two images of a distant point can be made to pass over one another. As the telescope can be used for this purpose, α and β can be made equal to within ten seconds or so.

The adjustment of the collimation error is much more troublesome. The telescope is sometimes mounted in an adjustable collar with two small setting screws, but the adjustment is hard to make at sea and, indeed, is not often attempted. The weakness of the rising piece and the unsubstantial design of the framework of the limb are so considerable in some sextants that slight pressure between the ocular end of the telescope and the side of the nose may cause a temporary collimation error when the instrument is in use. In addition the observer may take his observation away from the centre of the field, so that the value of γ is of necessity higher than α or β. If we take α and β equal and comparatively small relatively to γ, the approximate value of the error is

$$=-\gamma^2\tan\tfrac{1}{2}R+4\gamma\alpha\sin\tfrac{1}{2}R\cos(\alpha-\tfrac{1}{2}R)\sec\tfrac{1}{2}R.$$

The value of this is negligible at small angles. At 90° it becomes $-\gamma^2+2{\cdot}15\gamma\alpha$, and at 130°, which is about the maximum observable angle, $-2{\cdot}14\gamma^2+4{\cdot}85\gamma\alpha$.

It will be seen from the above that if the errors of the mirrors are carefully eliminated the error of the reading is inconsiderable except at the high angles, and that for sea work, where altitudes do not exceed 90°, collimation error of a degree is not serious. On the other hand, if the mirrors are out of adjustment an error of reading of four or five minutes is quite possible.

§ (20) FORMS OF SEXTANTS.—No very great change has been made in the design of sextants since the time of Hadley. With improvements

in the methods of cutting the scale and with the use of more accurate verniers for reading, it has been possible to reduce the radius of the limb without any loss in accuracy. Older patterns frequently had a radius of as much as 15 inches as against the 7-inch radius that is customary nowadays. Telescopes have been improved and have now better definition and larger field of view than formerly, but there is a limit to what is possible in the latter respect owing to the difficulty in increasing the size of the mirrors. Some improvement is possible if the mirrors are replaced by reflecting prisms in which the refractive effect of the glass can be utilised to give an enlarged aperture. For example, if a prism of angles 45°, 45°, and 90° (see *Fig.* 13) be used, a reflection can be obtained when the incident light is parallel to the reflecting face and at the same time the breadth of the reflected beam is about a quarter of the length of the reflecting face. If a mirror had been used in this way the breadth of the reflected beam would be *nil*.

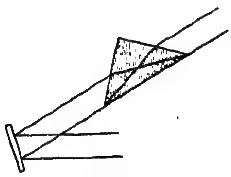

FIG. 13.

A prism used for reflection in place of a mirror need not have its angles exactly 45° and 90°, but the two base angles should be equal. For ordinary sea work the difference between the two base angles should not exceed half a minute, although an error up to ten minutes is permissible provided a suitable correction is applied to the reading. The value of the latter is very similar in its magnitudes to a centring error, and if the centre is made adjustable it is quite possible to throw the working centre out so that the true centring error thus introduced neutralises the prism error and leaves a balance of error below twenty seconds for all points of the arc.

The use of a prism in place of a mirror on the index arm gives another advantage. In order to obtain a wide range of readings (up to 130°) the sextant angle needs to be kept down to about 15°. This involves considerable space being left between the end of the telescope and the horizon mirror and between the latter and the index mirror in order to avoid any cutting off of light. The more these distances are increased the more difficult it is to obtain a wide external field of view. With the use of a prism to replace the index glass the sextant angle can be made larger and the spacing of the different parts much reduced without any loss in the working range of the sextant, and with actual gain in aperture at the high angles. Modern improvements in the production of prisms may possibly result in their replacing mirrors entirely in sextants.

Another direction in which tentative efforts at improvements in design have been made lies in the method of reading the arc. Under good conditions of illumination and with plenty of time to spare there is no great difficulty in reading a 7-inch sextant to ten or twenty seconds, but at night-time at sea it is much more difficult, and efforts have been made on the Continent to provide the navigator with a sextant which is easier to read and on the whole good enough for his needs. The usual form that this improvement has taken is the provision of a worm gearing round the edge of such a pitch as will give 720 teeth to the complete circle. The head of the worm is divided into sixty parts and a reading can be made with great ease. No great difficulty is experienced in obtaining accuracy within a minute, although there is always danger of burring the teeth of the gear by accident. A circular rack-and-pinion movement has also been tried for the same purpose, but not with the same success.

In addition to the ordinary sea uses of measuring the altitudes of heavenly bodies, sextants are sometimes required for the accurate determination of latitude and longitude of places on shore, or for the determination of the errors of chronometers at a place whose position is accurately known. In such cases the measurement of the altitude is made between the sun or star and its reflected image in a mercury trough. Usually a higher degree of accuracy is required with such an observation and the sextant is fitted with a telescope of higher power and has an arc of larger radius cut sometimes to 5 seconds. For the purpose of this type of observation the sextant is usually mounted on a stand, which is a light three-legged pedestal with a universal joint at the top to which the sextant is clamped. After an observation has been made a sextant has to be turned up to take the reading, and various stops are sometimes fitted to the stand so as to permit of the sextant being immediately turned back again to precisely the same position as before. In order to reduce errors of observation the navigator generally likes to make three observations at sea and at least five on shore, the mean of the altitude being assumed to correspond with the mean of the time. To avoid delay in having to read the sextant after each observation, various devices have been employed. In one such device the tangent screw is fitted with a ratchet and the pitch of the screw chosen so that each tooth of the ratchet is equivalent to one or two minutes change in altitude. With such an arrangement the navigator can obtain a set of observations

and does not need to read the sextant until they are completed.

Another device is by the use of a reflecting prism of small angle which is placed beyond the horizon glass. The edge of this prism is perpendicular to the plane of the limb, and according to whether the prism is placed base up or base down the horizon is lowered or raised. A set of three observations can be made (i.) by using the prism base up (see *Fig.* 14), (ii.) by removing it entirely (see *Fig.* 15), and (iii.) by using it base down (see *Fig.* 16). The mean of the three altitudes will be the sextant reading irrespective of the angle of the prism.

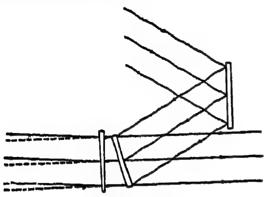

FIG. 14.

Another use to which sextants are frequently put is the measurement of horizontal angles between two fixed marks. In a hydrographical survey the positions of soundings are usually fixed in this way, two horizontal angles between three fixed objects being measured as nearly as possible simultaneously. The position of the sounding is subsequently plotted on the chart by means of a station pointer set at the measured angles. The sextant used for this purpose differs only slightly from the ordinary pattern. It usually has a shorter radius as a smaller degree of accuracy is necessary, the shades are abolished, and the telescope is of the Galilean variety so as to give an erect image. Efforts have been made to give the observer as wide a field of view as possible and also to make the sextant easy to read. Various types of "double angle" sextants have been tried in which the two angles can be measured at the same time, so as to avoid the objection of a lapse of time while the first angle is being read.

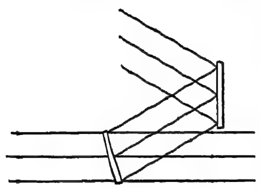

FIG. 15.

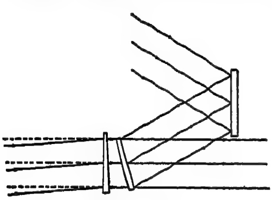

FIG. 16.

§ (21) BUBBLE AND PENDULUM SEXTANTS.—Owing to the difficulty that is frequently experienced at sea of seeing any horizon, attempts have been made many times to replace the sea horizon by some form of level or vertical that is controlled by gravity. In some of these devices the method adopted is to reflect into the field of view the image of the bubble of a spirit-level which indicates the direction of the vertical (see *Fig.* 17). The observation is made by bringing the centre of the sun to the centre of the bubble. In others a horizontal line moves up and down in the field of view under the control of a pendulum, and is exactly opposite a fixed pointer when the telescope is pointing towards the true horizon, so that when the sextant is held true and steady, observations of the sun can be made down to this artificial horizon in the same way as it is usually brought down to the visible sea horizon.

Of the two arrangements the bubble is preferable as it is self-damping if the liquid is sufficiently viscous, and there is an additional advantage that, with proper optical arrangements, the images of the sun and bubble will follow one another across the field even when the instrument is tilted in a vertical plane. Such an instrument can properly be called a sextant. The pendulum instruments are, more strictly speaking, clinometers.

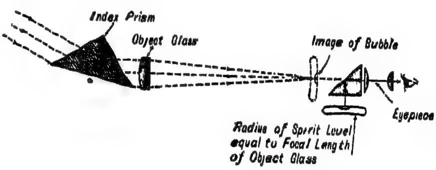

FIG. 17.

All sextants of this type are very severely handicapped by the movement of the ship and consequent horizontal acceleration of the observer and the sextant together. The bubble or pendulum sets itself under such circumstances not in accordance with the true vertical but with the false dynamical vertical compounded of earth's gravity and horizontal acceleration. Horizontal accelerations of 1 ft. per sec. per sec. are common. Such accelerations are only very approximately periodic, and the observer finds that if he brings sun and bubble together at noon, the former will wander up and down relatively to the latter by the amount of a degree or two on either side, and generally so slowly that it is impossible to form even an approximate idea of the mean position. Any method of damping that is practically available serves only to damp out the rapid vibrations of the observer's hand and leaves the slow oscillations untouched. In ordinary weather in the Atlantic, where the ship necessarily rolls and pitches,

and has further alternating horizontal accelerations due to the "send" of each succeeding wave, the probable error (even chance error) of a single such observation taken from the bridge may be put at about 20 minutes of arc. This must be multiplied by four to give the navigator something approximating to certainty, with the result that, having taken such an observation and laid down his position line on the chart, he has then to draw two others eighty miles on either side, and his "sight" tells him that it is reasonably certain that the ship's position is somewhere on the 160-mile strip so drawn.

The above statement explains how it is that bubble sextants which have an accuracy of two or three minutes when used on shore, and perhaps ten or fifteen minutes when used on a cross-channel voyage where alternation of acceleration is more rapid, fail entirely when used in open sea. Nothing can possibly succeed there except a gravity controlled pendulum whose period of oscillation is considerably longer than the periodicity of the ship's acceleration, and the only practical form is some sort of gyrostat.

One such device has already been tried with a certain amount of success, Admiral Fleuriais' gyro sextant. The mechanism is complicated and need not be described in detail. The gyro is spun by an air blast from a pressure tank pumped up by hand. An optical arrangement produces in the field of view of the telescope a spot of light which is reflected from the case of the gyro. The speed and weight of the gyro are insufficiently great to give the requisite length of period, and although the probable error of a single observation is distinctly lower than 20-minute value of the bubble, it is still not low enough for the instrument to be of real practical utility.

There appears to be no reason why the master gyro compass should not be modified so as to give an approximately horizontal level that can be reproduced on the bridge by the repeater mechanism. A mirror attached to the repeater could then be used in a similar manner to the mercury trough used on shore.

§ (22) The Artificial Horizon.—When taking sights on shore with a sextant the angular measurement is made between the sun or star and its image in a trough of mercury. The latter has usually a surface of about 3 by 5 in., and is covered by a glass shade to protect it from being disturbed by the wind. The glass of the shade should be made with its faces accurately parallel, but owing to the difficulty of doing this it is customary to eliminate the error by taking two sets of observations, the shade being turned end for end between the two sets.

Disturbance of the mercury surface can be prevented by using a very shallow pool of it upon a flat copper plate which has been amalgamed and levelled. Surface tension in such case permits of the use of a pool less than a millimetre deep, and if the copper plate is amalgamed only on its upper surface there is no risk of the mercury running off.

This arrangement is also very suitable for cleaning the mercury, which can be done by passing a glass rod lightly over the surface, when all the impurities of the mercury are collected on the rod.

§ (23) The Azimuth Mirror.—In order that the navigator may be able to take bearings of distant objects on the horizon or of heavenly bodies, the standard compass is usually fitted with a special arrangement to enable him to do so. The earliest form of this consisted merely of a foresight and backsight that could be trained on the object. The reading of this direction on the compass card could be approximately accomplished at the same moment.

For bearings of the sun a vertical shadow pin was fitted over the centre of the card and the bearing of the shadow read directly.

An improvement of these two methods is the Kelvin azimuth circle, in which a reflecting surface, usually in the form of a prism, is mounted above the compass. This prism is capable of a rotating movement round a horizontal axis, which has to be turned in azimuth so that it is at right angles to the vertical plane through the centre of the compass and the object (terrestrial or celestial) that is being observed. By turning this prism round its axis to a suitable position light from the object is reflected to a direction making about sixty degrees upwards from the horizontal, and the image so seen can be made to appear to the observer to be close to the nearest edge of the prism. In *Fig.* 18 a

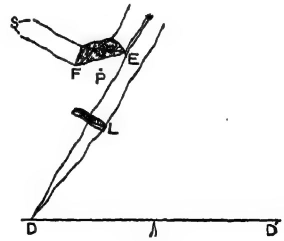

Fig. 18.

vertical section of the arrangement is shown, the plane of the paper being taken to be the vertical plane in which the object lies. The horizontal axis of rotation P is perpendicular to the plane of the paper. Light from the

body S is reflected in the face FE, and the observer can move his head into such a position that the object is seen close to the edge E. Below the prism is a lens L, whose axis also in the plane of the paper passes through the divisions D of the compass card DD′. The focal length of the lens is LD, so that the image of the divisions appears to the observer to be at infinity. Provided the focal length is also equal to the radius of the card, the angular breadth of a division as seen by him will be 1°. This is of importance, as otherwise two objects on the horizon 1° apart cannot be placed against two consecutive divisions of the card at the same time, and a sideways movement of the observer's eye will have a parallactic influence on the bearing as he reads it. Further, it is clear that for observations of objects on the horizon it is not essential that the object shall lie exactly in the plane through the centre of the compass at right angles to the axis of the mirror. For objects not on the horizon, however, the case is different. Two objects, each at altitude α and differing in bearing by 1°, are distant 1° cos α apart, and therefore cover this area on the image of the compass card. When one object appears on a division of the card the other will be at a distance 1° (1 - cos α) from the next division. In theory, therefore, it is necessary to turn the azimuth mirror round so that the object observed lies in the correct vertical plane. If the azimuth mirror is directed K° wrong in azimuth the error in reading will be K° (1 - cos α). The limitations of size of the mirror and lens make it impossible to see the object if K° exceeds 10°, and navigators, as a rule, are chary of trusting to bearings of heavenly bodies of greater altitudes than 30°, but, even so, there is a possibility of error of nearly $1\frac{1}{2}$° in the bearing. With an altitude of 45° this error is increased to 3°.

A further source of error at sea lies in the fact that when the ship is rolling or pitching neither the compass card nor the compass bowl, to which the mirror is fixed, is correctly horizontal, but is probably perpendicular to the false vertical of the moment. Azimuths are then being measured with reference not to the true vertical or horizontal but to the false, and the error made will be zero only when the false vertical is in the plane containing the object and the true vertical.

A second method of using the Kelvin mirror is available for objects on the horizon. This method involves the reflection of the card by the mirror, so that the observer has to look directly at the distant object and read its bearing against the divisions of the card as seen after transmission through the lens and reflection at the prism (*Fig.* 19).

A somewhat similar instrument is the Admiralty azimuth mirror used on the gyro-compass repeater. A vertical sectional view

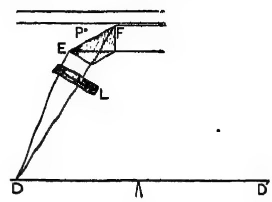

FIG. 19.

of this arrangement is shown in *Fig.* 20. The card is viewed through a lenticular prism A, two faces of which are plane while the third has a curve worked upon it. This prism becomes in effect a lens whose focal length is approximately the radius of the card, so that divisions of the card are projected to infinity

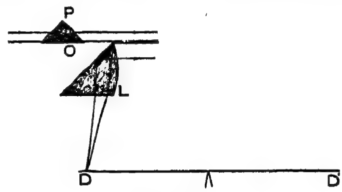

FIG. 20.

and two adjacent marks subtend 1° at the eye. Light from the sun or a star is reflected at the face EF of a prism capable of rotation about an axis perpendicular to the plane of the paper.

As in the Kelvin azimuth circle, errors arise in the case of bearings of objects not on the horizon, the amount of the error being exactly the same as before.

Various other types, similar in principle to the above, are also in use at sea. In all of them, in addition to the errors mentioned, there are defects in construction to be reckoned with which make the total error somewhat more complex than the expression K(1 - cos α) that has been considered. The full investigation of these errors is too long for it to be possible to make a detailed examination of them here.

The azimuth mirror is in constant use at sea for the purpose of obtaining the deviation of the compass when out of sight of land. A "time azimuth" observation is made, and the navigator calculates the true bearing that the sun or star had at the moment of his sight. To do this with absolute accuracy requires exact knowledge of his position on the surface of the globe, and this exact knowledge he seldom has; but, in general, his position is known to within a few miles, and the true

bearing can be calculated with a precision of a quarter of a degree. If this type of sight could always be made on Polaris or some star very close to the pole, whose bearing changed only slightly during twenty-four hours, very large errors could be allowed in his knowledge of his position without appreciably affecting the result of his calculation.

The true bearing being calculated, the observed bearing gives him the total compass error.

§ (24) Measurement of the Dip of the Sea Horizon.—All methods for the measurement of the depression of the visible horizon are based on the assumption that the amount is the same on all azimuths. Hence, if the angular distance is measured between two points on the sea horizon differing by 180° in azimuth, this angular distance will be in defect of 180° by twice the dip.

In *Fig.* 21 is shown the general optical plan of an instrument used specially for the

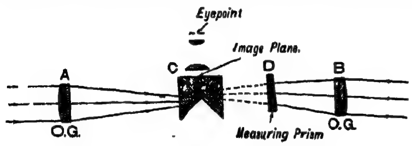

Fig. 21.

purpose. Two object glasses of equal focal lengths are placed at the right- and left-hand ends of the instrument. In the centre are two prisms C, cemented together, which reflect the light coming from the two object glasses upwards. The two object glasses have a common focal plane on the upper horizontal face of these two prisms, so that the cemented interface is seen as a dividing line of the field in sharp focus. A refracting prism P can be moved longitudinally between the right-hand OG and the central prisms, and its motion causes the images of the sea horizon to be displaced relatively to one another (see *Fig.* 22). The prism P can thus be adjusted so as to bring the two sea horizons into line, and the distance of P in front of the common focal plane is thus a measure of the dip. The instrument has to be made slightly more complicated, as with this arrangement it is not possible to measure down to zero depressions. A modification is made by interposing a fixed refracting prism between A and C, and by this means bringing the zero position of P to a point between C and B.

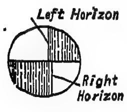

Fig. 22.

Another method of measurement of the dip is by means of a prism, designed by Lieutenant Blish of the U.S. Navy, which can be attached to the sextant, as shown in *Fig.* 23. If the two reflecting faces, A and B, are exactly at right angles to one another the image of the back horizon, as seen by way of the prism,

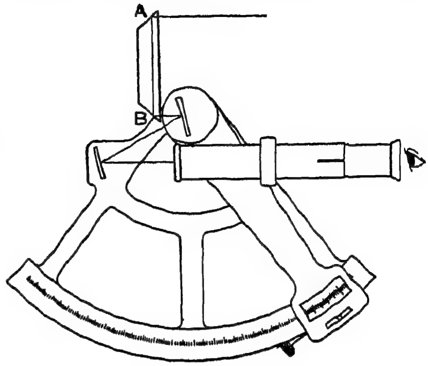

Fig. 23.

over the observer's head, is displaced 180°. The observer consequently sees two images of the sea horizon—one erect and the other inverted—which he can bring together by adjusting the index arm of the sextant. If there is no zero error of the sextant the sextant reading under such circumstances is twice the dip. In actual use this reading has to be corrected for zero error and for error of the prism from 90°.

§ (25) Methods of Directional Wireless Telegraphy.—During the European War the development of the detection of the direction of travel of wireless waves made very great advances.[1] Directional wireless stations were set up in various parts of the country, and by their means the direction in which a wave reached a station could be determined with an accuracy of the order of half a degree, even when the intensity of the wave was only very small. When two stations, say a hundred miles apart, picked up, directionally, the same wireless signal, a short comparison between the two observed bearings enabled the position of the sending station to be fixed with an accuracy of a mile or two, and a vessel at sea in doubts as to her position had only to send out a wireless signal for the shore stations to pick up and to communicate the position back to her.

In the earlier part of the war this method was used by Germany for the purpose of navigating her Zeppelins across the North Sea during their raids on England and Scotland; but ultimately the method was abandoned, as British stations, also picking up the signals, had a more accurate knowledge than Germany of an airship's position. British warships in the North Sea were in a similar situation in

[1] See "Wireless Telegraphy Apparatus," § (11), Vol. II.

respect of the German directional stations, and it soon became highly dangerous for a British ship to use wireless except in close proximity to our own coasts. Within fifty miles or so of our own stations, however, directional wireless had a very extensive use even in wartime, and ships were constantly given their position and guided into harbour in thick weather.

Owing to the danger, from a military standpoint, of the ship at sea sending out wireless signals, attempts were made to install a directional receiving apparatus on board, but not with complete success. The passage of the wave across the metallic structure of the ship produces a local disturbance in direction, so that the "wireless compass" has to reckon with a table of deviations more complex than those of the magnetic compass. In addition the effects of the electrical installations on board, being at very short range, may completely mask the reception of signals.

With aircraft greater success was obtained in the use of the directional wireless receiver, and towards the end of the war the larger machines were equipped with navigational apparatus that enabled them to fix their positions by "cross-bearings" of any stations that they were able to recognise.

Several forms of receiving apparatus were tried. In one of the earliest the receiver was merely a circular or rectangular coil in a vertical plane capable of orientation in azimuth. The maximum current is set up in such a coil when its plane lies in the direction in which the wave is travelling. By turning the coil until the noise in the telephone receiver connected with the coil has its maximum intensity the direction of the signal is determined. It is impossible, however, to do this with anything like sufficient accuracy. No difference in intensity can be noticed for quite 20° on either side of the maximum position.

When the plane of the coil is at right angles to the direction of travel of the wave the intensity is zero, but it is not possible to pick up this direction by trying for silence in the telephone receiver, as on account of the noise of the engines nothing at all can be heard over a considerable angular range.

Two coils were then tried, with planes both vertical and at right angles to one another, which formed a primary and a secondary circuit. Suitable switches made it possible to listen-in on one coil or on both. The primary was first directed as nearly as possible so as to lie in the plane of travel of the wave by listening for maximum intensity. If, in such a position, the current in the primary is A, and that in the secondary B, then by a suitable arrangement of switches the current A + B or A − B can be passed through the telephone receiver, and the ear has a much nicer discrimination of the difference in the two intensities than in the search for a maximum. It was found possible to pick up in this manner the direction with a precision of about half a degree under the best conditions.

In determining the actual direction in which the wave is received a magnetic compass is also needed. The bearing of the wave relative to the fore-and-aft line of the machine is read on a circular scale attached to the movable coils. This bearing requires correction for wireless deviation, which is approximately of the quadrantal type. The compass direction of the machine's head requires the ordinary corrections for magnetic deviation and variation. When flying directly towards or away from a station the magnetic compass is unnecessary, as the machine has only to be steered so that the main coil is in the fore-and-aft line when correctly receiving the bearing. This statement requires modification if the machine is making leeway. In such case, although the machine's head is always directed towards the station, her actual track will be of a spiral form, and she will ultimately reach the station coming up wind.

§ (26) Position Fixing by Directional Wireless.—When making a fix by cross-bearings of two visible objects, all that the navigator has to do is to draw through them on his chart straight lines in the requisite direction, and his position is their point of intersection. Visible distances do not exceed twenty miles as a general rule, and for that distance the effect of the earth's curvature is inappreciable. For wireless cross-bearing distances may go up to a thousand miles, and for such ranges the curvature effect is considerable.

Different means of taking account of this curvature effect have to be adopted according as whether the directional receiving apparatus is in two fixed shore stations or in the ship or aeroplane. In the former case the simple method is to plot the bearings on a gnomonic chart upon which great circles are represented by straight lines. A special "rose" has to be constructed round each station, as in such a chart, except at the centre, angles are not the same as those measured on the earth's surface. As wireless waves travel, in general, on great circles upon the earth's surface, the two straight lines drawn through the two stations to correspond with the two received bearings intersect in the position of the ship.

In the case of directional reception by the ship the problem is more complicated. Let B (see *Fig.* 24) be the position of the sending station and C that of the ship. Ordinarily the latter will be using charts constructed on a Mercator projection so that the great-circle track of the wireless wave will be BGC, a

curve which is hollow on the side towards the equator.

The straight line BRC is the rhumb-line track from B to C.

It will be seen from the figure that the direction at which the wireless wave starts, viz. TBN with the meridian, differs from the direction at which it arrives at C (T′CS with the meridian), which is the direction that C receives, this difference being the sum of the two angles TBR and T′CR.

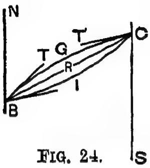

FIG. 24.

For ranges not exceeding 500 miles the Mercator projection of a great circle may be considered to be of constant curvature along its length, so that the two angles TBR and T′CR are equal and of a value which may be shown to be approximately ½ diff. long. × sin mid-lat.

The ship's navigator usually knows his position within thirty or forty miles, so that the difference of longitude between B and C is known to less than a degree. Hence it is possible to estimate to within a degree the value of the "conversion angle" T′CB that will alter the great-circle bearing that he receives to the rhumb-line bearing that he can plot. In this manner he is able to fix his position upon the Mercator chart.

Strictly speaking, having constructed the rhumb line, the navigator is not entitled to assume that his position is somewhere upon it. The *locus* of all points on the earth's surface for which B has the same true bearing is a curve whose shape is more or less that shown by BIC. Within the ranges under consideration this isoazimuthal (or isaz) curve has the same curvature as the great circle, but moves in the opposite sense, so that BGC and BIC are reflections of one another in the rhumb line.

The navigator's position line is consequently not a piece of the great circle CG, nor of the rhumb line CR, but of the isaz CI. For all practical purposes, and within the limits of accuracy with which bearings can be taken, the rhumb line is good enough. For distances over 500 miles and up to 1000 miles the curvatures of the great circle and the isaz curves can no longer be looked upon as constant along their length, and a second-order correction is necessary dependent upon the square of the range.

In addition to errors in directional wireless bearings due to lack of sensitivity of the receiving apparatus, to quadrantal deviation due to the structure of the ship or aeroplane, errors arise from a species of refraction effect when the track of the wave runs more or less along a coast line. No very precise statement can be made as to the amount of this effect, but as a general rule there appears to be a drag on that part of the wave which passes over the land as compared with that part which passes over the water. It would be anticipated, for instance, that a wireless bearing of Poldhu in Cornwall, taken from a position near Dover, would come in from a direction more south than it ought to be. At the same time it is difficult to dogmatise on the point, as possibly intervening land, like the Isle of Wight, might alter the effect completely.

This refractive effect has often been noted, and has usually been found to be more marked at ground level than up in the air. On Salisbury Plain, for example, bearings of Stonehaven taken from the ground are ordinarily about 2° in error. From an aeroplane at 2000 feet the error has almost disappeared.

In addition to errors resulting from the configuration of the land, serious atmospheric effects have to be reckoned with. Their causes are extremely obscure, and a great deal of observation and investigation is still necessary before the navigator can make any allowance for them. At times there appear to be definite tracks of the atmosphere, sometimes in the form of long lanes extending for considerable distances, along which wireless waves travel with greater ease than in any other direction. At times of sunset and sunrise very serious deviations occur, errors of 20° in direction being of common occurrence.

Such disturbances are far more serious than lack of sensitivity of the receiving apparatus, and probably it will not be for some years that the causes will have been sufficiently investigated for the method of directional wireless bearings to be completely sufficient for a ship on a long ocean voyage. Apart from this question, and apart from the quadrantal deviation produced by the metallic structure and the unscreened electrical gear on board, it would seem that the sensitivity of the receiving apparatus has already advanced to the point that the probable error of a single observation is of the order of half a degree, and that a ship fixing her position by cross-bearings of three stations each 500 miles distant can do so with a certainty of being upon a circle of some four or five miles radius.

OBJECTIVES, THE TESTING OF COMPOUND

The compound optical systems known as "objectives" may be divided into three main classes, namely, telescope objectives, photographic objectives (or camera lenses), and microscope objectives. The methods of testing their optical constants and general optical performance vary considerably in these three classes, but such variations are to a large extent due to differences in the dimensions (aperture, focal length, etc.) of the objectives. Although the present article is mainly concerned with the first class, namely, telescope objectives, a number of the methods of test to be described will be found applicable to one or both of the other two classes.[1]

The optical performance of any given compound system may be computed by means of theoretical methods if all the optical data of the system are known to a high degree of accuracy.[2]

It is not, however, usually convenient to separate an objective into its components and measure their constants. In the case of an objective in which one or more of the surfaces are locally figured it would be practically impossible to determine its general performance by dissecting it, because it would be difficult, for example, to measure the variations in

[1] For more detailed treatments of these classes see articles on "Camera Lenses, The Testing of," and "Microscope, Theory of the."

[2] For methods of measuring the optical constants of the components of a compound system, such as curvatures and refractive indices, see articles on "Spherometry," "Spectroscopes and Refractometers," and "Immersion Refractometry."

curvature of its surfaces, and even if these could be obtained, the theoretical computation would be very complicated. As a general rule, therefore, it is necessary to employ methods whereby an objective may be tested as a unit.

The chief optical data to be determined in the case of telescope objectives are (1) focal length, (2) aberrations, and (3) general definition.

§ (1) FOCAL LENGTH MEASUREMENT THEORY.—A great number of different methods of measuring the focal lengths of compound lenses have been devised; some of these can only be used in particular cases, while others are of more general application. All the methods are based on the properties of the focal planes, unit planes, nodal points, and conjugate points of an optical system. The fundamental definitions and relations,[1] proofs of which may be found in any text-book on Geometrical Optics, may be summarised as follows. A brief account of them is given in the article on "Lenses, Theory of Simple."

(a) A lens is a portion of a refracting medium bounded usually by parts of two spherical surfaces. The axis of the lens is the line joining the centre of these surfaces.

(b) *Principal Foci.*—There are two points on the axis of a lens known as principal foci, the one in the image and the other in the object space, which possess the properties that

(i.) Rays of light incident on the lens parallel to its axis pass after refraction through a principal focus;

(ii.) Rays of light diverging from a principal focus in the case of a convex lens, or converging to it in the case of a concave lens, are refracted so as to become parallel to the axis.

(c) *Conjugate Points and Planes.*—Conjugate points are two points on the axis such that the image of a small object at the one is formed at the other.

Conjugate planes are planes at right angles to the axis through the conjugate points.

(d) *Unit Points and Planes.*—The unit points are two conjugate points for which the magnification produced by the lens is unity.

The unit planes are planes at right angles to the axis through the unit points.

Thus the image of any point in one unit plane lies in the second unit plane, and the line joining the point and its image is parallel to the axis.

Unit planes are thus planes of unit magnification.

(e) *Nodal Points and Planes.*—The nodal points are two points on the axis such that a ray through the one nodal point, after refraction through the lens, passes through the second nodal point, and is parallel in direction to the incident ray.

The nodal planes are planes at right angles to the axis through the nodal points.

(f) *Principal Points.*—If the media on the two sides of the lens, in the object and image space respectively, be the same, the Unit and Nodal Points coincide, and are known as the Principal Points. (They were introduced by Gauss, who was the first to place on a firm foundation the consideration of lenses and consequently of lens systems.)

The Unit and Nodal Planes similarly become Principal Planes.

(g) The first and second focal lengths, usually denoted by f and f', are the distances between the focal planes and the unit planes in the object and image spaces respectively. If the first and final media are the same, $f=f'$. The cases in which the first and final media are air, are most commonly met with, a notable exception being that of microscope immersion objectives.

(h) If the sizes of an object (normal to the optical axis) and its image are y, y', and the angles which the object and image subtend at the corresponding foci are θ, θ' respectively, then

$$f=\frac{y'}{\tan\theta} \text{ and } f'=\frac{y}{\tan\theta'}. \quad . \quad . \quad (1)$$

(i) If the distances of an object and its image from the corresponding foci are x, x' respectively, and the magnification y'/y be denoted by m, then

$$x=\frac{1}{m}f \text{ and } x'=-mf', \quad . \quad . \quad (2)$$

where the sign notation is the same as is used in the usual system of co-ordinates.[2] From (2) it follows that

$$xx'=-ff',$$

or, in systems where the first and final media are the same,

$$xx'=-f^2. \quad . \quad . \quad . \quad (3)$$

In applying these relations to the practical determination of focal length it is of the utmost importance to be able to find the positions[3] of image planes as accurately as possible. For very rough measurements it is often sufficient to form the image on a piece of ground glass and to estimate its correct position by means of the naked eye. For most purposes, however, it is essential to adopt more refined methods. It is usual to employ a microscope of convenient power for focussing on an image; the power which one chooses depends, of course, on the nature of the object used, the kind of optical system under test, and the accuracy with which the position of the image plane requires to be determined. In the case of certain optical systems there

[1] See also "Optical Calculations,"

[2] In the general case the two focal lengths are assumed to be of the same sign.

[3] For details as to the methods of making some of these measurements, see "Lenses, Testing of Simple."

is a considerable depth of focus and it is sometimes very difficult to focus accurately on the image. In order to eliminate errors due to the range of accommodation of the eye it is advisable, when using a microscope, to employ a Ramsden eye-piece and to place cross-wires or a graduated scale at its focal plane. In the case of a low-power eye-piece, or in making naked-eye observations, the position of focus may be determined by moving a system of cross-wires until no relative displacement between the image and the cross-wires can be detected on moving one's eye from side to side across the field. The position of focus may also be found by covering the aperture of the system under test in such a way that light can only pass through two portions[1] at opposite ends of a diameter. Then two images will be observed unless the microscope is correctly focussed on the image plane. In this case it is assumed that the system is free from spherical aberration. A somewhat similar method, due to Hartmann,[2] is to allow two narrow excentric pencils of light to pass through the system and to measure the distances d_1, d_2 between the centres of the diffusion circles in two planes at some distance on either side of the image plane. If the distances D_1, D_2 of these planes from some arbitrary point are also measured, the distance D of the image plane from that point is given by the relation

$$\frac{d_1}{d_2}=\frac{D-D_1}{D_2-D} \text{ or } \frac{D-D_1}{D_2-D_1}=\frac{d_1}{d_1+d_2},$$

that is,

$$D=D_1+\frac{d_1}{d_1+d_2}(D_2-D_1). \quad . \quad . \quad (4)$$

Another accurate method of determining the position of the image plane of a system was devised by Foucault;[3] in this case an observing microscope is not used. A small illuminated pin-hole is employed as the object and the eye is placed in approximately the position of the image. When a suitable screen, for example a diaphragm with a sharp knife-edge, is moved in front of the eye in a direction normal to the optical axis, the aperture of the system will darken suddenly and uniformly *only* if the screen is in the plane of the image.

In making focal length measurements it is necessary to choose convenient objects; in the case where magnification methods are used the finely divided scales, engraved on glass discs, which are sold by microscope makers are found to be extremely useful. In order to determine the magnification of the observing microscope it is essential to use one of these scales in the focal plane of the eye-piece. For methods which depend on focussing, the most convenient objects are plates of silvered or platinised glass having fine scratches or rulings on the metallic deposit.[4]

§ (2) Focal Length Measurement Experiments. — The chief methods of focal length determination may now be considered in detail. In all cases it will be assumed that the first and final media are air, so that the first and second focal lengths are equal.

(i.) *Methods depending on the Use of Parallel Light.*—(*a*) The position of the second focal plane of an optical system may be found by using an object which is so far away that the rays which come from it may be considered parallel. The sun or a star may be taken as infinitely distant, but it is not always convenient to use such an object. For most purposes it is sufficiently accurate to make use of a terrestrial object, such as a distant church steeple; if the system under test has a long focal length it may be necessary to make a correction for the finite distance of the object.[5]

It is more usual, however, to make use of a collimator in order to obtain parallel light, a suitable object being placed accurately at the focus of the collimator. The image plane of the system is then determined by focussing the observing microscope on the image of this object. This process may be reversed by moving an object, placed in the neighbourhood of the focal plane of the system, until its image coincides with the focal plane of an observing telescope which has been previously focussed for infinity. Another alternative is to make use of an auto-collimating method; a simple way in which this may be applied is illustrated diagrammatically in *Fig.* 1. One half of a scale S (preferably ruled on silvered or platinised glass) is illuminated from the side by a lamp L with the aid of a small right-angle prism P. If the scale is in the focal plane of the objective O, the image of the

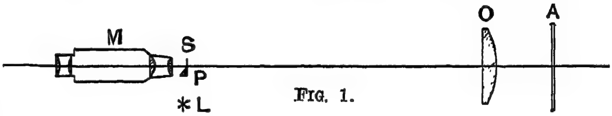

Fig. 1.

[1] The sizes of these portions should be chosen sufficiently large to prevent the definition being spoiled by diffraction effects.

[4] Cf. the Abbe test plate, for a description of which see *Microscopy*, by E. J. Spitta.

[5] If f is the focal length and v is the distance between the second nodal point and the image plane, the object being at a distance u from the system, then

$$v-f=\frac{f^2}{u}$$

provided that the difference $v-f$ is small.

illuminated portion, formed by light which is reflected back from an optically plane surface A placed normal to the axis, will coincide with the image of the other portion of the scale as seen in the observing microscope M.

These methods only serve to determine the position of the second focal plane and the back focal length (the distance between the last surface and the focal plane) of the system. In order to obtain the focal length one may employ two methods. The first is a direct one; the objective is mounted in such a way that it can be rotated about a fixed axis normal to the optical axis. The whole system is then moved along the optical axis until there is no lateral displacement of the image of a distant object when the objective is rotated about the normal axis. When this is the case, the normal axis passes through a point, called the nul point, which divides the distance between the nodal points into parts whose ratio is equal to the lateral magnification. If the incident light is parallel, the nul point coincides with the second nodal point; the focal length is then given by the distance between the normal axis and the focal plane. The principle of this method is made use of in the testing of camera lenses on the Beck bench.[1]

The second method is an indirect one and depends on the fact that the ratio of the back focal length to the focal length is equal to the ratio of the size of a mark placed on the last surface to the size of its image. This relation follows from equation (2) above, for if f_b is the back focal length, the equation

$$x' = -mf \text{ reduces to } \frac{f_b}{f} = m = \frac{y'}{y},$$

where y' is the size of the mark and y the size of its image. It is sufficient, therefore, to measure the dimensions of the mark as seen direct and through the system. The focal length can then be found if the back focal length is known.

A simple method of measuring the focal length of a photographic lens which can be divided into two parts, each capable of producing a real image of a distant object, is as follows.[2] Let f, f' be the focal lengths of the two components and F that of the complete lens. An image of a distant object is focussed on the ground-glass screen of the camera for four different cases: (1) the complete lens placed normally in the camera, (2) the front component removed, (3) the complete lens reversed in camera, and (4) the component now at the front removed. If d is the distance between the positions of the screen for (1) and (2) and d' the distance between the positions for (3) and (4), then

$$d = \frac{fF}{f'} \text{ and } d' = \frac{f'F}{f}.$$

Hence $\quad F = \sqrt{dd'}$, also $\dfrac{f}{f'} = \sqrt{\dfrac{d}{d'}}$.

These relations follow from the fact that the positions in which the images are formed by the separate components are conjugate foci for the complete lens, namely, that pair of conjugate foci for which the beam of light between the two components is parallel.

(*b*) A method of finding the focal length of a system follows at once from equation (1) above, for according to this equation the focal length is equal to the size of the image (in the second focal plane) of an object at infinity divided by the tangent of the angle subtended by the object at the first focal point. The focal length may thus be obtained by measuring the size of the image and the apparent angular size of the object. The reverse process may also be employed; in this case the apparent angular size of the image of an object of known length, placed in the focal plane, is measured. This method is applicable to telescope, camera, and microscope objectives. In the case of short focus objectives an object of known length y at a finite distance D may be used; the focal length f is then given by

$$f = \frac{y'}{y/D} = \frac{y'}{y}D,$$

where y' is the length of the image. This method can conveniently be carried out on an ordinary microscope supplied with a graduated scale in the focal plane of the eye-piece.

(ii.) *Methods depending on the Properties of Conjugate Points.*—When the positions of the first and second foci of an objective are not known, the focal length may be determined by finding the positions of a number of pairs of axial conjugate points.

(*a*) If the distances of conjugate points P, P′ (*Fig.* 2) from some fixed point Q, such as a mark on the mount of the objective O, are denoted by ξ, ξ', and the distances of Q from the foci are denoted by η, η' respectively, it follows from equation (3) above that

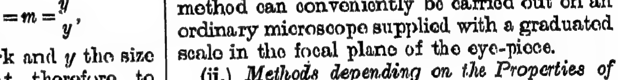

Fig. 2.

$$xx' = (\xi - \eta)(\xi' - \eta') = -f^2.$$

Now this equation contains three unknowns,

[1] See article on "Camera Lenses, The Testing of."
[2] T. Smith, *Phys. Soc. Proc.*, 1915, xxvii. 171.

η, η' and f. Thus the focal length, and the positions of the foci, may be found by measuring the distances ξ_1, ξ_1'; ξ_2, ξ_2'; ξ_3, ξ_3' of three pairs of conjugate points from a fixed point.

(*b*) If N, N′ are the nodal points of the objective,

$$\eta' - \eta = 2f + d,$$

where $d = \mathrm{NN}'$. Thus in cases where d is known or may be neglected it is sufficient to determine the distances ξ_1, ξ_1'; ξ_2, ξ_2' of two pairs of conjugate points. This method is most easily carried out by keeping the positions of the object and image planes fixed and moving O along the axis into the two positions for which the image falls in the latter plane. The distances of object and image from Q are then measured for the two positions, Q being kept fixed relatively to O.

(*c*) The distance D between conjugate points is given by

$$\mathrm{D} = -x + x' + 2f + d.$$

Now it follows from the equation $xx' = -f^2$ that $-x + x'$ is stationary when $-x = x' = \pm f$. The negative sign gives the two nodal points, while the positive sign gives two points on the opposite sides of the foci from the nodal points and at distances from the foci equal to f. In this case

$$\mathrm{D} = 4f + d.$$

Thus if d is known or may be neglected, the focal length may be found by moving the objective until the distance between object and image is a minimum.

It may be noted that in method (ii.) (*a*) the focal length may be found by measuring ξ, ξ' for one pair of conjugate points if the positions of the foci F, F′ are known, that is, if η, η' are known. A knowledge of f then enables one to determine the distance d between the nodal points by means of methods (ii.) (*b*) or (*c*).

The methods in group (ii.) can be carried out most conveniently on an optical bench. They are specially applicable to objectives of medium focal length. The chief objection to employing them in the case of long focus objectives is the great length of space required, the minimum distance between conjugate points being, as we have seen, approximately four times the focal length.

(iii.) *Magnification Methods.*—There are a number of methods of determining focal length which depend on the measurement of the lateral magnification. The most important of these are as follows.

(*a*) The magnification is measured for two positions of the object, the system under test being kept fixed. Then, if x_1, x_2 are the distances of the object from the first principal focal plane and m_1, m_2 are the magnifications for the two positions, it follows from equation (2) above that

$$x_1 = \frac{1}{m_1} f, \quad x_2 = \frac{1}{m_2} f.$$

Thus $$f = \frac{x_1 - x_2}{1/m_1 - 1/m_2}.$$

It is only necessary, therefore, to measure the distance $x_1 - x_2$ through which the object has been moved, in addition to the magnifications. The focal length may also be found by keeping the system fixed, moving the image plane a distance $x_1' - x_2'$, and measuring the corresponding magnifications. In this case

$$x_1' = -m_1 f, \quad x_2' = -m_2 f.$$

Thus $$f = \frac{x_1' - x_2'}{m_2 - m_1}.$$

A simple direct reading method based on this relation can be employed in finding the focal length of a camera lens. The image of a very distant object is focussed on the ground-glass screen of the camera and the screen is then racked back through a distance d until the image of a scale, mounted near the lens in a plane at right angles to the optical axis, is focussed on it. The length of the portion of the scale, whose image lies between two marks separated by a distance d on the screen, is then the focal length of the lens.

(*b*) The distance ξ_1 of the object from a fixed point Q (*Fig.* 2) on the objective is measured and the objective is then reversed and moved along the optical axis until the same magnification is obtained, the object and image planes being thus interchanged. The distance of the original object from Q is now measured. Since the positions of F and F′ are interchanged owing to the reversal of the system, it follows that

$$\xi_1 = -\mathrm{D} + x' + \eta', \quad \xi_2 = x - \eta'.$$

Therefore

$$\xi_1 + \xi_2 = -\mathrm{D} + x + x' = -\mathrm{D} + \frac{1}{m} f - mf$$

or $$f = -\frac{\mathrm{D} + (\xi_1 + \xi_2)}{m - 1/m}.$$

If, in the second position of the system, the distance ξ_2' of the original image plane from Q is measured, then

$$f = -\frac{\xi_1 + \xi_2'}{m - 1/m}.$$

(*c*) The magnifications m_1 and m_2 are measured for two values D_1 and D_2 of the distance between the object and image planes. If, for example, the distance is increased by an amount d, we have

$$\mathrm{D}_2 - \mathrm{D}_1 = d = (-x_2 + x_2') - (-x_1 + x_1'),$$

since $D=-x+x'+FF'$ and FF' remains constant. Thus

$$d=\left(-\frac{1}{m_2}f-m_2f\right)-\left(-\frac{1}{m_1}f-m_1f\right)$$

$$=f\left\{(m_1-m_2)+\left(\frac{1}{m_1}-\frac{1}{m_2}\right)\right\}$$

or
$$f=\frac{dm_1m_2}{(m_1-m_2)(m_1m_2-1)}.$$

(*d*) The system is kept fixed and the positions of the image are determined for which the magnifications are -1, -2, -3, etc. The corresponding distances of the images from the second focal plane are then given by

$$x_1'=f,\quad x_2'=2f,\ x_3'=3f,\ \text{etc}$$

Thus the image has to be moved through a distance equal to the focal length in passing from one magnification to the next. Similarly the distances of the object from the first focal plane, corresponding to the magnifications -1, $-\frac{1}{2}$, $-\frac{1}{3}$, etc., in the image plane, are given by $x_1=-f$, $x_2=-2f$, $x_3=-3f$, etc. In this case, therefore, the object is moved through a distance equal to the focal length in passing from one magnification to the next.

It is most convenient to make use of an optical bench in connection with the methods of group (iii.). The methods, like those of group (ii.), are especially applicable to the case of objectives of medium focal length.

(iv.) *Methods applicable to the Measurement of Short Focal Lengths.*—There are two simple microscope methods which can be used in the case of microscope objectives and eye-pieces; they really come under the previous groups, but may for convenience be dealt with separately.

(*a*) A short focus collimator, having a suitable scale in its focal plane, is fitted under the stage of a microscope, and the objective or eye-piece under test is placed on the stage with its axis collinear with the collimator and microscope axes. The microscope, fitted with a micrometer eye-piece, is then focussed on the image of the collimator scale. If f_1, f_2, f_3 are the focal lengths of the collimator objective, the system under test, and the microscope objective respectively, the magnification observed in the lower focal plane of the micrometer eye-piece is given by

$$\frac{f_2}{f_1}\cdot\frac{\Delta}{f_3},$$

where Δ is the distance between the upper focal plane of the microscope objective and the micrometer scale. The method may be made a direct reading one by choosing the values of f_1, f_3, and Δ, so that $\Delta=f_1f_3$. The magnification observed is then numerically equal to the focal length of the system under test.

(*b*) The objective or eye-piece to be tested is fitted to the end of a microscope tube and a suitable scale is placed on the microscope stage. The magnifications of the scale are then measured for two different tube-lengths by means of a micrometer scale in the eye-piece. The focal length of the system is then given by the difference of the tube-lengths divided by the difference of the magnifications. This follows at once from the relation

$$f=\frac{x_1'-x_2'}{m_2-m_1}.$$

The Abbe focometer[1] is an instrument which is specially designed for carrying out such tests.

§ (3) Measurement of Aberrations.—In designing compound objectives it is not possible to obtain systems which are perfectly corrected; there are always certain amounts of residual aberrations present. In a well-corrected system these are usually very small, so that it is necessary to employ very sensitive methods for measuring them. The chief quantities which require to be determined are spherical and chromatic aberrations, coma, distortion, and curvature of field. In the case of telescope objectives it is mainly the first two which are of primary importance; the measurement of the other quantities is dealt with in the article on "Camera Lenses, The Testing of."

Practically all the methods of measuring the aberrations of an objective depend on the use of an accurately parallel beam of light. If a collimator is employed for this purpose it is necessary that the collimator objective itself should be as free from aberrations as possible, otherwise the results will be vitiated. It is usual, therefore, to employ a well-corrected collimator objective of larger aperture than that of the objective under test. This, however, is not always possible, especially when it is necessary to test large aperture lenses; in such cases one or other of the following methods may be used.

(*a*) When one is dealing with an astronomical telescope objective, it may be fitted on a telescope mount and the measurements made with a star as the object. This gets rid of the necessity of using a collimator, but the method can only be used where special equipment is available.

(*b*) If the objective has not a very long focal length, an illuminated pin-hole mounted at a considerable distance may be used as the object. In this case, however, only approximate values of the aberrations can be obtained owing to the fact that one is not dealing with strictly parallel light, the process of introducing corrections for the finite distance of the object being rather laborious.

[1] S. Czapski, *Zeits. Instrumentenk.*, 1892, xii. 185; see also C. v. Hofe, *Zeits. Techn. Phys.*, 1920, i. 191.

(*c*) Where an objective of similar construction to that of the one under test is available, it may be used as a collimator objective. Then, if the aberrations of each objective are of the same sign and of about the same dimensions, the values of the measured aberrations will be approximately double those of each objective taken separately.

(*d*) If two additional objectives of similar dimensions are available, the three objectives may be tested in pairs, each one in turn serving as the collimator objective. The aberrations of each may then be deduced from the measured aberrations of the combinations, even if the former differ considerably in the three cases.

(*e*) In the case of large objectives, when a suitable collimator objective is not available, a convenient method is one which is now being used at the Reichsanstalt.[1]

The principle of the method is illustrated in *Fig.* 3, which represents a horizontal section of the arrangement. A well-corrected collimator objective C of relatively small aperture, having an illuminated pin-hole S at its focus, is set up with its axis in the plane of, and at right angles to, the axis of the objective O which is to be tested. A good quality pentagonal prism P is mounted on a slide in front of the collimator objective so that it can be moved along the collimator axis across a diameter of the objective O into positions such as P′, P″. Since the direction of the rays which emerge from P is not altered by a slight rotation of the prism about a vertical axis, the rays will be parallel to the objective axis in all positions. Any tilt of the prism about a horizontal axis may be prevented by using a level on the top of the prism and adjusting the prism, if necessary, in its different positions. The method allows one to determine the position of focus for different portions of the aperture. If it is necessary to measure the aberrations along different diameters, the objective may be mounted so that it can be rotated about its axis.

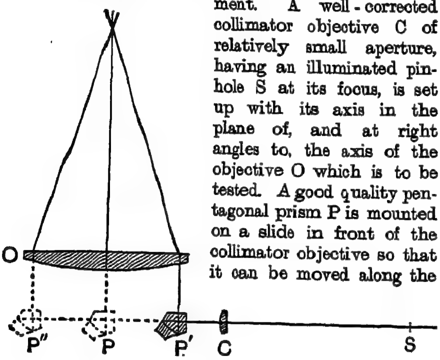

FIG. 3.

(*f*) An auto-collimating method (cf. *Fig.* 1) may be employed, if a sufficiently large optically plane surface is available. This has the advantage of double sensitivity, but for very accurate work the mirror surface used must be plane to a high degree of accuracy.

There are three main methods of measuring the aberrations of an objective. In considering these it will be assumed, as already indicated, that a well-corrected collimator objective of larger aperture than that of the objective under test is employed, though any of the above-mentioned devices may be used instead.

[1] *Zeits. Instrumentenk.*, 1920, xl. 96.

(i.) *Microscope Method.*—The objective, the collimator, and a suitable observing microscope are set up in such a way that their optical axes are collinear, the microscope being placed behind the focal plane of the objective and mounted on a slide so that it can be moved along the axis of the system. A minute pin-hole[2] is fixed at the focus of the collimator objective and is illuminated by a strong source of light. The image of the pin-hole which is formed in the focal plane of the objective consists of a bright circular disc surrounded by a series of concentric diffraction rings. The relative number of rings and the colour visible in planes at small equal distances inside and outside the focus give a qualitative estimate of the spherical and chromatic corrections of the objective.[3] In order, however, to determine these aberrations quantitatively, it is necessary to find the positions of best focus of the central disc when different zones of the objective and different wave-lengths of light are used. For spherical aberration determinations the aperture of the objective should be divided into about 4 or 5 concentric zones of equal area, and a series of opaque stops made of such sizes and shapes that each one only allows light to pass through one of these zones. If the slide, on which the microscope is mounted, is provided with a scale and vernier, or, preferably, an accurate micrometer motion, the axial differences of focus for the different zones can be measured.

In order to measure the chromatic aberration a similar procedure is adopted, colour filters being placed, one at a time, between the pin-hole and the source of light or between the eye-piece of the microscope and the observer's eye. The positions of the microscope, for which the image of the pin-hole is focussed for each of the filters, then enable one to determine the positions of the foci for different colours and hence the chromatic correction of the objective. It is advisable to choose colour filters which are approximately monochromatic and to determine the predominant wave-length transmitted by each. A series of Kodak colour filters, giving about 5 wave-lengths fairly evenly spaced along the spectrum between red and violet, is found very suitable. For very accurate work, however, colour filters may be dispensed with and a monochromatic illuminator placed between the source of light and the collimator pin-hole. In this way monochromatic light of any given wave-length may be employed.

The chromatic differences of spherical

[2] A brightly illuminated small bicycle ball forms a very good substitute for an illuminated pin-hole. In some cases it is preferable to employ fine cross lines or a suitable scale.

[3] See *The Adjustment and Testing of Telescopic Objectives*, by Messrs. T. Cooke & Sons, Ltd., of York.

aberration may be determined by placing concentric stops in front of the objective and measuring the positions of focus for the different zones and the different wave-lengths.

(ii.) *Shadow Method.*—This method, to which reference has already been made in dealing with the methods of finding position of focus, was introduced by Foucault [1] in connection with the figuring of optical surfaces. In order to apply it to the measurement of aberrations a narrow illuminated slit is placed in the focal plane of the collimator objective and a diaphragm with a straight edge is mounted behind the objective under test. The diaphragm is adjusted until its edge is parallel to the slit, the plane of the diaphragm being normal to the axis. If the aperture is covered except for one particular zone, and the observer's eye is placed near the focus of the objective, this zone will be seen illuminated. If, now, the diaphragm is moved across the optical axis in front of the observer's eye, the zone becomes darkened gradually, unless the diaphragm is in the focal plane corresponding to the zone, in which case it becomes darkened suddenly and uniformly. Thus by a method of trial the positions of focus for different zones and different wave-lengths may be found. From these the spherical and chromatic aberrations of the objective may be deduced.

The writer has employed a more symmetrical way of applying the shadow method to the testing of objectives. A small illuminated pin-hole is fixed at the focus of the collimator objective and, instead of the diaphragm with the straight edge, a small opaque circular disc on a glass plate is used. It is convenient to employ a small point image on a photographic plate, its size being approximately that of the diffraction image of the illuminated pin-hole. By means of this arrangement it is possible to find the three co-ordinates of the focus for any zone or to combine the shadow method with the following method (Hartmann's) by measuring the co-ordinates of the points where the pencil of rays from any given region of the objective aperture cuts two planes, one inside and the other outside the focus; in this latter case the plate with the opaque point must be mounted on a mechanism capable of recording measurements in three mutually perpendicular directions.

Methods (i.) and (ii.) are, of course, only applicable to the case of visual measurements. Where it is necessary to determine the aberrations of an objective designed for photographic work, the chromatic corrections being made for wave-lengths in the actinic region of the spectrum, the following method is practically the only one that can be employed; it can be used in the case of any large aperture objective.

[1] L. Foucault, *Ann. de l'Observatoire de Paris*, 1859, v. 197; *Recueil des travaux scientif.* Paris, 1878, p. 232.

(iii.) *Hartmann's Method.*—In this method [2] the positions of the foci for different zones of the objective are determined indirectly. An illuminated pin-hole is mounted axially in the focal plane of the collimator objective, and an opaque diaphragm, containing a number of circular holes arranged in concentric rings, is placed symmetrically in front of the objective. A photographic plate is mounted at right angles to the optical axis in a plane at some distance outside the focus and an exposure made. The plate holder is then moved to a position inside the focus and another plate exposed. Thus records are obtained of the diffusion circles in which the narrow pencils of light, passing through the holes in the diaphragm, meet the two planes in which the plates were placed. The co-ordinates of the centres of these diffusion circles can then be obtained by measuring the plates,[3] and if the distances of the two planes from some fixed arbitrary point have been carefully measured, the positions of the foci, relative to that point, for different zones may be deduced from the relation (4) given above. Chromatic aberrations may be obtained by making a series of measurements with light of different wave-lengths.

If carefully carried out, this method is a very accurate one, but it suffers from the disadvantage that a considerable amount of time is required in order to complete a series of measurements.

In addition to the above methods the aberrations of an objective may be measured by means of interferometry.[4]

§ (4) Determination of General Definition.—The general definition given by an objective depends on the degree to which the system is corrected for the various aberrations. It is difficult, however, to deduce from measurements of the residual aberrations how good the definition will be, for, generally speaking, there are no data available which give the maximum amounts of the different aberrations that may be present without spoiling the definition. A good idea of the definition may, however, be obtained by placing a suitable test object (a fine graduated scale or a microscopic test object may conveniently be employed) at the focus of the collimator objective and examining its image in the focal plane of the objective under test by means of a microscope. As definition is partly a subjective quality, it is always advisable to compare the definition of any

[2] J. Hartmann, *Zeits. Instrumentenk.*, 1900, xx. 51.

[3] Instead of making photographic records the co-ordinates may be determined by means of direct visual observations.

[4] See article on "Interferometers: Technical Applications"; also E. Waetzmann, *Ann. d. Physik.*, 1912, xxxix. 1042; F. Twyman, *Brit. Journ. of Phot.*, 1918, lxv. 556, 567.

given objective with that of a similar objective whose general optical performance is known. The definition of a telescope objective may also be tested by an examination of the extrafocal diffraction images of a distant point source.[1] The resolving power may be determined by observations on double stars.

OPHTHALMIC DYNAMOMETER, LANDOLT'S: an ophthalmic instrument for determining the maximum of convergence of a subject's eyes. See "Ophthalmic Optical Apparatus," § (3).

OPHTHALMIC OPTICAL APPARATUS

§ (1).—Until the introduction of cylindrical lenses for spectacle use, ophthalmic optical apparatus was of the crudest, and consisted mainly of sets of pairs of spherical lenses fitted into horn frames known as "triers." With cylindrical lenses and the necessity for rotation of the lenses, came the full trial-case, the ophthalmoscope, ophthalmometer, and retinoscope.

Ophthalmic instruments may be divided roughly into a subjective class, where the results are obtained from the answers of the subject or patient relating his impressions of what he actually sees by means of the instrument, and into an objective class, where results are arrived at by deductions being made from what is seen by the observer in or of the eye of the patient without reference to any questioning of the patient.

§ (2) SUBJECTIVE INSTRUMENTS.—Among subjective instruments we can include:

Phorometers for testing and exercising the strength, deviation, and direction of the external ocular muscles.

Perimeters and scotometers for plotting and measuring the field of vision.

Photometers for light perception.

Chromo-optometers for colour perception.

Ophthalmic lenses.

Test-cases of trial lenses (the Donders method).

Test-types for measurement of visual acuity and form perception.

Diffusion-area instruments relying upon the distortion or aberration produced by ametropia.

Optometers, a term given to instruments generally of telescope design, and dependent upon a personal adjustment of focus by the patient.

§ (3) PHOROMETERS.—Phorometric instruments deal with the measurement of ocular muscular want of balance, and the muscular exercises for its correction. The muscles of a normal pair of eyes are so balanced that the eyes involuntarily converge upon any fixed object, each eye conveying to the brain a similar picture. The exact superposition of these two pictures creates a single picture with stereoscopic relief. Should there be some difference in the size or definition of these two pictures due to difference in the focal strength of the eyes, or should a single picture be obtained with difficulty, the result is either that a strain is thrown upon the extra-ocular muscles in an attempt to secure single stereoscopic vision, or else failure to secure such vision results in a more or less pronounced squint or strabismus, with a temporary suppression of vision in one eye, in order to avoid confusion. It is obvious that, if two separate images are seen by the two eyes, a fusion of the images can be obtained by placing in front of one eye a prism, which will cause one of the images to deviate and superpose itself over the other image, and thus secure stereoscopic vision.

Supposing always that the eye refraction has been corrected, and pictures of equal size and definition secured, it is one of the simplest of optical procedures to find a prism which will give the required deviation. The first thing is to make one of the images seem so altered or distorted that the brain no longer attempts to associate it with the other image, and consequently ceases to make any muscular effort to superpose the two images. This distortion is usually effected by glass rods or cones or similar distorting contrivances.

One of the most effective of these is the Maddox set of rods or grooves (*Fig.* 1), which

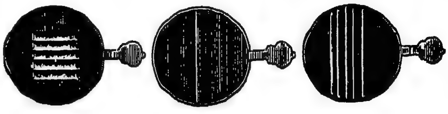

FIG. 1.

consists of a set of short coloured convex cylindrical thin glass rods, or concave cylindrical grooves fixed side by side in a small disc for use in the oculist's trial-frame. A bright small light seen through one of these rods produces a small fine line as an image, the several rods or grooves making in continuation a long decided line of light which can easily be

[1] See *The Adjustment and Testing of Telescopic Objectives*, by Messrs. T. Cooke & Sons, York.

fixed by the patient. This line is so different from the image of the object seen by the other eye that there is no effort on the part of the patient to secure superposition or overcome what is called his "dynamic strabismus." Successive prisms are now placed before one of the eyes until this streak of light appears to coincide in position with the original light.

The Risley or Herschell prism, which consists of two equal-powered prisms superposed and rotating at equal rates in opposite directions, is often used in order to obviate the necessity of trying successive prisms.

Another method of correcting the defect is that of the Stevens phorometer, which consists of two equal prisms (one before each eye) rotating in opposite directions. With either of such instruments, or some similar phorometer, the strength of the external eye muscles may be measured. There are many varieties of this class of instrument, varying chiefly in the number of small trial-case accessories attached to save time in adjustment.

Nearly all instruments for testing the ocular muscles depend upon their ability to create a diplopia which will not be overcome mentally by the patient, and having created it to indicate the prism giving fusion or a single image.

In order to induce diplopia, Thorington uses an ingenious form of truncated cone ground in two 7·00-dioptre prisms, separated by an interval of plane glass 3 mm. wide, which produce the combined effect of a Maddox rod and doubling prism in one piece of glass, with the important addition of a centre light as a starting-point.

An excellent but little-known instrument is the Remy Diploscope, which consists of a wide, short, hollow cylinder blackened on the inside, 28 cm. in length and 9 cm. in diameter, open at the eye-end, and closed at the other end by a disc with four round holes about 2 cm. in diameter, two of which are 4 cm. apart, and the others 1 cm. apart. By revolving a shutter, one pair of holes is kept closed while the other pair is open, and by revolving the disc the pair which is open may be set at an angle which is required for a test. In front of the open end of the cylinder there is a black square frame to block out stray rays of light, and a black bar at the top of the frame can be either lowered vertically across the opening, moved at an angle to one or the other side, or lifted away altogether. This cylinder is mounted on a long rod with its axis parallel to the rod so that the disc containing the holes is midway between the two ends. The length of the rod is 120 cm., the disc is thus 60 cm. from the eye, while the distance between the centres of one pair of holes is approximately equal to the distance between the eyes. At the other end of the rod is a test-card carrying four letters arranged horizontally at distances of about 6 cm. apart. If a patient with binocular vision looks at the holes he will see all four letters. Each eye sees a different letter through each of the two holes. If he suffers from convergent squint only two letters will be visible. By employing the second disc with the holes closer together and a second test-card on which there are two letters one above the other, further tests can be made.

Another popular instrument used in the British army is "Bishop Harman's Diaphragm test." This is the reverse of Javal's well-known bar-reading test. Instead of a bar there is a screen with a single hole in it (*Fig.* 2).

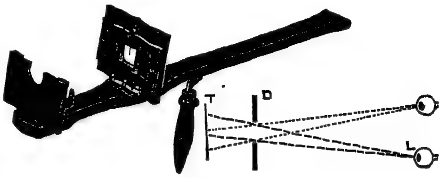

FIG. 2.

Into this hole the patient can look with both eyes without suspecting the test to which his vision is being subjected. The instrument is held with the end of the bar against the face and a screen with a suitable design is mounted in the holder at the other end of the bar. The patient sees part of this screen with the right eye, part with the left, and a small central region with both, as shown in the sketch. From the extent and location of these various fields the nature and amount of the squint, if any, can be deduced.

The difficulty of fitting prisms to cure the defect does not lie in the manipulation of the instruments, but rather in the inability of the patient, as a rule, to wear anything approaching the prism or Maddox correction which gives perfect fusion, possibly due to an inconstant variation in convergence on the part of the patient, and also to the distortion, astigmatism, and chromatic aberration inseparable from prisms of any strength. It is also possible that the exact relation between a prism giving fusion, and the correction of eye-strain and strabismus, has not yet been satisfactorily settled. When this question of fitting prisms and lenses has reached the certainty of determination of that used in the prescription of spherical and cylindrical lenses, a new and universal type of spectacle lens must immediately follow.

In England considerable attention has been given to the question of muscular anomalies. Of late years the tendency has been to recommend muscular exercises for the cure of

strabismus or squint, rather than interference by surgical operation. Nearly all instruments that are used are based, more or less, on the principle of the stereoscope.

For determining the maximum of convergence, an instrument known as Landolt's Ophthalmodynamometer may be used. This consists of a metal cylinder blackened on the outside placed over a small light or candle flame. The cylinder has a vertical slit 0·3 mm. wide covered by ground glass. The luminous vertical line is the object on which attention is to be fixed. Beneath the cylinder is a tape measure graduated in cm. on one side, and on the other in a corresponding number of meter angles. The cylinder is gradually approached towards the patient until double vision of the line of light occurs.

An instrument for testing latent torsion is the Optomymometer of the Geneva Optical Company, which consists of two tubes about 20 in. long, one of which is moved horizontally only, while the other can be elevated or depressed to any angle. At one end of each tube is a rotatable disc in which a slit is cut. On looking down the tubes, one slit is seen with each eye; by adjusting the inclinations of the tubes one slit may be made to appear vertically above the other, and by rotating the discs they may be made to appear parallel. There are many variations of this instrument, one of which is that of the clinoscope of Cooper, and the more recent one of Stevens.

§ (4) Pupilometers.—The size and shape of the pupil and its position in the centre or otherwise in the iris field is a matter of some importance both in discussing pathological questions and also in accounting for the uncertain results sometimes obtained in the estimation of refraction. It has been found that the visual axis rarely passes through the centre of the pupillary opening. Various methods have been devised to measure either the size of the pupil or its position. The simplest, and the one in common use, as in *Fig.* 3, is to have a series of various-sized

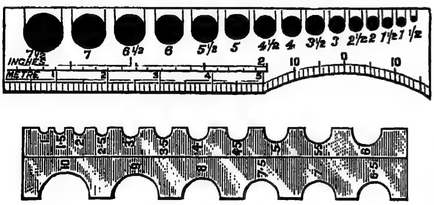

Fig. 3.

black dots on a card, and to compare them with the actual pupil, or to make similar comparisons with an ordinary wedge-shaped gauge. The other methods have been confined to the laboratory, and have consisted chiefly in the use of ophthalmometers with the doubling prisms removed, and by adjusting the size of the images of the mires or bringing them into contact on the cornea until they just cover it, an estimate of the diameter of the pupil has been made. Another ingenious method due to Landolt was to use a Fresnel doubling prism, and so adjust the distance between the two images until they just touch. Photography to scale has also been employed.

§ (5) Perimeters.—Perimeters or scotometers are for the measurement of the field of vision from the macula to the peripheral parts of the retina, and the plotting out of portions of the retina which are totally or partially atrophied. The measurements can be made for the colour as well as the light field.

Roughly the field of vision can be ascertained by making the patient look fixedly at a spot, such as the eye of the surgeon. A test object, such as a small ball, is then placed in front of the eye in various positions until the limits of indirect vision are determined. Usually elaborate instruments are used, allowing the travel of a test object along an arc having the patient's eye as its centre. Such instruments are generally furnished with mechanism for the silent and unobserved movement of the object, and the simultaneous recording of the limits of vision by a puncher, pricker, or pencil on a graphic chart behind the instrument.

Aubert and Forster constructed an instrument in 1847 upon which most of the subsequent perimeters have been based, amongst which are the McHardy, Skeel, Dana, Stevens, Schweigger, Landolt, Bardsley, and Priestley Smith perimeters and scotometers. These vary chiefly in the mechanism for the test-object carrier and the method of making the chart. *Fig.* 4 shows the McHardy instrument.

Tomlinson, in order to avoid the large and cumbersome arc, designed a system of a tilting mirror which gives an imaginary movement to the object.

Many surgeons use the Bjerrum screen, which consists of a large square black screen 2 metres in breadth, at a distance of 2 metres from the patient. This system has the advantage of increasing all the measurements—the blind spot, for instance, measuring 20 cm. on the screen instead of about 2½ cm. with the ordinary perimeter. Beyond 45°, measurements on a flat surface are not of much use. R. H. Elliott has recently made considerable improvements on this method. He uses in front of the Bjerrum background a movable disc in which there are small illuminated objects.

In the Campimeter of De Wecker the patient fixes a small cross in the middle of a black screen on which are marked radial lines;

the test object is moved from the periphery to the centre, the limits of recognition being marked on each line in turn. The points on

FIG. 4.

the various radiating lines are then joined, showing the area of the visual field.

The same principle applies to nearly all the perimeters. In some like the Priestley Smith, the McHardy, the Skeel, etc., the test objects travel on an arc centred round the patient's eye, instead of at a tangent, as in the case of the Wecker and Bjerrum screens. The differences in the many arc instruments are rather in details of workmanship and mechanism than principle.

Hand perimeters are rather for clinical or bedside use.

The uncertainties of perimetry are due chiefly to the tendency of the patient to allow his eye to wander away from the fixation point and also to the various degrees of intelligence on the part of the patient.

§ (6) PHOTOMETERS. — Until the war and recently, comparatively few experiments had been made as to the perception of light in the estimation of refraction and eyesight. The prevalence of night-blindness, the possibilities of malingering, and insurance problems, brought into use some of the many well-known photometers.[1] Perception scales such as those of Parinaud, which consist of ten graded squares of grey colour from white to black or a black background on which various colour shades are outlined in small squares to be counted by the patient, constitute probably the quickest and simplest method.

§ (7) CHROMO-OPTOMETERS. — Since attention has been drawn by the Board of Trade and Admiralty to the necessity for stricter tests, the examination for colour vision has become a much more general practice. Some observers employ the confusion test of a series of coloured wools (Holmgren), while others, such as Butler-Harrison and Edridge-Green, rely upon the use of lanterns showing by rotation and superposition a series of colours which the patient is called upon to classify or compare.

Another useful test is that of the bead-box of Edridge-Green, where a variety of coloured beads is given to the patient to classify.

An ingenious instrument is that of Chibret, in which a plate of quartz ground parallel to its axis is placed between Nicol prisms. The plate is seen coloured, and the colour depends on the thickness of the quartz. If the Nicol analyser is rotated, the colour changes. At 45 degrees the field is white, on rotating the prism to 90 degrees one obtains the complementary colour which increases the intensification of colour. By replacing the analyser with a bi-refringent crystal, in the form of a prism, one of the images has the complementary colour to the other. In the instrument of Chibret, by varying the obliquity of the prism, it is possible to obtain the whole range of colour and intensities. The patient is asked to regulate the instrument so that at any degree of intensity he is sure to secure equal colouring of the two fields. Failure to do this indicates his degree of colour sensitiveness.

§ (8) OPHTHALMIC LENSES. — Ophthalmic spectacle lenses differ from photographic, projection, microscope, or what may be termed image-forming lenses or systems, in that they are usually of approximately one diameter or aperture, one thickness, and except in the cases of special bifocal and cemented lenses, they are thin single lenses of two surfaces only.

Spectacle lenses are made of ordinary white glass similar to that of a good window glass. The English glasses are generally very white but softer than the French or St. Goban glass. Recently Schott of Jena have manufactured a hard and dense glass for better class meniscus lenses.

Until about twenty years ago the more expensive lenses were made of Brazilian pebble or "rock-crystal." It was claimed that the extra density of the crystal allowed a thinner lens, and cooler to the eye; but on the other hand there were many faults, such as that of double refraction, striae, and surface imperfections in working, that made them inferior to ordinary good white glass. The introduction of cylindrical and prism lenses resulted in comparatively few lenses being made of pebble owing to the difficulties and expense of working the surfaces.

[1] See "Photometry and Illumination."

With spectacle lenses a large variety of surfaces and combinations, useful only in ophthalmic lens work, are employed.

(*a*) The plano-spherical, where one side is plane, the other convex or concave spherical.

(*b*) The bi-spherical, where both sides are spherical, either convex-concave or else concave or convex.

(*c*) The plano-cylindrical, where one side is plane and the other is a simple cylinder.

(*d*) The periscopic, a term given in the trade, of which one surface is concave, the other convex, and in which the concave side is about 1·25 to 2 dioptres in strength, the other side having an excess of convexity to secure the necessary focus.

(*e*) Meniscus lenses, practically deep periscopics, where the concave surface ranges from 6·00 to even 12·00 dioptres.

(*f*) Ordinary sphero-cylinders, where one side is convex- or concave-spherical and the other a convex or concave cylinder.

(*g*) Toric lenses, where the one surface is that of a segment of a torus, or anchor ring. A good illustration of a toric surface may be taken from that of a bicycle tyre which has two differing curves, one at right-angles to the other. The advantage of a toric lens is that it provides a sphero-cylindrical lens in the form of a meniscus combination.

Prisms are also used with any of the above lenses or combinations. If the prism required is comparatively weak and the spherical power fairly strong, this may be secured easily by decentration of the lens in the spectacle frame, but if the prism required is fairly strong, without a corresponding increase or ratio of strength in the spherical, then the spherical curves are usually worked upon a prism or wedge-shaped glass.

There are some forms of special spectacle lenses which call for special mention, not only for the special purpose for which they are intended, but on account of their very beautiful workmanship, such as the bifocal, aspherical, and cataract lenses.

(i.) *Bifocal Lenses.*—The bifocal is a spectacle lens having two different powers or foci set in the same eye-wire or spectacle frame; the upper power or focus being used for distance and the lower for reading or close work. A bifocal lens is generally useful in the case of a person who is ametropic and who requires, on account of age, two separate foci, one for distance and one for reading, and wishes them to be in the same spectacle frame in order to avoid having two pairs of spectacles.

There are many forms of bifocals, the oldest being the Franklin bifocal, made of two half lenses of different foci joined together with a straight joining line. The drawback to this pattern is that the half-lenses are liable to jump out of the frame, the junction retains dirt, while the lower half presents inconvenience, and is usually too large for the purpose for which it is intended. This is sometimes avoided by placing the lower half into a curve cut out of the upper piece. Very many suggestions and patents have been taken out for bifocals, but most of them have been discarded on account of the difficulty of securing good centring and also because the dividing line or ridge is generally in the way. The commonest form of bifocal consists of small thin segments of additional powers cemented on to an ordinary lens of the focus required for distance. The segment is usually so thin as to be almost imperceptible, but is liable to become disturbed through heat, strain or concussion. One very modern form is generally known as the fused solid bifocal, which is made by grinding or gouging out a small depression or curve in the lower part of the distance lens, which should be of low refraction. Into this depression or curve or small basin is dropped and fused another small lens of very much denser refraction. The difficulty in manufacture is to secure a perfect join between the two surfaces without introducing air bubbles. After fusing, the whole surface is then ground to a specified curve, in appearance one lens only, although there are two separate foci. The process requires such extreme care in manufacture that the lenses have become almost a proprietary article.

Another equally modern form is that of the solid bifocal, where two separate curves are ground on the same surface. A small but almost imperceptible ridge is formed between the two parts of different foci, which are ground out of the same piece of glass and therefore do not depend on two different refractions. The method of manufacture calls for a kind of optical grinding that has not been used in any other kind of optical work. All opticians are aware that all optical lenses are surfaced by means of optical tools having the same curvature, and by means of emery and rouge are polished afterwards on the same tools with a piece of cloth. This bifocal is ground quite a different way, in that the surfaces of all the lenses, no matter what the foci, are ground by means of a thin ring tube about half the diameter of the part to be ground out from the lens. The end of this tube rotates at a different rate from the lens, which is fixed on a shaft, and the difference in rotation results in varying curves, spherical curves of extra curvature being ground. Theoretically the one tool grinds every curve. The difference in the rate of the abrasion between the outer and inner edges of the cutting tube produces the curve desired.

(ii.) *Aspherical Lenses.*—The optical formulae of ordinary spherical lenses are of the

simplest and do not require discussion. Von Rohr has pointed out that the formulae hold good only in the case when the axis of the spectacle lens is directed towards that particular object-point that is the principal object of contemplation, which would mean that in order to realise such conditions we should have to move our heads continually in looking around: this is avoided in the ordinary way by moving the eye instead of the head and thus getting what is called direct vision.

The result is that when the eye moves and looks towards the edge of the lens, fresh optical conditions are set up which result in aberration. It has not been found possible in actual practice to correct vision by the usual combinations such as are met with in photographic cemented objectives on account of the expense, weight, fragility, and liability of the lenses to become uncemented. Any attempts made to correct this aberration have been in the direction of giving definite form to the surfaces of meniscus lenses, according to the resultant focus required. Wollaston, Ostwalt, Tscherning, Percival, Gullstrand, and Whitwell have at various times drawn up a definite series of tables defining the curves which are likely to give the least amount of aberration with certain foci. The problem has naturally been more difficult in the case of toroidal or cylindrical lenses. Gullstrand has devised an aspherical surface of revolution where the meridian curve is different from the arc of a circle, and includes such surfaces of revolution as elliptic, parabolic, and hyperbolic surfaces. Undoubtedly this is an ideal form of curvature and is limited only by difficulties of manufacture.

(iii.) *Cataract Lenses.*—As lenses for aphakic patients are generally above 13·00 D in strength, the weight of the lens is a great drawback. Attempts have been made to do away with this by cementing on an ordinary plano-lens a small convex lens, which does away with weight and reduces the aperture and consequently the aberration.

§ (9) Test-case of Trial Lenses.—There is probably no piece of ophthalmic apparatus which is more universally used or relied upon by both oculists and opticians than the test-case of trial lenses. No matter what method or instrument may be used, almost invariably, at some stage of the procedure, use is made of the test-case and trial-frame.

The Trial-frame.—Lenses when used for testing a patient's vision are usually mounted in a trial-frame, of which there are numerous patterns with adjustments to suit the patient and to rotate the lenses. *Fig.* 5 illustrates one form.

A test-case consists of a series of the lenses forming the various combinations possible of spectacle lenses. They are nearly always circular, 38 mm. in diameter, unmounted or mounted in metal rings with handles. Some-

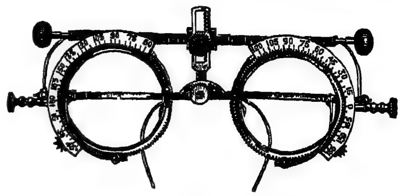

Fig. 5.

times they consist in their simplest form of a small series of about 50 single spherical lenses for use in retinoscopy in the dark room, or they may include a full case of pairs of convex and concave sets of spherical and cylindrical lenses grading by 0·12 intervals up to about 3·00 D, by 0·25 intervals up to about 4·00 D and 0·50 intervals to about 8·00 D. The larger cases generally contain very many accessories, such as a full set of prisms, blanks, pinholes, and stenopaic slit discs, together with a full range of coloured glasses. Some trial-cases also contain extra smaller sets of bifocal and cataract lenses. Almost any combination can be made by combining one, two, or three lenses together, although the distances from the eye and the separation of the lenses must be taken into account when ordering the actual spectacle lenses.

For that reason, the ideal test-case should consist of plano-spherical lenses rather than bi-spherical.

The Optical Society set up some years ago a set of standards for trial-cases, and lenses are tested to these standards at the National Physical Laboratory.

The pinhole discs consist of small various-sized perforated discs which afford a speedy means of determining whether imperfect vision is due to ametropia or to other conditions. In pure ametropia, the pinhole reduces the circles of diffusion and gives good vision with a certain loss of illumination. In other cases it makes the vision worse. The cases in which it is likely to be misleading are of an unequal surfaced or faceted cornea or conical cornea, where better vision is sometimes secured by a pinhole disc and yet no suitable correcting lens can be found.

The stenopaic slit acts very similarly in cases of astigmatism, where the diffusion areas on the retina are greater in one principal meridian than in another. The stenopaic slit limits them at right angles to its length.

The ordinary use of test-lenses is to test each eye separately, giving the strongest convex lens in the case of hypermetropia, and weakest concave one in the case of myopia, consistent in each case with best vision. In similar fashion, but applicable to one meridian

only, use is made of cylindrical lenses for astigmatism. The difficulties likely to be encountered in the subjective use of the trial-case arise chiefly through having to rely upon the answers of the patient and the tendency there is to excite the accommodative apparatus of the eye.

Some operators use, in order to save time, apparatus consisting of a series of test-lenses revolving before the eye of the patient. These are sometimes termed refractometers, or by various proprietary names.

Subjective testing, or the use of trial lenses, cannot be regarded as thoroughly satisfactory until the conditions of the lenses in the trial-frame on the patient's face approach those of the actual spectacles. To this end the lenses should be very thin; if a combination of two is used, then each trial lens should be half the thickness of the spectacle lens. The trial-lens should be plano-spherical or plano-cylindrical. The two plano surfaces of these should face each other; the separation between them should be almost nil; and the distance of the farthest lens from the eye and its tilt should be the same as the actual spectacle lens worn. These conditions of course are difficult to fulfil, although instruments have recently been devised to measure the distance of the spectacle lenses from the eye, and also of the trial lens, and to make comparison.

Many users of test-cases prefer to estimate the refraction by such objective methods as retinoscopy, ophthalmometry, and ophthalmoscopy, putting up an approximate combination into the trial-frame and then by slight adjustment or alteration determining the final correcting glasses. Some, however, prefer to rely entirely on subjective methods and more or less adopt a definite system and rigid routine in its use.

A careful operator who relies principally upon his test-case without preliminary objective findings nearly always uses some kind or other of "fogging" method. This consists in blurring the vision by a positive lens of power in excess of that required for correction and interposing negative lenses of gradually increasing power until distinct vision is obtained. By approaching the desired correction from this side the patient's accommodation is prevented from coming into play and producing an apparent increase in myopia. A fan line diagram or similar test chart should be used, otherwise mixed astigmatism may be overlooked.

One such modern subjective system consists of the use of the usual set of test-letters, a set of fan lines and a block or series of parallel lines capable of being rotated to any particular meridian. The procedure is to use the test-letters only to ascertain the visual acuity before and after testing, and to rely upon fitting separately the two principal meridians without further reference to the test-letters. The patient is asked to state which lines in the fan are the clearest. The set or block of parallel lines is then fixed at right angles to the clearest line and therefore at the worst position at which they can be seen. Convex spherical lenses are tried upon this, and if the vision is improved are increased in strength until the best result is obtained; the fan lines are then again resorted to and the patient is asked to pick out the best set; a suitable concave cylindrical lens is then put in the trial frame and turned until the fan lines appear equal in clearness. Should, however, convex spherical lenses not improve the block lines in the first instance, the procedure is repeated from the start with the block lines at the opposite meridian or axis. If convex sphericals are still useless, concave sphericals are tried and the same procedure followed. If the block is still seen most clearly without the aid of a lens, it is assumed that that particular patient is emmetropic and that a concave cylinder with its axis properly oriented is alone required. The advantage of such a system is that the most difficult complicated cases of astigmatism are gradually eliminated at the outset; there is little tendency to excite the accommodation, and by the use of concave cylindrical lenses only instead of convex the best form of periscopic lenses is secured. Any system which does not allow of an exact placing of the cylinder in the trial frame is haphazard and casual.

§ (10) Diffusion-area Instruments.—These instruments depend upon diffusion areas for the estimation of refraction. The Culbertson prisoptometer in optical construction is rather like an ophthalmometer in that it has a double prism which can be revolved through the various degrees of the scale. The patient looking through the circular opening in the centre of the instrument sees two circles. If, when the instrument is adjusted, the circles are just in contact, the case is one of emmetropia; if they overlap each other it is myopia; and when they separate it is a case of hypermetropia. Theoretically, it is a very ingenious instrument, but as the intelligence of the patient is called into play, exactness and accuracy do not always follow.

Another ingenious diffusion instrument is the ametrometer of Thomson, which consists of two very small flames or sources of light, one stationary and the other movable on a graduated arm, revolving about the first flame as a centre. The method is to move one flame along the arm until the two flames appear to fuse. The approximate strength of the lens required is marked on the scale.

Under the head of different tests may come that of the Cobalt-blue lens. For the purposes

of this test a cobalt-blue glass, which appears dark blue but contains as much red, is fitted in the trial-frame. Cobalt-blue glass has the power to exclude all but blue and red rays. Blue rays are more refrangible, and therefore focus sooner than red. If such a glass is placed before the patient's eye and a small flame used as a test object an emmetropic patient will see a small circle composed of two colours equally mixed—that is to say, purple—but a hypermetropic patient will see a red ring of light with a blue centre, and a myopic patient will see a blue ring with a red centre.

§ (11) Optometers.—Optometry is a term sometimes applied to all ocular methods of estimating the refraction of the eye. We confine the application here to that generally accepted in Europe, *i.e.* to instruments where an adjustment of lenses is made by the patient in order to obtain the clear image of an object and the result recorded on the metric scale. Hence the term. Prior to the introduction of retinoscopy and phorometry, the optometer was almost the only method of estimating the refraction other than the trial case of lenses. There are probably more varieties of optometers than of all other ophthalmic instruments put together, probably due to their construction being so closely allied to that of the ordinary optical bench. In actual practice their use has been almost entirely discontinued, chiefly owing to the uncertain accommodation of the patient which so easily confuses the result. This involuntary act of accommodation is due to the fact that all such optometers are provided with a small eye-piece aperture; and this, combined with the need to rely upon the ability of the patient to decide very accurately as to comparisons of clear focus, calls into play the accommodation and imagination.

The most of the older optometers rely upon the well-known principle of Scheiner's experiment that if a card in which two small holes are pierced at a distance from each other less than the pupillary diameter is held in front of the eye, a luminous point seen from a distance will appear to a normal-sighted person as one light, whereas to one with defective vision, it will appear as two lights.

De la Hire, Porterfield, Thomas Young, Helmholtz, Bull, and many others followed on with modifications of instruments, all based on this principle, but while all of them are optically interesting they are unsatisfactory in actual practice.

Subsequently Coccius, Donders, De Graefe, Perrin, Badal, Hardy, De Zeng, and many others designed optometers to obviate the effects of accommodation. Most of these employ a fixed convex lens serving as an eye-piece and a movable illuminated object. The patient places the object where he sees it most clearly and notes its position relative to the principal focus of the lens. If it be between the lens and the principal focus the rays which enter his eye are divergent, he is short sighted; if it is beyond the principal focus, he is long sighted. The difficulty of obtaining accurate results is that while optically accommodation may be eliminated, yet the mental effect on the patient of seeing something at a distance which really is close to upsets his judgment and he gives inaccurate positions for that of the clearest vision.

Optically the best of these is the instrument of Badal, where a fixed single biconvex lens is placed so that its principal focus coincides either with the nodal point of the patient's eye or with its anterior focus. In either case the size of the retinal image of an object situated at any distance in front of the lens is unaffected by moving the object nearer or further away. This destroys the sense of varying distance and prevents the accommodative efforts which result from this. This optometric system is the best if one can rely upon the accurate judgment of comparison by the patient.

J. H. S.

Optic Axis: a direction in a crystal along which there is no separation of the ordinary and extraordinary rays. Crystals having one such direction are known as uniaxial; those having two such directions as biaxial. See "Polarised Light and its Applications," § (5).

Primary and secondary. See *ibid.* §§ (7) (ii.) and (18) (iii.).

Optical Activity: the power possessed by certain substances of rotating the plane of polarisation of a beam of light passing through them. See "Polarised Light and its Applications," § (20).

Optical Bench, for testing of lenses. See "Camera Lenses, Testing of"; "Lenses, Testing of Simple."

OPTICAL CALCULATIONS

§ (1) Trigonometrical Methods. — The methods employed almost exclusively in the past in the computation of optical systems have consisted in tracing step by step the paths of a few rays selected according to rules which are largely empirical in character. From the point of view of the computer this system has much to recommend it. The amount of calculation involved is limited, and with a certain amount of past experience to indicate in what direction modifications intended for the improvement of a system already approximately determined are most likely to prove satisfactory, the evolution of

systems attaining such a degree of correction as has in the past proved necessary is possible in not too prolonged a time. The methods most extensively employed are trigonometrical, and it will be convenient to record here the systems of equations very commonly used for tracing rays through a series of coaxial spherical refracting surfaces. In the first example the ray lies in a plane passing through the axis of the system, and the problem is simply two-dimensional. This case covers by far the greater part of the calculations normally made. In the second case the ray does not lie in an axial plane, and the portions of the path lying in three successive media will not usually be coplanar.

Suppose that there are n spherical refracting surfaces having their centres of curvature on a straight line coincident with the x axis of co-ordinates. Let the surfaces be distinguished by the n numbers $1, 2, 3, \ldots m, \ldots n$, the order of the numbers being that in which the surfaces are met by a ray of light traversing the system from the object space to the image space. The radius of curvature of a surface is denoted by r, to which is added as a suffix the number of the particular surface. The sign convention adopted, which is almost universally accepted, requires r to be regarded as a positive quantity when the light is incident on the convex side of the surface, negative when incident on the concave side. Thus with a positive radius of curvature, and with the light represented in diagrams passing from the left to the right, the centre of curvature will be situated to the right of the vertex or point in which the refracting segment of the sphere meets the axis. Each surface marks the separation of media of different refractive indices, and it is convenient to use numbers to distinguish these also. The total number of these media is $n+1$, and they will be denoted by the numbers $0, 1, 2, \ldots n$. Thus the number of any medium is the same as that of the surface which bounds it on the left or object side, and is less by unity than the number of the surface forming the boundary on the right or image side. This notation is an easy one to remember, but several others are commonly employed. In some cases even numbers are used for surfaces and odd numbers for media, in others the converse arrangement is adopted, while yet another system involves the introduction of half integers. Such variety in the notation is apt to lead to mistakes, and that here adopted, which is less clumsy than most alternatives, will be generally followed in the articles of this Dictionary.

All the quantities required to specify the position of a ray or the configuration of the refracting system can be divided into two groups, in the first of which the quantity is naturally referable to a particular surface, while in the second it is associated with the medium. In the former group the quantity bears the suffix corresponding to the surface, in the latter case the suffix of the medium is used. Examples of the former are the co-ordinates of the point of refraction at a surface, or the angles of incidence and refraction; and of the latter the refractive index, the axial separation of the two bounding surfaces, and co-ordinates giving the direction of a ray in the medium.

The refractive index throughout the present article will be denoted by μ. The axial distance between the vertices of two surfaces is denoted by t, and will for convenience be referred to as the thickness whether this distance is the actual thickness of a lens or the axial separation of neighbouring surfaces of two lenses. The distance between the centres of curvature of two surfaces may be denoted by a, so that if t is regarded as essentially positive, and a is positive if the centre of curvature of the surface of lower suffix is to the left of that which follows, the relation

$$r_m + a_m = t_m + r_{m+1} \quad . \quad . \quad . \quad (1)$$

will hold in all cases. In trigonometrical calculations the formulae present themselves most readily in a form suited for logarithmic computation when the centre of curvature is taken as a reference point, and the separation of successive centres of curvature must be determined from this equation.

Symbols are required to denote the quantities by which the position of the ray is determined in relation to the refracting surfaces. The angle made by the ray with the axis of symmetry of the system will be denoted by ψ with the addition of the suffix of the medium. The angles of incidence and refraction at any surface will be represented by ϕ and ϕ' respectively, with the surface suffix. When the ray lies in an axial plane the point in which it meets the axis, together with ψ, will fix its position. This point is referred to the centre of curvature of the surface, and consequently the surface suffix is used. The

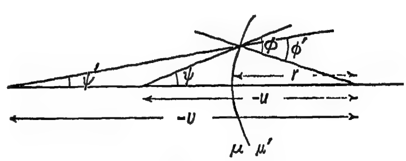

Fig. 1.

distances from the centre of curvature, measured in the light direction, to the crossing points of an incident and the corresponding refracted ray will be denoted by u and v respectively (*Fig.* 1).

For a single surface it is evident that

$$\sin\phi = -\frac{u}{r}\sin\psi \quad . \quad . \quad . \quad (2)$$

is the equation from which ϕ will be found when the position of the incident ray is given. ϕ' is, of course, determined from the refraction relation

$$\mu'\sin\phi' = \mu\sin\phi, \quad . \quad . \quad . \quad (3)$$

and since the distance on the surface of the point where refraction takes place from the axis is given by either $r(\phi-\psi)$ or $r(\phi'-\psi')$, the inclination to the axis of the refracted ray is obtained from the angular relation

$$\psi' = \psi - \phi + \phi'. \quad . \quad . \quad . \quad (4)$$

The remaining quantity v required to specify the position of the refracted ray is derived from

$$-v = \frac{r\sin\phi'}{\sin\psi'}. \quad . \quad . \quad . \quad (5)$$

For a series of surfaces these formulae, together with one additional relation transferring the reference point for the refracted ray to the centre of curvature of the succeeding surface, take the form

$$\sin\phi_m = -\frac{u_m}{r_m}\sin\psi_{m-1},$$

$$\mu_m\sin\phi'_m = \mu_{m-1}\sin\phi_m,$$

$$\psi_m = \psi_{m-1} - \phi_m + \phi'_m,$$

$$-v_m = \frac{r_m\sin\phi'_m}{\sin\psi_m},$$

$$u_{m+1} = r_m - a_m.$$

These equations are obviously well suited for logarithmic work, and the only details requiring special attention are the signs. For paraxial rays[1] the same formulae are generally used by trigonometrical workers with the sines of the angles replaced by any convenient multiple of the angles themselves. Where this system is used tables of logarithmic sines based on the decimal division of the radian are much to be preferred to those in ordinary use.

The chief weakness of this system is that when a radius becomes infinitely great an entirely distinct set of formulae must be used, and that when any radius is relatively large an increase in the number of significant figures is necessary to avoid loss of accuracy. To obviate this latter difficulty special formulae for long radii are frequently introduced. For an account of these reference may be made to *Applied Optics*, Steinheil and Voit, translated by French.

[1] *I.e.* rays always close to the axis at the time of refraction and only slightly inclined thereto.

The process of tracing rays trigonometrically when they do not lie in an axial plane is much more troublesome. The system most generally used is due to von Seidel, and is discussed in the work just mentioned. The formulae may be readily verified by reference to the accompanying figure.

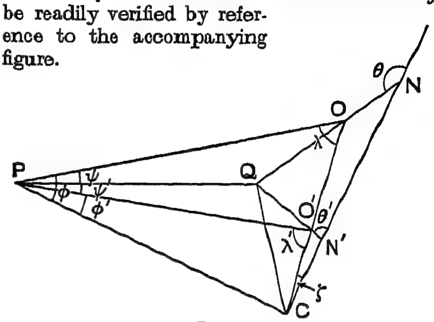

FIG. 2.

The incident ray PO encounters at P a refracting sphere of radius r and centre C. PO′ is the refracted ray. The plane through C normal to the axis cuts these rays in O and O′, and the normal to it through P in Q. An arbitrary reference plane through the axis cuts QO and QO′ in N and N′. C, O, O′ are collinear, and the line determined by them makes angles λ and λ' with the incident and refracted rays. Denote the lengths CO and CO′ by l and l' respectively. Let ζ be the angle made by the lines OO′ and NN′ which meet at C, and let QON, QO′N′ make angles θ and θ' with CNN′. Other letters retain the meanings already applied to them in considering a ray in an axial plane. The formulae to be used suppose that l, ζ, θ, ψ are given and that the corresponding quantities for the next refraction are to be found. They are

$$\cos\lambda = \sin\psi\cos(\theta-\zeta),$$

$$r\sin\phi = l\sin\lambda,$$

$$\mu'\sin\phi' = \mu\sin\phi,$$

$$\lambda' = \lambda + \phi - \phi',$$

$$l' = \frac{r\sin\phi'}{\sin\lambda'} = \frac{l\mu\sin\lambda}{\mu'\sin\lambda'},$$

$$\frac{\sin\psi'\sin(\theta'-\zeta)}{\sin\lambda'} = \frac{\sin\psi\sin(\theta-\zeta)}{\sin\lambda},$$

$$\sin\psi'\cos(\theta'-\zeta) = \cos\lambda'.$$

These give l', θ', ψ'; it is evident that ζ is unchanged. For the next incidence introduce the suffix 1. Then simple projection gives

$$l_1\sin(\theta_1-\zeta_1) = l'\sin(\theta'-\zeta),$$

$$l_1\cos(\theta_1-\zeta_1) = l'\cos(\theta'-\zeta) - a\tan\psi',$$

which completes the solution on noting that

$$\theta_1 = \theta', \quad \psi_1 = \psi'.$$

A number of other distinct solutions have been evolved by various workers, but into these it is unnecessary to enter. This example illustrates fairly the complexity of the best trigonometrical methods of tracing skew rays.

§ (2) Algebraic Methods.—Such methods of calculation as have just been described, essentially trigonometrical in character, were for a period the only means of obtaining results of high accuracy for general optical systems. The recent development of machines for the mechanical performance of arithmetical operations has largely altered the prospects, and at the present time calculations of this kind can be carried out much more expeditiously without employing logarithms at all. The old formulae for the most part seem to be still used with the new tools, but this course is not to be recommended, for greater accuracy and more valuable information become available by an entire change in the basis of the calculations. There is no need with the new formulae to employ a trigonometrical notation, for tables need not be used, though in certain cases they may be introduced as an independent check on a series of operations. It is convenient to have a separate name for these newer methods, and the distinction just noted provides the convenient distinctive name "algebraic" as opposed to "trigonometric" which describes the older methods.

In developing these algebraic methods it is desirable to conform as far as possible with the conventions generally adopted in analytical geometry of three dimensions, and in some branches of mathematical physics. All points and lines will accordingly be referred to a right-handed system of orthogonal axes, of which the axis of x is assumed to coincide with the axis of symmetry of the optical train. The light in general travels in the direction of x increasing. The co-ordinates of a typical point on an incident ray may be denoted by (x, y, z), and those of a point on a refracted ray by (x', y', z'). The direction cosines of a ray may be represented by L, M, N. The point on a surface at which refraction takes place may be represented by (ξ, η, ζ). It is convenient to introduce R, equal to $1/r$, to represent the curvature of the refracting surface. Consider for the moment a system consisting of a single surface. The general problem awaiting solution is the determination of a set of six quantities $(x', y', z', \mathrm{L}', \mathrm{M}', \mathrm{N}')$ for the refracted ray when any set $(x, y, z, \mathrm{L}, \mathrm{M}, \mathrm{N})$ has been given for the incident ray. The origin may conveniently be chosen as the intersection of the axis with the refracting surface, so that the equation to the surface is

$$2\xi=(\xi^2+\eta^2+\zeta^2)\mathrm{R}. \qquad . \quad . \quad (6)$$

Now since (ξ, η, ζ) is on the given ray, the co-ordinates are of the form

$$\left.\begin{aligned}\xi&=x-\mathrm{L}\rho\\ \eta&=y-\mathrm{M}\rho\\ \zeta&=z-\mathrm{N}\rho\end{aligned}\right\}, \qquad . \quad . \quad . \quad . \quad (7)$$

where ρ is the distance along the ray from the surface to the known point in the positive direction of travel. The substitution of these values in the surface equation gives

$$2(x-\mathrm{L}\rho)=\{x^2+y^2+z^2-2\rho(\mathrm{L}x+\mathrm{M}y+\mathrm{N}z)+\rho^2\}\mathrm{R}$$

as the equation from which ρ is to be found. The solution to be chosen is that in which ρ tends to zero with x, y, z: thus

$$\left.\begin{aligned}\rho&=\mathrm{L}(x-r)+\mathrm{M}y+\mathrm{N}z-[\{\mathrm{L}(x-r)+\mathrm{M}y+\mathrm{N}z\}^2-x^2-y^2-z^2+2xr]^{\frac{1}{2}}\\ &=\frac{x^2+y^2+z^2-2xr}{\mathrm{L}(x-r)+\mathrm{M}y+\mathrm{N}z+[\{\mathrm{L}(x-r)+\mathrm{M}y+\mathrm{N}z\}^2-x^2-y^2-z^2+2xr]^{\frac{1}{2}}}\\ &=\frac{2x-(x^2+y^2+z^2)\mathrm{R}}{\mathrm{L}-(\mathrm{L}x+\mathrm{M}y+\mathrm{N}z)\mathrm{R}+[\{\mathrm{L}-(\mathrm{L}x+\mathrm{M}y+\mathrm{N}z)\mathrm{R}\}^2+2x\mathrm{R}-(x^2+y^2+z^2)\mathrm{R}^2]^{\frac{1}{2}}}\end{aligned}\right\}, \quad (8)$$

the last form being always determinate. The point where refraction takes place is thus known. It is next necessary to find the direction of the refracted ray. To obtain this in a suitable form for algebraic calculation consider the triangle PUV (*Fig.* 3), where P is the point of refraction and PU and PV lie

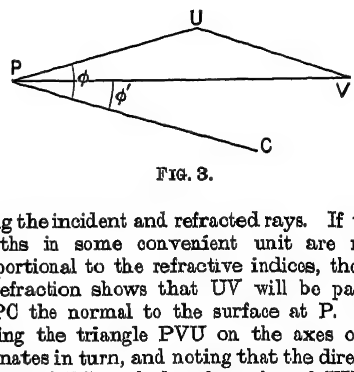

Fig. 3.

along the incident and refracted rays. If these lengths in some convenient unit are made proportional to the refractive indices, the law of refraction shows that UV will be parallel to PC the normal to the surface at P. Projecting the triangle PVU on the axes of co-ordinates in turn, and noting that the direction cosines of PC, and therefore also of UV, are $1-\xi\mathrm{R}$, $-\eta\mathrm{R}$, $-\zeta\mathrm{R}$,

$$\mu'\mathrm{L}'-\mathrm{UV}(1-\xi\mathrm{R})-\mu\mathrm{L}=0,$$

$$\mu'\mathrm{M}'-\mathrm{UV}\ (-\eta\mathrm{R})-\mu\mathrm{M}=0,$$

$$\mu'\mathrm{N}'-\mathrm{UV}\ (-\zeta\mathrm{R})-\mu\mathrm{N}=0,$$

or since $\quad \mathrm{UV}=\mu'\cos\phi'-\mu\cos\phi,$

the refraction equations take the form

$$\frac{\mu'\mathrm{L}'-\mu\mathrm{L}}{1-\xi\mathrm{R}}=\frac{\mu'\mathrm{M}'-\mu\mathrm{M}}{-\eta\mathrm{R}}=\frac{\mu'\mathrm{N}'-\mu\mathrm{N}}{-\zeta\mathrm{R}}$$

$$=\mu'\cos\phi'-\mu\cos\phi. \quad (9)$$

This equation requires ϕ and ϕ' to have been previously determined. The equations for these are

$$\cos\phi = \mathrm{L}-(\mathrm{L}\xi+\mathrm{M}\eta+\mathrm{N}\zeta)\mathrm{R} \quad . \quad (10)$$

and

$$\mu'\sin\phi' = \mu\sin\phi. \quad . \quad . \quad (3)$$

Finally the co-ordinates of any point on the refracted ray are of the form

$$\frac{x'-\xi}{\mathrm{L}'}=\frac{y'-\eta}{\mathrm{M}'}=\frac{z'-\zeta}{\mathrm{N}'}=\rho', \quad . \quad (11)$$

where ρ' is the distance of the point selected from the place of refraction.

Although the equations as they stand provide a complete solution of the problem, they are not in the best form for numerical calculation since an unnecessary amount of work is involved. From (10) and (7)

$$\begin{aligned}\cos\phi &= \mathrm{L}-(\mathrm{L}x+\mathrm{M}y+\mathrm{N}z-\rho)\mathrm{R}\\ &= [\{\mathrm{L}-(\mathrm{L}x+\mathrm{M}y+\mathrm{N}z)\mathrm{R}\}^2+2x\mathrm{R}\\ &\qquad -(x^2+y^2+z^2)\mathrm{R}^2]^{\frac{1}{2}} \quad (12)\end{aligned}$$

by (8), a result more directly obtainable from a figure in the form

$$\begin{aligned}\sin^2\phi &= (1-x\mathrm{R})^2+(y^2+z^2)\mathrm{R}^2\\ &\qquad -\{\mathrm{L}-(\mathrm{L}x+\mathrm{M}y+\mathrm{N}z)\mathrm{R}\}^2. \quad (13)\end{aligned}$$

The use of this equation and the square of (3) enables the last of the equal quantities of (9) to be calculated on the machine by extracting two square roots. Of these, that representing $\cos\phi$ is the square root which appears in the final form in equations (8). The complete solution thus depends upon these two square roots and direct multiplication.

When a series of surfaces with their centres of curvature on the axis of x are substituted for the single surface, the values of ξ, η, ζ for one surface may be taken as the x, y, z, with a correction t for the x co-ordinate, for the next surface. It is thus only necessary to repeat the process described for each surface in turn. The problem may, however, be much simplified by noting that no attention need be paid to the y and z co-ordinates. Suppose that m denotes a typical member of a train of refracting surfaces numbered from 1 to n. Denote by K_m the quantity

$$(\mu_m\cos\phi'_m-\mu_{m-1}\cos\phi_m)\mathrm{R}_m, \quad . \quad (14)$$

and let τ_m be the length of the ray intercepted between surfaces m and $m+1$. Assume for the moment that all the τ's and K's are known. The y and z equations in (9) and (11) take the form

$$\left.\begin{aligned}\mu_m\mathrm{M}_m &= \mu_{m-1}\mathrm{M}_{m-1}-\eta_m\mathrm{K}_m\\ \eta_{m+1} &= \eta_m+\mu_m\mathrm{M}_m\frac{\tau_m}{\mu_m}\\ \text{and}\quad \mu_m\mathrm{N}_m &= \mu_{m-1}\mathrm{N}_{m-1}-\zeta_m\mathrm{K}_m\\ \zeta_{m+1} &= \zeta_m+\mu_m\mathrm{N}_m\frac{\tau_m}{\mu_m}\end{aligned}\right\}, \quad . \quad (15)$$

from which it is evident that linear relations connect any three of the four members of the groups

$$\mu_0\mathrm{M}_0,\ \eta_1,\ \mu_n\mathrm{M}_n,\ \eta_n,$$
$$\mu_0\mathrm{N}_0,\ \zeta_1,\ \mu_n\mathrm{N}_n,\ \zeta_n.$$

the coefficients being linear functions of the various K's and τ's. The forms of these coefficients may easily be found by induction. Construct the quantities

$$\mathrm{K}_{1,n},\ \frac{\partial\mathrm{K}_{1,n}}{\partial\mathrm{K}_1},\ \frac{\partial\mathrm{K}_{1,n}}{\partial\mathrm{K}_n},\ \frac{\partial^2\mathrm{K}_{1,n}}{\partial\mathrm{K}_1\partial\mathrm{K}_n}$$

from the equations

$$\left.\begin{aligned}\mathrm{K}_{1,m} &= \mathrm{K}_{1,m-1}+\mathrm{K}_m\frac{\partial\mathrm{K}_{1,m}}{\partial\mathrm{K}_m}\\ \frac{\partial\mathrm{K}_{1,m}}{\partial\mathrm{K}_1} &= \frac{\partial\mathrm{K}_{1,m-1}}{\partial\mathrm{K}_1}+\mathrm{K}_m\frac{\partial^2\mathrm{K}_{1,m}}{\partial\mathrm{K}_1\partial\mathrm{K}_m}\\ \frac{\partial\mathrm{K}_{1,m}}{\partial\mathrm{K}_m} &= \frac{\partial\mathrm{K}_{1,m-1}}{\partial\mathrm{K}_{m-1}}-\frac{\tau_{m-1}}{\mu_{m-1}}\mathrm{K}_{1,m-1}\\ \frac{\partial^2\mathrm{K}_{1,m}}{\partial\mathrm{K}_1\partial\mathrm{K}_m} &= \frac{\partial^2\mathrm{K}_{1,m-1}}{\partial\mathrm{K}_1\partial\mathrm{K}_{m-1}}-\frac{\tau_{m-1}}{\mu_{m-1}}\frac{\partial\mathrm{K}_{1,m-1}}{\partial\mathrm{K}_1}\end{aligned}\right\}, \quad (16)$$

by putting m in turn equal to 1, 2 . . . n. The initial values are

$$\mathrm{K}_{1,1}=\mathrm{K}_1;\quad \mathrm{K}_{1,0}=0;\quad \frac{\partial\mathrm{K}_{1,1}}{\partial\mathrm{K}_1}=1;\quad \frac{\partial^2\mathrm{K}_{1,1}}{\partial\mathrm{K}_1^2}=0. \quad (17)$$

Since the equations are linear the quantities thus defined by separate symbols justify the differential form selected, which indicates how the four quantities to which the equations lead are related to one another. It is important to note that the four are not independent in value. For, on combining the first and third of the equations,

$$\mathrm{K}_{1,m}=\left(1-\frac{\tau_{m-1}}{\mu_{m-1}}\mathrm{K}_m\right)\mathrm{K}_{1,m-1}+\mathrm{K}_m\frac{\partial\mathrm{K}_{1,m-1}}{\partial\mathrm{K}_{m-1}},$$

and similarly from the second and fourth

$$\frac{\partial\mathrm{K}_{1,m}}{\partial\mathrm{K}_1}=\left(1-\frac{\tau_{m-1}}{\mu_{m-1}}\mathrm{K}_m\right)\frac{\partial\mathrm{K}_{1,m-1}}{\partial\mathrm{K}_1}+\mathrm{K}_m\frac{\partial^2\mathrm{K}_{1,m-1}}{\partial\mathrm{K}_1\partial\mathrm{K}_{m-1}},$$

and therefore on simplification

$$\begin{aligned}&\frac{\partial\mathrm{K}_{1,m}}{\partial\mathrm{K}_1}\cdot\frac{\partial\mathrm{K}_{1,m}}{\partial\mathrm{K}_m}-\mathrm{K}_{1,m}\frac{\partial^2\mathrm{K}_{1,m}}{\partial\mathrm{K}_1\partial\mathrm{K}_m}\\ &\qquad =\frac{\partial\mathrm{K}_{1,m-1}}{\partial\mathrm{K}_1}\cdot\frac{\partial\mathrm{K}_{1,m-1}}{\partial\mathrm{K}_{m-1}}-\mathrm{K}_{1,m-1}\frac{\partial^2\mathrm{K}_{1,m-1}}{\partial\mathrm{K}_1\partial\mathrm{K}_{m-1}},\end{aligned}$$

and is therefore independent of the value of m. On putting $m=1$ the left side reduces at once to unity and thus the relation

$$\frac{\partial\mathrm{K}_{1,n}}{\partial\mathrm{K}_1}\cdot\frac{\partial\mathrm{K}_{1,n}}{\partial\mathrm{K}_n}-\mathrm{K}_{1,n}\frac{\partial^2\mathrm{K}_{1,n}}{\partial\mathrm{K}_1\partial\mathrm{K}_n}=1 \quad . \quad (18)$$

connects the four quantities.

Returning now to equations (15), say the first pair, assume that for some value of m it has been shown that

$$\left.\begin{aligned}\mu_m\mathrm{M}_m &= \mu_0\mathrm{M}_0\frac{\partial\mathrm{K}_{1,m}}{\partial\mathrm{K}_1}-\eta_1\mathrm{K}_{1,m}\\ \text{and}\quad \eta_m &= -\mu_0\mathrm{M}_0\frac{\partial^2\mathrm{K}_{1,m}}{\partial\mathrm{K}_1\partial\mathrm{K}_m}+\eta_1\frac{\partial\mathrm{K}_{1,m}}{\partial\mathrm{K}_m}\end{aligned}\right\}, \quad . \quad (19)$$

both of which are evidently true for $m=1$. From the second of equations (15)

$$\tau_{m+1} = -\mu_0 M_0 \left\{ \frac{\partial^2 K_{1,m}}{\partial K_1 \partial K_m} - \frac{\tau_m}{\mu_m}\frac{\partial K_{1,m}}{\partial K_1} \right\} + \eta_1 \left\{ \frac{\partial K_{1,m}}{\partial K_m} - \frac{\tau_m}{\mu_m} K_{1,m} \right\}$$

$$= -\mu_0 M_0 \frac{\partial^2 K_{1,m+1}}{\partial K_1 \partial K_{m+1}} + \eta_1 \frac{\partial K_{1,m+1}}{\partial K_{m+1}},$$

by (16). Hence also

$$\mu_{m+1} M_{m+1} = \mu_0 M_0 \left\{ \frac{\partial K_{1,m}}{\partial K_1} + K_{m+1} \frac{\partial^2 K_{1,m+1}}{\partial K_1 \partial K_{m+1}} \right\} - \eta_1 \left\{ K_{1,m} + K_{m+1} \frac{\partial K_{1,m+1}}{\partial K_{m+1}} \right\}$$

$$= \mu_0 M_0 \frac{\partial K_{1,m+1}}{\partial K_1} - \eta_1 K_{1,m+1}$$

by the same equations, thus verifying the accuracy of the forms assumed in (19). Evidently another relation of the same form holds if N and ζ are substituted for M and η respectively. The calculation of the four quantities thus defined therefore serves to determine the direction of the emergent ray, since two direction cosines are found, and the position of the point in which the ray meets the last surface, since this is known from two of the co-ordinates. The ray is thus completely determined.

Before considering how the K's and τ's are to be found, it is desirable to note the symmetrical character of the K's found from formula (16). If the ray already considered were retraced through the system in the reverse direction the individual K's and τ's would be unaltered. This is evident as regards the latter, since they represent lengths which are essentially positive. As regards the former the first factor changes sign since the various refracting media are encountered in the reverse order; this change of sign is compensated by a change in the sign of the curvature, for the surface which was before convex to the incident light is now concave, and *vice versa*. The individual powers, like the individual τ's, thus remain unchanged. It follows that the various quantities to be derived on retracing the path of the ray will be identical with those already obtained if $K_{1,n}$ is symmetrically composed of the component K's and τ's with respect to the two ends. When n is small it is easy to see that this is the case. For instance, if $n=2$,

$$K_{1,2} = K_1 + K_2 - \frac{\tau_1}{\mu_1} K_1 K_2,$$

and if $n=3$,

$$K_{1,3} = K_1 + K_2 + K_3 - \frac{\tau_1}{u_1} K_1 K_2 - \left(\frac{\tau_1}{\mu_1} + \frac{\tau_2}{\mu_2} \right) K_1 K_3 - \frac{\tau_2}{\mu_2} K_2 K_3 + \frac{\tau_1}{\mu_1} \frac{\tau_2}{\mu_2} K_1 K_2 K_3$$

when written out in full. To show it in general construct the quantities

$$K'_{1,n}, \quad \frac{\partial K'_{1,n}}{\partial K_1}, \quad \frac{\partial K'_{1,n}}{\partial K_n}, \quad \frac{\partial^2 K'_{1,n}}{\partial K_1 \partial K_n}$$

by repeated application of

$$\left. \begin{aligned} K'_{m,n} &= K'_{m+1,n} + K_m \frac{\partial K'_{m,n}}{\partial K_m} \\ \frac{\partial K'_{m,n}}{\partial K_m} &= \frac{\partial K'_{m+1,n}}{\partial K_{m+1}} - \frac{\tau_m}{\mu_m} K'_{m+1,n} \\ \frac{\partial K'_{m,n}}{\partial K_n} &= \frac{\partial K'_{m+1,n}}{\partial K_n} + K_m \frac{\partial^2 K'_{m,n}}{\partial K_m \partial K_n} \\ \frac{\partial^2 K'_{m,n}}{\partial K_m \partial K_n} &= \frac{\partial^2 K'_{m+1,n}}{\partial K_{m+1} \partial K_n} - \frac{\tau_m}{\mu_m} \frac{\partial K'_{m+1,n}}{\partial K_n} \end{aligned} \right\} . \quad (20)$$

It follows exactly as before, that

$$\frac{\partial K'_{1,n}}{\partial K_1} \cdot \frac{\partial K'_{1,n}}{\partial K_n} - K'_{1,n} \frac{\partial^2 K'_{1,n}}{\partial K_1 \partial K_n} = 1, \quad . \quad (21)$$

and that

$$\left. \begin{aligned} \mu_0 M_0 &= \mu_n M_n \frac{\partial K'_{1,n}}{\partial K_n} + \eta_n K'_{1,n}, \\ \eta_1 &= \mu_n M_n \frac{\partial^2 K'_{1,n}}{\partial K_1 \partial K_n} + \eta_n \frac{\partial K'_{1,n}}{\partial K_1} \end{aligned} \right\}, \quad . \quad (22)$$

as may indeed be inferred by analogy on noting that the M's and N's are changed in sign with the reversal of the ray, while the η's and ζ's are unaltered. Now eliminate η_n from (22); thus

$$\mu_0 M_0 \frac{\partial K'_{1,n}}{\partial K_1} - \eta_1 K'_{1,n} = \mu_n M_n$$

by (21); similarly on eliminating M_n

$$-\mu_0 M_0 \frac{\partial^2 K'_{1,n}}{\partial K_1 \partial K_n} + \eta_1 \frac{\partial K'_{1,n}}{\partial K_n} = \eta_n,$$

with similar relations between the N's and ζ's. Comparison of these relations with (19) shows that $K_{1,n}$ and $K'_{1,n}$ are identical.

It still remains to find the individual K's and τ's so that four co-ordinates sufficient to determine the final ray can be found from (19) and the corresponding equations with N and ζ substituted for M and η. Formulae for this purpose may be arranged in many different forms, each of which has its own special advantage. In general the simplest forms for the purposes of numerical work are open to the objection that they assume indeterminate forms for flat surfaces and cause loss of accuracy for surfaces of slight curvature. On the other hand, forms may readily be found of universal applicability which involve no loss of accuracy, but they require a slight extension in the number of operations at each surface.

It is not possible in the space available for this article to discuss thoroughly any of these forms, but since accuracy is usually more important than brevity one of the many possible arrangements of the second class may be noted. Let the square of the distance of the point of refraction from the vertex of the surface be denoted by 2χ, and the lengths intercepted on the incident and refracted rays between the feet of perpendiculars to them from the vertex and the point of refraction be respectively p and p'. χ is invariant on refraction, and by (6)

$$\xi = \chi R,$$

and therefore from (9) p and p' are connected by the relation

$$\mu'p'=\mu p-\chi K, \quad . \quad . \quad . \quad (23)$$

while the inclination of the ray to the axis after refraction takes the form

$$L'=\cos\phi'+p'R. \quad . \quad . \quad . \quad (24)$$

It is at once evident that to complete the system for tracing rays it is only necessary to derive equations giving the values of χ, p, and $\cos\phi$ for the next surface. Equation (12) gives

$$\sin^2\phi_{m+1}=(1+t_mR_{m+1})^2-\{L_m(1+t_mR_{m+1})-p'_mR_{m+1}\}^2-2\chi_m a_m R_m R^2_{m+1}, \quad (25)$$

a result easily derived directly from a figure. Since

$$a_mR_mR_{m+1}=R_m-R_{m+1}+t_mR_mR_{m+1},$$

every term in the equation is always finite, and $\cos\phi_{m+1}$, $\cos\phi'_{m+1}$, and K_{m+1} are derived in the usual way after the extraction of two square roots. From equation (8) the value of τ_m is found—

$$\tau_m=\frac{t_m(2+t_mR_{m+1})-2\chi_m a_mR_mR_{m+1}}{L_m(1+t_mR_{m+1})-p'_mR_{m+1}+\cos\phi_{m+1}}, \quad (26)$$

and other obvious relations are

$$p_{m+1}=p'_m+\tau_m-t_mL_m, \quad . \quad . \quad (27)$$

$$\chi_{m+1}(2+t_mR_{m+1})=\chi_m(2-t_mR_m)+\tau_m(p_{m+1}+p'_m). \quad (28)$$

§ (3) Advantages of the Method.—The whole process, though quite straightforward, is somewhat tedious, but experience shows that in this respect it is in no way inferior to the logarithmic method generally used in the past, for the references to tables which that system involves, and which take up a large part of the total time, are completely avoided. The advantages of the algebraic method do not, however, end here, for the results not only give the point of intersection of the emergent ray with the assumed image surface, but it is seen at once whether the whole of the image in the neighbourhood of the point to which the rays relate is free from defects. In the most usual case both object and image surfaces are required to be planes normal to the axis. If aberrations are absent in the image of the point from which the rays considered have been traced, the condition for freedom in the neighbouring portion of the image plane is that the values of $K_{1,n}$ for all these rays shall be identical. Further important information is derivable from the way in which the value of $K_{1,n}$ depends upon the position of the object point from which the ray has been traced.

The significance of $K_{1,n}$ and the derived quantities is made clear by considering the co-ordinates of points on the ray in the object and image spaces at selected distances (measured along the ray) from the first and last surfaces. Let these distances measured in the positive direction from the surfaces be denoted by ρ and ρ', so that their co-ordinates satisfy

$$y=\eta_1+M_0\rho, \qquad y'=\eta_n+M_n\rho',$$
$$z=\zeta_1+N_0\rho, \qquad z'=\zeta_n+N_n\rho',$$

and therefore by (19)

$$y'+y\left(\frac{\rho'}{\mu_n}K_{1,n}-\frac{\partial K_{1,n}}{\partial K_n}\right)$$
$$=\mu_0M_0\left\{\frac{\rho}{\mu_0}\cdot\frac{\rho'}{\mu_n}K_{1,n}-\frac{\rho}{\mu_0}\frac{\partial K_{1,n}}{\partial K_n}+\frac{\rho'}{\mu_n}\frac{\partial K_{1,n}}{\partial K_1}-\frac{\partial^2 K_{1,n}}{\partial K_1\partial K_n}\right\}$$
$$=\frac{\mu_0M_0}{K_{1,n}}\left\{\left(\frac{\rho}{\mu_0}K_{1,n}+\frac{\partial K_{1,n}}{\partial K_1}\right)\left(\frac{\rho'}{\mu_n}K_{1,n}-\frac{\partial K_{1,n}}{\partial K_n}\right)+1\right\} \quad (29)$$

by (18). A similar relation holds if z and N are substituted for y and M. Now considerations of symmetry show that we should expect to find the image point in the same axial plane as the object point, or

$$\frac{y'}{y}=\frac{z'}{z}=G, \text{ say.}$$

If the image is plane and free from aberrations G is obviously its linear magnification compared with the object, and will be positive if the image is upright, negative if the image is inverted. Without assuming that aberrations are absent we may conveniently regard G as a magnification associated for a given object point with this particular ray.

§ (4) Conjugate Points.—Equation (29) shows that if by conjugate points we mean a pair of points on the ray, one in the object space and one in the image space, which lie in the same axial plane, their distances from the end surfaces are connected by the relation

$$\frac{\rho}{\mu_0}\cdot\frac{\rho'}{\mu_n}K_{1,n}-\frac{\rho}{\mu_0}\frac{\partial K_{1,n}}{\partial K_n}+\frac{\rho'}{\mu_n}\frac{\partial K_{1,n}}{\partial K_1}-\frac{\partial^2K_{1,n}}{\partial K_1\partial K_n}=0 \quad (30)$$

and that in terms of the magnification G,

$$\left.\begin{aligned}-\frac{\rho}{\mu_0}K_{1,n}&=\frac{\partial K_{1,n}}{\partial K_1}-\frac{1}{G}\\ \frac{\rho'}{\mu_n}K_{1,n}&=\frac{\partial K_{1,n}}{\partial K_n}-G\end{aligned}\right\}. \quad . \quad (31)$$

Particular instances of these results of great importance in the theory of optical instruments are that the image of the first surface of the instrument is within the image space at a distance

$$\mu_n\frac{\partial^2K_{1,n}}{\partial K_1\partial K_n}\bigg/\frac{\partial K_{1,n}}{\partial K_1}$$

from the last surface, and that for light travelling in the reverse direction the image

of the nth surface is in the first medium at a distance

$$\mu_0 \frac{\partial^2 K_{1,n}}{\partial K_1 \partial K_n} \Big/ \frac{\partial K_{1,n}}{\partial K_n}$$

from the first surface. Again, if the ray traced is a member of a pencil which is refracted telescopically, so that $K_{1,n}=0$, the magnification is independent of the distance of the object if this is finite, and is equal to $\partial K_{1,n}/\partial K_n$, or $1/(\partial K_{1,n}/\partial K_1)$. It is important, however, to note from (30) that the fact of a system being telescopic does not mean that the image of an object at a finite distance is not itself at a finite distance. On the contrary, the peculiarity of the telescope is that it is only objects which are themselves at infinity which have an image at an infinite distance from the instrument.

Conjugate points have so far been defined as the points in which a skew ray meets an axial plane. It is important to extend the definition in such a way as to have a definite meaning when the ray lies entirely in a plane. Equation (30) would serve as a basis for this purpose, for this equation remains determinate whether the ray lies in a plane or not. An alternative definition of importance which is consistent with this is obtained by eliminating $\partial K_{1,n}/\partial K_1$ and $\partial K_{1,n}/\partial K_n$ from (31) by means of (19) and (22). Thus

$$\left.\begin{aligned} \mu_0 M_0 - G\mu_n M_n &= GyK_{1,n} = y'K_{1,n} \\ \mu_0 N_0 - G\mu_n N_n &= GzK_{1,n} = z'K_{1,n} \end{aligned}\right\}, \qquad (32)$$

or eliminating G,

$$K_{1,n} = \frac{\mu_0 M_0}{y'} - \frac{\mu_n M_n}{y} = \frac{\mu_0 N_0}{z'} - \frac{\mu_n M_n}{z}. \qquad (33)$$

If a ray lies very nearly in an axial plane, say the plane $z=0$, all the N's and ζ's will be small quantities of the first order, and K will differ from the value for a ray actually in this plane by a second order quantity. It follows that the conjugate points for a ray in a plane are the points of intersection of the ray with the focal line which lies in the axial plane when the image is not free from aberration.

§ (5) Paraxial Rays and Collinear Images.—An example of the first importance of the application of the above formulae is for rays which meet each surface near its vertex and which always make small angles with the axis. In such cases, if second order quantities are neglected, every cos ϕ and cos ϕ' may be replaced by unity and every τ reduces to t, the axial thickness. It is convenient to denote the special value of the K in this instance by κ, so that

$$\kappa_m = (\mu_m - \mu_{m-1})R_m, \qquad (34)$$

and the four fundamental Gaussian constants of the system are derived by applying equations modelled on (16) or (20). The quantity $\kappa_{1,n}$ is called the power of the system, and its simplest interpretation is expressed in terms of the change of curvature an incident paraxial wave front undergoes on traversing the system.

Since $\kappa_{1,n}$ is invariable for all paraxial rays, whether skew or plane, it follows that the image of any plane object normal to the axis formed by such rays itself lies in a plane normal to the axis, and since all these rays enter and leave the system at points indistinguishable from points in the tangent planes to the first and last surfaces at their vertices, there will be no aberrations in the images formed by the rays, and the image will be identical with that which would result from collinear theories of imagery. This result, however, cannot in general hold for non-paraxial rays. For suppose there is no aberration over the whole plane image of a plane object when the magnification is G. By analogy with (31) the object and image planes for paraxial rays for magnification G′ will be displaced along the axis by

$$\mu_0 \frac{(1/G' - 1/G)}{\kappa_{1,n}} \text{ and } \mu_n \frac{G - G'}{\kappa_{1,n}}$$

from those for magnification G. It at once follows from (31) that if L_0 and L_n are the cosines of the inclination of the ray to the axis before and after refraction the magnification for the point in which this general ray meets the new object plane is G″, where

$$\left(\frac{1}{G''} - \frac{1}{G}\right)\frac{1}{K_{1,n}} = \left(\frac{1}{G'} - \frac{1}{G}\right)\frac{1}{L_0 \kappa_{1,n}},$$

and its conjugate point is not in the new image plane for paraxial rays, but at a perpendicular distance from it equal to

$$\frac{\mu_n (G - G')\{G(L_n \kappa_{1,n} - K_{1,n}) + G'(L_0 \kappa_{1,n} - K_{1,n})\}}{\kappa_{1,n}\{GK_{1,n} + G'(L_0 \kappa_{1,n} - K_{1,n})\}}.$$

The conjugate point will therefore only coincide with the collinear image point if

$$L_0 = L_n = \frac{K_{1,n}}{\kappa_{1,n}}, \qquad (35)$$

a relation which cannot hold for wide pencils of rays. It follows that collinear imagery in general is impossible, but that where an approach to it is of importance, as in photographic objectives, the most satisfactory results will be obtained by so arranging the stops that rays shall, as far as possible, lie after refraction parallel to their incident directions, or, in other words, the centres of the stops should lie close to the nodal points.

The impossibility of collinear imagery is seen more readily from (31) if the result given earlier but not yet proved is assumed, that $K_{1,n}$ must have a constant value for rays passing through any given point of the aberra-

tionless plane image. These equations at once show that the conjugate points for some other value of the magnification lie on the surfaces of spherical shells with the points in this plane as centres. The confused character of the image elsewhere is at once apparent on considering the aggregate of these surfaces. Evidently the more unequal the inclinations of the rays to the axis before and after refraction the more complete is the confusion out of the proper image plane for which the system is corrected, and hence follows the supreme importance of exact focussing with microscope objectives of large numerical aperture.

§ (6) PRINCIPLES OF IMAGE CORRECTION.—Equations (31) and (35) show that it is to be expected that $K_{1,n}$, while agreeing in sign with $\kappa_{1,n}$, should be numerically smaller in the case of all rays concerned with images in the outer parts of the field of view. On the other hand, for a single surface at which the deviation is δ equations (9) give

$$\left(\frac{K}{\kappa}\right)^2 = 1 + \frac{2\mu\mu'(1-\cos\delta)}{(\mu'-\mu)^2},$$

so that at every surface K tends to be greater than κ, which is its minimum value in refraction. This natural tendency to bad correction is accentuated where τ tends to be smaller than t, as in a simple converging lens. It can evidently be corrected in two ways: either there must be in the system some surfaces having powers differing in sign from that of the complete system, and at which the incidence of the marginal and oblique rays tends to be greater than in the case of surfaces of like power to that of the entire system, or, alternatively, the system may be constructed of separated lenses so arranged that the τ's for the marginal and oblique rays exceed the corresponding t's to an extent which more than compensates for the increased values of the K's due to the oblique incidence. As a rule where the principle of separation is employed the alternative principle is introduced as well. These two principles will provide a key to the design of many optical systems.

§ (7) THIN LENSES.—It will not be possible here to attempt any detailed discussion of the general problem of lens design, but on account of its importance in physical instruments some consideration will be given to the theory of "thin" lenses and the application of the results to lenses which it is possible to construct and which may be called "close" lenses, from the consideration that while their thicknesses are not negligible, yet they are kept as small as the attainment of the required aperture and power will allow, some margin being allowed in addition to secure the minimum substance necessary both for strength in use and for the rigidity in working on which the attainment of surfaces of good figure depends.

Consider, in the first place, a single lens of material of refractive index μ immersed in air. Suppose that the axial thickness is small, though not necessarily zero. The curvatures of the surfaces are R_1 and R_2. For convenience write ϖ for $1/\mu$. Then if ρ and ρ' are the distances from the two surfaces of the conjugate points for which $G=1$, equations (31) give

$$\rho K_{1,2} = \varpi\tau K_2, \quad \rho' K_{1,2} = -\varpi\tau K_1,$$

and similar formulae apply to paraxial rays with κ and t substituted for K and τ. If τ is not large, and the inclination of the ray to the axis is small, the distance of the ray from the axis will be approximately equal at the intersections with the surfaces of the lens and at the unit points as defined above. Denote the square of this distance by 2χ. Then these points will lie on spheres of curvatures σ and σ' through the axial unit points, where

$$\chi R_1 + \frac{\varpi\tau K_2}{K_{1,2}} = \frac{\varpi t\kappa_2}{\kappa_{1,2}} + \chi\sigma,$$

and
$$\chi R_2 - \frac{\varpi\tau K_1}{K_{1,2}} = -\frac{\varpi t\kappa_1}{\kappa_{1,2}} + \chi\sigma';$$

also
$$\chi R_1 + \tau = t + \chi R_2,$$

and therefore, neglecting to this approximation the differences between the K's and κ's as well as the squares of t and τ,

$$\sigma - \sigma' = (R_1 - R_2)(1-\varpi),$$
$$= \varpi\kappa_{1,2}, \quad . \quad . \quad . \quad . \quad (36)$$

if the thickness is neglected.

The unit surfaces therefore cannot both be planes in a thin lens. It should be noted that their relative curvature has the opposite sign to that of wave surfaces refracted paraxially, for the curvature of the refracted wave exceeds that of the incident wave by $\kappa_{1,2}$. Thus the statement sometimes made that a wave front, which at some instant coincides with some object surface will at some subsequent instant after refraction coincide with the corresponding image surface is incorrect. On the simplest general grounds, the idea that the time taken to form the image of, say, a plane surface is independent of the part of the image considered is evidently without foundation.

From (31) it is easily seen that if the suffixes 1 and 2 are used to denote two different pairs of conjugate points on a ray

$$\frac{\rho_1' - \rho_2'}{\mu_n} = \frac{\rho_1 - \rho_2}{\mu_0} G_1 G_2.$$

It follows that the magnification in the immediate neighbourhood of these surfaces

is unity in all directions, and that the curvature of any object near the first surface exceeds that of the image by the constant amount $\varpi\kappa_{1,2}$.

It remains to be seen how the exact value of the curvatures of these unit surfaces depends on the shape of the lens itself. From symmetry the curvatures will become equal and opposite in sign when the same is true of the refracting surfaces of the lens. On adding and simplifying, the equations giving σ and σ' lead to

$$\sigma+\sigma'=(R_1+R_2)(1+\varpi),$$

so that the increment of the curvature of each surface of the lens by a given amount increases the curvature of each unit surface by $(1+\varpi)$ times that amount. If the lens is thin and the curvature of each surface exceeds that of the equiconvex form by $S\kappa_{1,2}$ the curvatures of the unit surfaces are

$$\{\tfrac{1}{2}\varpi+S(1+\varpi)\}\kappa_{1,2} \text{ and } \{-\tfrac{1}{2}\varpi+S(1+\varpi)\}\kappa_{1,2}$$

respectively. These results can be readily derived from the consideration of a positive lens of small thickness the surfaces of which intersect when the aperture is small, if it is assumed that unit surfaces exist, that they are spherical and pass through the axial unit points and the circle in which the lens surfaces meet. It is evident from (31) and (32) that the shape of the unit surfaces, and hence the shape of the lens, affords means of altering the relation between M_0 and M_2 or N_0 and N_2 while maintaining a constant value for the paraxial power.

The conclusion that the unit surfaces are not planes prompts the inquiry whether a similar conclusion is true for images remote from the lens. The investigation is made most simply by considering a lens of zero thickness, and regarding the rays which are refracted at the common vertex of the surfaces. At the first surface

$$\cos\phi_1=1-\tfrac{1}{2}(M_0^2+N_0^2),$$

$$\cos\phi_1'=1-\frac{1}{2\mu^2}(M_0^2+N_0^2) \text{ approximately,}$$

and therefore

$$K_1=\kappa_1\left\{1+\frac{\varpi}{2}(M_0^2+N_0^2)+\ .\ .\ .\right\}.$$

Similarly at the second surface

$$K_2=\kappa_2\left\{1+\frac{\varpi}{2}(M_2^2+N_2^2)+\ .\ .\ .\right\},$$

but since refraction is at this point through a thin parallel film $M_2=M_0$, $N_2=N_0$. Thus for the lens as a whole

$$K_{1,2}=\kappa_{1,2}\left\{1+\frac{\varpi}{2}(M_0^2+N_0^2)+\ .\ .\ .\right\}, \quad (37)$$

and for magnification G the object surface in the neighbourhood of the axis is a sphere of curvature

$$\frac{(1+\varpi)\kappa_{1,2}}{1-1/G},$$

and the image surface a sphere of curvature

$$-\frac{(1+\varpi)\kappa_{1,2}}{1-G}.$$

The curvature of the object surface thus exceeds that of the image surface by the constant amount

$$(1+\varpi)\kappa_{1,2},$$

a result which it is easy to extend to the image of any spherical object since (30) takes the form

$$\frac{1}{\rho'}-\frac{1}{\rho}=K. \quad . \quad . \quad . \quad (38)$$

It will be borne in mind that in this discussion we have interpreted the "image" as the intersection of the ray with the focal line contained in an axial plane. It will be necessary later to consider the surfaces in which the focal line normal to an axial plane meets the ray, and the corresponding results will be found to differ from those derived above only in the numerical coefficients to be assigned to the characteristic terms.

It is desirable to extend these results to a system consisting of any number of thin lenses in contact with one another on the axis. For an oblique ray refracted through the system at the common vertex equations such as (37) and (38) apply to each individual lens, and since the K's are directly additive the above results may be at once applied to the complete system by substituting

$$(1+\varpi_{1,n})\kappa_{1,n}$$

for the special case with $n=2$, $\varpi_{1,n}$ being defined by

$$\varpi_{1,n}\kappa_{1,n}=\Sigma\varpi_m\kappa_{m,m+1}, \quad . \quad . \quad (39)$$

where the summation includes each thin lens of the system.

The results first established relating to the shape of the unit surfaces may now be extended. It is not permissible, without further examination, to infer that the ϖ appearing in the expressions for the curvatures of these surfaces in the case of a single lens may be generalised for a group of lenses according to the law expressed by (39). The axial thickness will be taken as zero, and the values of the τ's for a non-paraxial ray sufficiently small for the product of any two or more τ's to be negligible. The assumption that we are treating rays which traverse the system approximately at a constant distance from the axis gives

$$\tau_m=\chi(R_{m+1}-R_m),$$

and if the external media are of unit refractive index

$$\chi\sigma=\chi R_1+\rho,$$

$$\chi\sigma'=\chi R_n+\rho'.$$

To the approximation here required

$$\frac{\partial K_{1,n}}{\partial K_1}=1-\Sigma\varpi_m\tau_m\kappa_{m+1,n},$$

$$\frac{\partial K_{1,n}}{\partial K_n}=1-\Sigma\varpi_m\tau_m\kappa_{1,m},$$

$$K_{1,n}=\kappa_{1,n},$$

and therefore

$$\left.\begin{aligned}\sigma&=R_1+\frac{1}{\kappa_{1,n}}\Sigma\varpi_m(R_{m+1}-R_m)\kappa_{m+1,n}\\ \sigma'&=R_n-\frac{1}{\kappa_{1,n}}\Sigma\varpi_m(R_{m+1}-R_m)\kappa_{1,m}\end{aligned}\right\}, \quad (40)$$

where the summations extend over the internal media, *i.e.* from $m=1$ to $m=n-1$. Considering first the curvature difference

$$\begin{aligned}\sigma-\sigma'&=R_1-R_n+\Sigma\varpi_m(R_{m+1}-R_m)\\ &=\sum_1^n R_m(\varpi_{m-1}-\varpi_m)\\ &=\sum_1^n \kappa_m\varpi_{m-1}\varpi_m\\ &=\varpi_{1,n}\kappa_{1,n}, \quad . \quad . \quad . \quad . \quad . \quad . \quad (41)\end{aligned}$$

by (39) since we are regarding, as we may do without any loss of generality, that every alternate medium is that in which the whole system of thin lenses is immersed, and thus has its ϖ equal to unity.

By addition (40) gives

$$\sigma+\sigma'=R_1+R_n$$
$$-\frac{1}{\kappa_{1,n}}\Sigma\varpi_m(R_{m+1}-R_m)(\kappa_{1,m}-\kappa_{m+1,n}).$$

It is convenient to group together the curvatures in pairs, taking together each odd m with the next higher even integer. Each ϖ of even suffix is unity. The equation then reduces immediately to

$$(\sigma+\sigma')\kappa_{1,n}=\Sigma(R_m+R_{m+1})\kappa_{m,m+1}(1+\varpi_m)$$
$$+\Sigma\varpi_m\kappa_{m,m+1}(\kappa_{1,m-1}-\kappa_{m+2,n}),$$

where the summation is taken for all the individual lenses, m having all odd values from 1 to $n-1$ inclusive. Since σ and σ' have the dimensions of a curvature, we may write

$$\sigma+\sigma'=\beta\kappa_{1,n}, \quad . \quad . \quad . \quad . \quad (42)$$

where β is a pure number, and if we take S_m as the deformation of the typical lens from its symmetrical form we find, with a slight alteration in the notation,

$$\beta\kappa_{1,n}^2=2\Sigma S_m(1+\varpi_m)\kappa_m^2$$
$$+\Sigma\varpi_m\kappa_m(\kappa_{1,m}-\kappa_{m,n}), \quad (43)$$

where now κ_m is the power of a complete component lens, and not of a single surface.

If the curvature of every surface in the system is increased by the same amount $S\kappa_{1,n}$, it is evident that β is increased by

$$2S(1+\varpi_{1,n}), \quad . \quad . \quad . \quad (44)$$

a result in complete accordance with that found for a single lens. It is not difficult to establish the generalised results (41), (42) from those for the single lens in their general form by so bending the system as a whole that the corresponding unit surfaces of the components have the same curvature while the required difference of curvature in the boundaries of the air lens is maintained.

It would be quite possible to take as the standard form for reference in this compound system that configuration in which the curvatures of the unit surfaces are equal and opposite, but it is found more convenient to adopt the form determined by the condition

$$\beta\kappa_{1,n}^2=\Sigma S_m\kappa_m^2, \quad . \quad . \quad . \quad (45)$$

for reasons which will shortly be apparent. In the lens combinations found in actual instruments the values of β determined by this condition are invariably small.

The fact that the curvatures of the unit surfaces have been found in a form which only involves the powers for paraxial rays shows that the results obtained apply for all rays, whether skew or otherwise, which satisfy the assumptions made in this investigation. In particular no distinction need be drawn between the two focal lines, the results thus differing markedly from those which hold for the images of objects at some distance from the lens. The unit surfaces in the neighbourhood of the axis of a thin lens are entirely free from astigmatism, and indeed it is this fact which makes the presence of astigmatism elsewhere unavoidable. It appears necessary for astigmatism to be present throughout the field of such systems as are of practical importance, with the possible exception of limited regions, and to obtain freedom from astigmatism where it is required, as in photographic lenses, it is necessary to introduce it in the neighbourhood of the lenses themselves. It is for this reason that in systems where the correction of astigmatism is desired a number of lenses well separated from one another are employed. Such systems tend to be the reverse of compact, and much skill is called for in combining to as great an extent as is possible the contradictory requirements of a compact lens and a field corrected for astigmatism.

§ (8) THIN LENSES—DETAILED CONSIDERATION.—Having now located the unit surfaces for any thin system it is next necessary to consider how $K_{1,n}$ varies not merely with the obliquity of the ray but also with the distance of its point of incidence from the axis. Approximate values of the τ's are known, and it has been shown that the difference between the K for any surface and the corresponding κ depends upon $1-\cos\delta$, where δ is the deviation at this surface. It is important that all the new terms should be expressed in terms of the external independent variables, and equations (19) and (22) will first be transformed to express the direction and position

of the ray at an intermediate stage of its passage through the system in terms of its initial and final co-ordinates. Let η and ζ without any suffix indicate the co-ordinates derived from (31) by putting $G=1$. Then η and ζ may relate at will to either the object or the image space. Equations (32) give

$$\left.\begin{aligned}\eta K_{1,n}&=\mu_0 M_0-\mu_n M_n\\ \zeta K_{1,n}&=\mu_0 N_0-\mu_n N_n\end{aligned}\right\} \quad . \quad . \quad . \quad (46)$$

Equations of the form of (19) and (22) provide independent sets of equations for any of the intermediate quantities, and on simplifying by using well-known relations there result the relations

$$\left.\begin{aligned}\mu_m M_m K_{1,n}&=\mu_0 M_0 K_{m+1,n}+\mu_n M_n K_{1,m}\\ \eta_m K_{1,n}&=\mu_0 M_0\frac{\partial K_{m,n}}{\partial K_m}-\mu_n M_n\frac{\partial K_{1,m}}{\partial K_m}\end{aligned}\right\}, \quad (47)$$

with similar equations for N_m and ζ_m.

For the special case of a thin system it is convenient to rearrange these equations, substituting κ's for K's in the form

$$2\mu_m M_m=\mu_0 M_0+\mu_n M_n-\eta(\kappa_{1,m}-\kappa_{m+1,n}),$$

so that

$$\begin{aligned}2(M_m-M_{m-1})=\frac{\mu_m-\mu_{m-1}}{\mu_m\mu_{m-1}}[&-(\mu_0 M_0+\mu_n M_n)\\ &+\eta\{\kappa_{1,m}-\kappa_{m,n}-R_m(\mu_m+\mu_{m-1})\}]\end{aligned}$$

and therefore

$$\begin{aligned}K_m=\kappa_m+\frac{\kappa_m}{8\mu_m\mu_{m-1}}[&(\mu_0 M_0+\mu_n M_n)^2+(\mu_0 N_0+\mu_n N_n)^2\\ &-2\{(\mu_0 M_0+\mu_n M_n)\eta+(\mu_0 N_0+\mu_n N_n)\zeta\}\\ &\times\{\kappa_{1,m}-\kappa_{m,n}-R_m(\mu_m+\mu_{m-1})\}\\ &+(\eta^2+\zeta^2)\{\kappa_{1,m}-\kappa_{m,n}-R_m(\mu_m+\mu_{m-1})\}^2].\end{aligned}$$

Now introduce the conditions that the external media are of unit refractive index, and suppose also that the same is true of the media ${}_{m-1}$ and ${}_{m+1}$. Then after slight simplification

$$\begin{aligned}K_m+K_{m+1}=\kappa_{m,m+1}&\\ &+\tfrac{1}{8}\{(M_0+M_n)^2+(N_0+N_n)^2\}\varpi_m\kappa_{m,m+1}\\ &+\tfrac{1}{4}\{(M_0+M_n)\eta+(N_0+N_n)\zeta\}\{(R_m+R_{m+1})(1+\varpi_m)\\ &-(\kappa_{1,m-1}-\kappa_{m+2,n})\varpi_m\}\kappa_{m,m+1}\\ &+\tfrac{1}{8}(\eta^2+\zeta^2)\{4R_m^2\kappa_m+4R_{m+1}^2\kappa_{m+1}\\ &-2(R_m+R_{m+1})(\kappa_{1,m-1}-\kappa_{m+2,n})(1+\varpi_m)\kappa_{m,m+1}\\ &+2(R_m-R_{m+1})(1+\varpi_m)\kappa_m\kappa_{m+1}\\ &+(\kappa_{1,m-1}-\kappa_{m+2,n})^2\varpi_m\kappa_{m,m+1}\\ &+\varpi_m(\kappa_m^2+\kappa_{m+1}^2)\kappa_{m,m+1}\}.\end{aligned}$$

The simplification of the last term will not yield the correct coefficient for $(\eta^2+\zeta^2)$ on summing up for the component lenses, for $K_{1,n}$ is less than ΣK_m by the amount

$$\Sigma\frac{\tau_m}{\mu_m}\kappa_{1,m}\kappa_{m+1,n},$$

and the terms in this sum which involve R_m and R_{m+1} are

$$\begin{aligned}&\tfrac{1}{2}(\eta^2+\zeta^2)[R_m\kappa_{1,m-1}\kappa_{m,n}\\ &\quad+(R_{m+1}-R_m)\varpi_m\kappa_{1,m}\kappa_{m+1,n}-R_{m+1}\kappa_{1,m+1}\kappa_{m+2,n}]\\ &\quad=\tfrac{1}{8}(\eta^2+\zeta^2)[(R_m-R_{m+1})(1-\varpi_m)\kappa_{1,n}^2\\ &\qquad-R_m(\kappa_{1,m-1}-\kappa_{m,n})^2\\ &\qquad-(R_{m+1}-R_m)\varpi_m(\kappa_{1,m}-\kappa_{m+1,n})^2\\ &\qquad+R_{m+1}(\kappa_{1,m+1}-\kappa_{m+2,n})^2]\\ &=\tfrac{1}{8}(\eta^2+\zeta^2)[\varpi_m\{\kappa_{1,n}^2-(\kappa_{1,m-1}-\kappa_{m+2,n})^2\}\\ &\qquad+2(R_m+R_{m+1})(1+\varpi_m)(\kappa_{1,m-1}-\kappa_{m+2,n})\\ &\qquad-(R_m-R_{m+1})\kappa_{m,m+1}\\ &\qquad+(1-\varpi_m)(R_m+R_{m+1})^2]\kappa_{m,m+1}.\end{aligned}$$

On taking these terms into account, it is found that

$$\begin{aligned}K_{1,n}=\kappa_{1,n}&+\tfrac{1}{8}\{(M_0+M_n)^2+(N_0+N_n)^2\}\varpi_{1,n}\kappa_{1,n},\\ &+\tfrac{1}{4}\{(M_0+M_n)\eta+(N_0+N_n)\zeta\}\beta\kappa_{1,n}^2,\\ &+\tfrac{1}{8}(\eta^2+\zeta^2)(\gamma-\varpi_{1,n}-1)\kappa_{1,n}^3, \quad . \quad . \quad (48)\end{aligned}$$

where, since

$$\kappa_{1,n}^3=\Sigma\kappa_m^3+3\Sigma(\kappa_{1,m}-\kappa_{m,n})^2\kappa_m,$$

$$\begin{aligned}\gamma\kappa_{1,n}^3=\Sigma\Bigl\{\Bigl(\frac{\kappa_m}{1-\varpi_m}\Bigr)^2&+4(1+2\varpi_m)S_m^2\kappa_m^2\\ &-8(1+\varpi_m)S_m\kappa_m(\kappa_{1,m}-\kappa_{m,n})\\ &+(3+2\varpi_m)(\kappa_{1,m}-\kappa_{m,n})^2\Bigr\}\kappa_m, \quad (49)\end{aligned}$$

and each κ now relates to a separate thin lens.

When the curvature of every surface in the system is increased by the same amount $S\kappa_{1,n}$, $\varpi_{1,n}$ remains constant, and the change in β has already been considered. The increase in $\gamma\kappa_{1,n}^3$ is, by (49),

$$\begin{aligned}4S^2\kappa_{1,n}^2&\Sigma(1+2\varpi_m)\kappa_m\\ &+8S\kappa_{1,n}\Sigma\{(1+2\varpi_m)S_m\kappa_m^2\\ &-(1+\varpi_m)(\kappa_{1,m}-\kappa_{m,n})\kappa_m\}\end{aligned}$$

or

$$4(1+2\varpi_{1,n})S^2\kappa_{1,n}^3+8(\beta\kappa_{1,n}^2-\Sigma S_m\kappa_m^2)S\kappa_{1,n},$$

and the meaning of the selection of condition (45) for the determination of the standard form is that we are choosing the configuration for which γ is a minimum. Any general curvature change from this form alters β according to a linear and γ according to a parabolic law.

It is easy to discover a meaning for the new quantity γ. Consider a beam of light arising from a point on the axis placed to give an inverted image of a small transverse object equal to the object itself for paraxial rays. To the approximation here required the refracted ray lies in the direction determined by $M_0+M_n=N_0+N_n=0$. Let A (*Fig.* 4) be the object point, B its paraxial image, and B′ the point in which a non-paraxial ray meets the axis. Let this ray meet the unit surfaces

whose vertices are at C, C′ in the points P, P′ and the spheres through C and C′ with centres

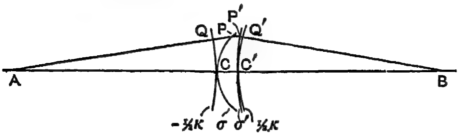

FIG. 4.

A and B in Q and Q′. Then Q, P, P′, Q′ lie on spheres of curvatures

$$-\tfrac{1}{2}\kappa_{1,n},\ \sigma, \sigma', \tfrac{1}{2}\kappa_{1,n},$$

so that

$$QP = \tfrac{1}{2}(\tfrac{1}{2}\kappa_{1,n} + \sigma)(\eta^2 + \zeta^2),$$

$$P'Q' = \tfrac{1}{2}(\tfrac{1}{2}\kappa_{1,n} - \sigma')(\eta^2 + \zeta^2),$$

and

$$\frac{1}{AP} + \frac{1}{P'B} = \frac{1}{(2/\kappa_{1,n}) + QP} + \frac{1}{(2/\kappa_{1,n}) + P'Q'}$$

$$= \kappa_{1,n} - \tfrac{1}{8}(\kappa_{1,n} + \sigma - \sigma')\kappa_{1,n}^2(\eta^2 + \zeta^2)$$

$$= \kappa_{1,n} - \tfrac{1}{8}(1 + \varpi_{1,n})\kappa_{1,n}^3(\eta^2 + \zeta^2) \text{ by (41);}$$

or, on comparison with (48),

$$\tfrac{1}{4}B'B\kappa_{1,n}^2 = \frac{1}{P'B'} - \frac{1}{P'B} = \tfrac{1}{8}(\eta^2 + \zeta^2)\gamma\kappa_{1,n}^3,$$

showing that γ is a numerical measure of the spherical aberration for the magnification -1. When γ is positive the axial intersection point B′ is displaced towards the lens from the paraxial position B, and the aberration is conventionally described as positive or undercorrected.

If $\gamma = 0$ the axial aberration is removed for this image point, and K falls as the aperture increases. The apparent contradiction between this result and that given in § (3), to the effect that K should be constant for all rays from a given object point, is due to the impossibility with a thin lens system of achieving an aberrationless plane image of a plane object.

Since the variation of the power and the shapes of the unit surfaces have been expressed in terms of three quantities—ϖ, β, γ—these suffice to determine completely to this order of accuracy the properties of the system for all object positions. The calculation of any thin system therefore resolves itself into the problem of securing for these quantities arbitrarily assigned values, and it is important to know what values must be adopted to attain the effects required. A slight generalisation of the investigation into the meaning of γ will suffice for this purpose. If the object and image surfaces for magnification G are considered, and it is assumed that these have uniform curvatures s and s', the length of the ray between the unit surface at $\frac{1}{2}(\eta^2 + \zeta^2)\sigma$, η, ζ and the object at $(1/G - 1)/\kappa + \frac{1}{2}(y'^2 + z'^2)s/G^2$, y'/G, z'/G being ρ and the corresponding image length between $\frac{1}{2}(\eta^2 + \zeta^2)\sigma'$, η, ζ and $(1 - G)/\kappa + \frac{1}{2}(y'^2 + z'^2)s'$, y', z' being ρ', it is readily seen that

$$\frac{1}{\rho'} - \frac{1}{\rho} = \kappa$$

$$-\frac{\kappa^2}{2(1-G)^2}[\{\sigma G^2 - \sigma' + \kappa(1 + G + G^2)\}(\eta^2 + \zeta^2)$$

$$-2\kappa(1 + G)(\eta y' + \zeta z') + (\kappa - s + s')(y'^2 + z'^2)].$$

Also from (32) and (46)

$$M_0 + M_n = \frac{2y' - \eta(1 + G)}{1 - G}K,$$

with a similar equation for the N's, and the substitution of these values in (48), on replacing the K's by their approximate κ values, yields

$$K = \kappa + \frac{\kappa^3}{8}\Big[\frac{4\varpi}{(1-G)^2}(y'^2 + z'^2)$$

$$+ \frac{4}{1-G}\left(\beta - \varpi\frac{1+G}{1-G}\right)(\eta y' + \zeta z')$$

$$+ \left\{\gamma - \varpi - 1 - 2\beta\frac{1+G}{1-G} + \varpi\left(\frac{1+G}{1-G}\right)^2\right\}(\eta^2 + \zeta^2)\Big].$$

The relation (38) then gives, as the necessary conditions for an extended object-image relation between the spherical object and image the spherical aberration condition,

$$\gamma - 4\beta\frac{1+G}{1-G} + (3 + 2\varpi)\left(\frac{1+G}{1-G}\right)^2 = 0, \quad (50)$$

a second condition, which will subsequently be identified with the sine condition,

$$\beta - (2 + \varpi)\frac{1+G}{1-G} = 0 \quad . \quad . \quad (51)$$

and the curvature relation

$$s - s' - (1 + \varpi)\kappa = 0. \quad . \quad . \quad (52)$$

The discrepancy between (41) and (52) should be particularly noted. The explanation is evident if it is noted that, whatever G may be, (52) holds if $\eta = \zeta = 0$, and that it is assumed in obtaining this relation that the rays involved are those which are incapable of predicting what the curvature of the unit surfaces will be.

If the value of β determined by (51) is substituted in (50) it is seen that

$$\gamma - (5 + 2\varpi)\left(\frac{1+G}{1-G}\right)^2 = 0. \quad . \quad . \quad (53)$$

Introduce now the special convention as regards β and γ that the addition of the suffix $_0$ signifies that the coefficient relates to the system in its zero configuration. Then if the curvature addition from this form is $S\kappa_{1,n}$

$$\gamma = \gamma_0 + 4(1 + 2\varpi)S^2,$$

$$\beta = \beta_0 + 2(1 + \varpi)S.$$

If in this form β and γ have the values required by (51) and (53) the elimination of S gives

$$\left(\frac{1+G}{1-G}\right)^2+2\frac{1+G}{1-G}(1+2\varpi)(2+\varpi)\beta_0 -(1+2\varpi)\beta_0^2-(1+\varpi)^2\gamma_0=0,$$

showing that bending the system as a whole will in any given case only yield two object positions, other than contact with the lens, for which the satisfaction of the sine condition is consistent with the removal of spherical aberration.

These two solutions are both imaginary unless

$$(1+2\varpi)(5+2\varpi)\beta_0^2+\gamma_0$$

is positive, and this condition cannot be satisfied with most combinations of two glasses to form a cemented achromatic doublet. Although both these conditions should be satisfied in such a system as a telescope objective, it frequently happens that the sine condition is deliberately ignored because the use of other glasses simplifies the construction from the manufacturing standpoint, and the faults present are not very conspicuous when the field of view is small.

§ (9) The Cemented Doublet.—On account of the great importance of lenses of the cemented doublet class it is desirable to consider them in some detail.

The powers of the component lenses are determined by the assigned focal length or power of the combination and the colour conditions which are to be satisfied. It is therefore assumed that these powers are known.

From equations (43) and (45) it is evident that the common curvature addition required to attain the standard form is

$$-\frac{1}{(1+2\varpi)\kappa}\sum_1^n\{(1+2\varpi_m)S_m\kappa_m -\varpi_m(\kappa_{1,m}-\kappa_{m,n})\}\kappa_m,$$

where in the absence of a suffix $_{1,n}$ is to be understood. It at once follows that

$$\beta_0(1+2\varpi)\kappa^2=\sum_1^n(\varpi-\varpi_m)(2S_m\kappa_m-\kappa_{1,m}+\kappa_{m,n})\kappa_m,$$

and since the range of indices of available glasses is very restricted the first factor on the right is normally small, and β_0 is a small quantity. The small range in the possible values of ϖ and β_0 involves the conclusion that the main problem concerns the attainment of a suitable value for γ_0, either by the initial selection of suitable varieties of glass or by an arbitrary division of the system. If Q_m is written for $2S_m\kappa_m-\kappa_{1,m}+\kappa_{m,n}$, k_m for $(1+2\varpi_m)\kappa_m$, and j_m for $\kappa_m/(1-\varpi_m)$, and the double suffix notation is used to denote summation, the equations for β_0 and γ_0 may be written

$$2\beta_0\kappa=\frac{1}{\kappa}\Sigma Q_m\kappa_m-\frac{1}{k}\Sigma Q_m k_m, \quad . \quad (54)$$

$$\gamma_0\kappa^3=\Sigma\{j_m^2\kappa_m+Q_m^2k_m-2Q_m(\kappa_{1,m}-\kappa_{m,n})\kappa_m\} -\frac{1}{k}\{\Sigma Q_m k_m\}^2, \quad . \quad (55)$$

where the suffix $_{1,n}$ is to be understood when none is given. It is evident by inspection that the equation for β_0 is unaffected by making any common addition to all the Q's, and the same becomes obvious for γ_0 by writing the last equation in the form

$$\gamma_0\kappa^3=\Sigma\{j_m^2\kappa_m+\frac{1}{k}k_l k_m(Q_l-Q_m)^2 +2(Q_m-Q_{m+1})\kappa_{1,m}\kappa_{m+1,n}\}.$$

Now assume for Q_m the form

$$-Q_m=P_{1,m-1}-P_{m,n-1}+j_{1,m}-j_{m,n},$$

where $P_1, P_2, \ldots P_{n-1}$ are $(n-1)$ unknown quantities and the double suffix carries its general additive meaning. Substituting for the Q's and j's in terms of the S's and κ's gives

$$S_m\kappa_m-\frac{\kappa_m}{2(\mu_m-1)}=P_m+S_{m+1}\kappa_{m+1}+\frac{\kappa_{m+1}}{2(\mu_{m+1}-1)}$$

and

$$S_1\kappa_1+\frac{\kappa_1}{2(\mu_1-1)}+S_n\kappa_n-\frac{\kappa_n}{2(\mu_n-1)}=0,$$

showing that the curvatures of the extreme surfaces of the system as given by the Q's are equal and opposite, and that P_m is the curvature difference between the consecutive surfaces belonging to lenses $_m$ and $_{m+1}$. For a cemented system the P's will all be zero, and γ_0 may be calculated from

$$\gamma_0\kappa^3=\Sigma\left\{j_m^2\kappa_m+\frac{1}{k}k_l k_m(j_{l,m-1}+j_{l+1,m})^2 +2(j_m+j_{m+1})\kappa_{1,m}\kappa_{m+1,n}\right\}.$$

When the system consists of only two members convenient expressions for numerical use are

$$\beta_0\kappa^2k=-(\varpi_1-\varpi_2)\kappa_1\kappa_2 j, \quad . \quad . \quad (56)$$

which illustrates the general rule that unlike ϖ and γ_0, which are unaltered, β_0 changes sign when the system is reversed, and

$$\gamma_0\kappa^2=j_1^2\kappa_1+j_2^2\kappa_2+2j\kappa_1\kappa_2+k_1k_2j^2/k. \quad (57)$$

In an achromatic objective one component is positive and one negative, while κ, j, k agree in sign. Thus only one of the terms gives a positive contribution to γ_0, which has a strong tendency to be negative. In this respect a doublet is in marked contrast with a single lens, which necessarily has a positive γ_0. While this difference enables the combination to be corrected for spherical aberration, it usually prevents the simultaneous

correction of spherical aberration and the sine condition. From the condition obtained earlier it is evident that for the simultaneous correction γ_0 when negative must be numerically small. It is seen on considering the results for a cemented doublet and a single lens that the fault lies in too great a difference of refractive index between the two glasses employed.

To obtain a general idea of the kind of variation of γ_0 implied by the above expression, assume that the refractive indices of the two glasses are given and that the power of the cemented combination is unity. Consider the change in γ_0 as the power of one component falls from a large positive to a large negative value, and the other consequently rises from a large negative to a large positive value. Let component 1 have the lower refractive index, that is $\varpi_1 > \varpi_2$. At the extremes the sign of γ_0 is given by the highest power of $\kappa_1 - \kappa_2$ and is obtained by writing $\frac{1}{2}(\kappa_1 - \kappa_2)$ for κ_1, and $-\frac{1}{2}(\kappa_1 - \kappa_2)$ for κ_2. The result is the value

$$-\frac{(\kappa_1-\kappa_2)^3(\varpi_1-\varpi_2)(1+8\varpi_1\varpi_2)}{16(1-\varpi_1)^2(1-\varpi_2)^2},$$

showing that with powerful lenses of opposite signs γ_0 tends to assume a positive value when the component with the higher index is of the same sign as the combination, and a negative value when the component with the same sign as the combination has the lower index. These extreme values illustrate the general tendency of the change in the series, and agree with the well-known construction for telescope objectives in which the combination and the lens of lower refractive index are positive or converging, and the system is corrected for spherical aberration by bending to an extent dependent on the magnitude of the negative γ_0. It must not be thought, however, that the variation in γ_0 is throughout uniform in direction. For taking the series in the direction from γ_0 negative to γ_0 positive we reach $\kappa_2=0$, $\kappa_1=1$ before $\kappa_1=0$, $\kappa_2=1$. In these cases γ_0 reduces to the single-lens formula $\gamma_0=(1-\varpi)^{-2}$, and since $0<\varpi<1$ and $\varpi_1>\varpi_2$, the value of γ_0 in the earlier case exceeds that in the later. There must therefore exist within the range positions where γ_0 becomes stationary. In the neighbourhood of $\kappa_2=0$ equation (57) gives

$$\gamma_0=\frac{1}{(1-\varpi_1)^2}\left[1-\frac{2\kappa_2}{\kappa}(\varpi_1-\varpi_2)\ .\ .\ .\right],$$

showing that stationary points exist outside the region in which both components have the same sign. The stationary point near this region for which γ_0 is a minimum would be of great importance if γ_0 reached values in the neighbourhood of zero, but this is found not to be the case. A typical curve exhibiting the variation of γ_0 in the region of practical interest is shown for $\varpi_1=\frac{2}{3}$, $\varpi_2=\frac{5}{8}$, corresponding to $\mu_1=1{\cdot}5$, $\mu_2=1{\cdot}6$ (*Fig.* 5). The values of

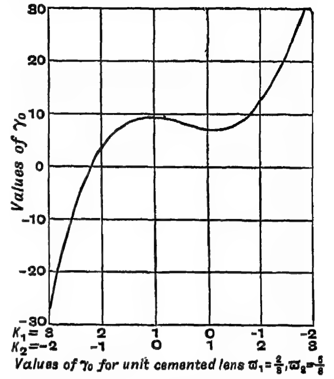

FIG. 5.

γ_0 at the stationary points do not differ much from those when one component falls to zero power.

If a number of curves of this kind are constructed, with one of the glasses of fixed index while the other is variable, it becomes possible to exhibit the variation of γ_0 for cemented doublets, when one independent variable is the refractive index that is not fixed, or a convenient function of this index, and the other determines the relative magnitude of the powers of the two component lenses, by drawing lines on a chart, in which those variables are represented by distances measured in perpendicular directions, through the points which have common values of γ_0. The contour map in which one of the variables is $(\kappa_1-\kappa_2)/(\kappa_1+\kappa_2)$ is most instructive, but for practical use in detailed work it is more convenient to substitute $\log(-\kappa_1/\kappa_2)$. The two maps are of course quite dissimilar, and it is not easy with the latter variable to trace the effect of a continuous variation of one of the component powers from positive through zero to negative values. Its special advantage is that it enables an important group of problems to be solved rapidly by showing which pairs of glasses are suitable for the purpose in hand. It is supposed that the colour conditions are given in a form which fixes the ratio of the component powers in terms of the "constringence" of the glasses, *i.e.* the coefficient ν. If, then, two charts are prepared, one exhibiting the contour lines for γ_0, and one representing by points the various glasses known to be available, both charts having the refractive index represented on the same scale, and the other variable being in the first case $\log(-\kappa_1/\kappa_2)$, and in the other $\log \nu_1/\nu_2$ or other appropriate representation of the colour

condition required, the best pair of glasses can be selected by superposing the two charts and moving them in slide-rule fashion over one another, provided the upper one is drawn on transparent material. The accompanying figures show such a pair of charts for finding

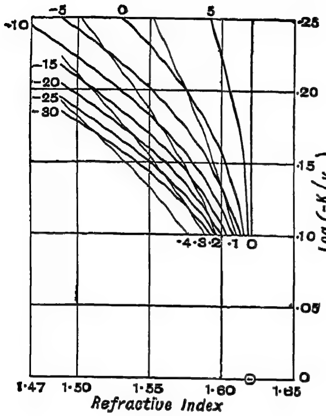

FIG. 6.

glasses fully corrected for colour. The fixed refractive index is 1·62, but the same charts may be used for a considerable range of values for this index. It will be noted that to secure

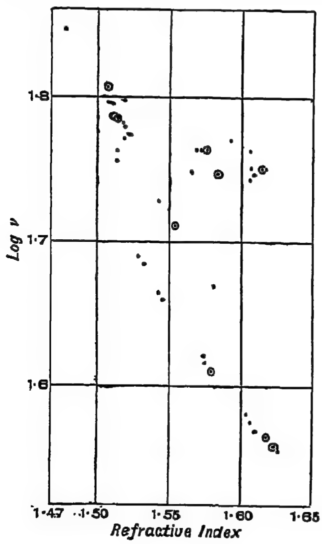

FIG. 7.

simultaneous correction for colour, spherical aberration, and coma in a thin cemented objective the precise dense flint selected is of little importance, but that in the crowns the index of the ordinary silicate glasses is too small while that of the dense barium crowns is too great. Of intermediate glasses the medium barium crowns are suitable, as are also the phosphate crowns introduced in 1886 at Jena, but since withdrawn on account of their instability, and also the fluor crowns introduced in 1913.

§ (10) EXTENSION OF THE CEMENTED DOUBLETS.—When suitable glasses are not available to meet the conditions that must be satisfied, two courses are open, both of which have as their object the securing of an additional degree of freedom. One of these consists in removing the restriction that the inner curvatures of the two components are to be complementary, so that the lenses may be cemented together; the other retains the condition that the inner surfaces are to be cemented, and secures the required freedom by dividing the total power to be contributed by one of the two glasses into two arbitrary parts, the final lens thus consisting of the lens of the other glass cemented between two lenses of the glass that has been divided.

Considering first the case in which the requirement that there shall be no air-gap is abandoned, the value $\bar{\gamma}_0$ for γ_0 when an air-gap P is present is given by

$$(\bar{\gamma}_0-\gamma_0)\kappa^3 k_1 k_2 k=(2\mathrm{P}k_1k_2+\kappa_1\kappa_2 k+k_1k_2 j)^2 -(\kappa_1\kappa_2 k+k_1k_2 j)^2.$$

In the cases of practical importance k has the same sign as κ, and k_1 and k_2 differ in sign. The introduction of the air-gap thus gives a limited opportunity of increasing γ_0, and offers a theoretically unlimited range of smaller values of γ_0. It is thus obvious that when an air-gap may be introduced any one aberration condition can always be satisfied, a result which does not apply to a cemented objective of two components, and as a rule two conditions can be complied with. The problem reduces in all cases to the solution of a quadratic equation, since one condition gives a linear and the other a quadratic relation between the amounts to which the two components must be bent, or, what is equivalent, between the bending of the complete lens and the air-gap curvature.

When one of the lenses is to be divided the cemented system that is to be determined may either be regarded as two achromatic cemented lenses cemented together with their like glasses in contact,[1] or treated directly as a triple lens without air-gaps. If κ_1, κ_2, κ; j_1, j_2, j; k_1, k_2, k have exactly the same values as they bore for the doublet lens, the elements for the triple lens may be represented by $\kappa_1(1-\theta)$, κ_2, $\kappa_1\theta$; $j_1(1-\theta)$, j_2, $j_1\theta$; $k_1(1-\theta)$, k_2, $k_1\theta$, and the values of the Q's will be $j-j_1(1-\theta)$,

[1] See *Proc. Phys. Soc. Lond.* xxvii. 405.

$-j_1(1-2\theta)$, $-j+j_1\theta$. The substitution of these values in (54) and (55) leads at once to

$$\bar{\beta}_0=\beta_0(1-2\theta) \quad . \quad . \quad . \quad (58)$$

and $$\bar{\gamma}_0-A'=(\gamma_0-A')(1-2\theta)^2, \quad . \quad (59)$$

where

$$A'\kappa^2=(\kappa\kappa_1+jk_1)j_2+j_1^2\kappa_1+j_2^2\kappa_2+\kappa_1\kappa_2 j$$

$$=j^2\kappa-j_1j_2(\varpi_1-\varpi_2)(j+j_2)\varpi_1, \quad . \quad (60)$$

and the coefficients with a bar above relate to the triple lens, while those without refer to the cemented doublet. It will be noted that the last three terms in the first expression for A′ have been found in evaluating γ_0. The meaning of A′ becomes evident at once on putting $\theta=\frac{1}{2}$, which gives $\bar{\gamma}_0=A'$. Since the lens is then quite symmetrical in construction, and $\bar{\gamma}_0=0$ is the condition for freedom from spherical aberration at magnification -1, it follows that $A'=0$ is the condition that a parallel beam incident on the second component of the doublet with the external surface flat should be brought to a focus without aberration.

The corresponding result when the second component of the doublet is divided to form two external lenses may be written down by analogy. If the three components are $\kappa_2\theta$, κ_1, $\kappa_2(1-\theta)$ equation (58) is unaltered, and in (59) A′ must be replaced by A where

$$A\kappa^2=(\kappa\kappa_2+jk_2)j_1+j_1^2\kappa_1+j_2^2\kappa_2+\kappa_1\kappa_2 j$$

$$=j^2\kappa+j_1j_2(\varpi_1-\varpi_2)(j+j_1)\varpi_2,$$

and represents the spherical aberration for an object at infinity when the light is incident on the cemented doublet 1, 2 with the first surface plane.

It is evident that a triple lens may have any value of γ_0 on the same side of A′ or A, as the case may be, as the γ_0 of the cemented doublet. As a rule it will be possible to satisfy two conditions, and four solutions will in general be found for any given problem, two of which have external lenses of one glass, and two of the other.

These results may readily be generalised to yield simple equations for the solution of any problem with two given glasses when the lens is to consist of any number of thin components cemented together, the two glasses occurring alternately.[1] In all cases a solution may be obtained by solving a quadratic equation.

§ (11) A Telescope Objective free from Spherical Aberration and Coma.—As examples of the application of the foregoing expressions let it be required to find the curvatures for lenses free from spherical aberration, and where possible from coma also, for an object at infinity, with

$$\mu_1=1{\cdot}5, \quad \mu_2=1{\cdot}6, \quad \kappa_1=3, \quad \kappa_2=-2.$$

Then

$$\varpi_1=\tfrac{2}{3}, \quad \varpi_2=\tfrac{5}{8}, \quad j_1=9, \quad j_2=-\tfrac{16}{3}, \quad k_1=7, \quad k_2=-\tfrac{9}{2}.$$

For a cemented doublet

$$\varpi=3\times\tfrac{2}{3}-2\times\tfrac{5}{8}=\tfrac{3}{4},$$

$$\beta_0=\tfrac{2}{5}\times\tfrac{11}{3}\times\tfrac{1}{24}\times3\times2=\tfrac{11}{30},$$

$$\gamma_0=243-\tfrac{512}{9}-44-\tfrac{847}{5}=-27\tfrac{13}{45},$$

illustrating the small value of β_0 and the tendency to negative values of γ_0. In the standard form the curvatures of the end surfaces are

$$\pm\tfrac{1}{2}(j-\kappa)-\frac{1}{2k}\Sigma Q_m k_m,$$

or $$\pm\tfrac{4}{3}-\tfrac{19}{30},$$

or $\frac{7}{10}$ and $-\frac{59}{30}$ respectively. The equation for S, the curvature addition required to give freedom from spherical aberration, is

$$-27\tfrac{13}{45}+10S^2-\tfrac{41}{30}-14S+3+\tfrac{3}{2}=0,$$

which has the two solutions

$$S=\frac{7}{10}\pm\frac{8\sqrt{41}}{30}.$$

The first solution corresponds to the well-known form in which the curvature of the last surface is small. When the lens is reversed so that the parallel beam of light falls on the second component, the signs of the third and fourth terms must be changed. The solutions for this case are therefore

$$S=-\frac{7}{10}\pm\frac{2\sqrt{590}}{30}.$$

The extent to which the sine condition is not satisfied is measured by the value of the left side of (51). In the four cases just considered these values are, with lens 1 leading,

$$\frac{1\pm14\sqrt{41}}{15},$$

and with lens 2 leading,

$$\frac{20\pm7\sqrt{590}}{30},$$

all large errors with the signs differing in the two members of each pair.

Consider next the removal of this aberration by the introduction of an air-gap between the two components. The conditions to be satisfied are

$$\gamma=5+2\varpi$$

and $$\beta=\pm(2+\varpi),$$

the sign depending upon whether the first or the second component is met by the parallel

[1] See *Proc. Phys. Soc. Lond.* xxx. 31.

beam of light. Instead of making use of special formulae for this case it is simpler to solve from (43) and (49) for $S_1\kappa_1$ and $S_2\kappa_2$. The first condition gives

$$28(S_1\kappa_1 - \tfrac{10}{7})^2 - 18(S_2\kappa_2 - \tfrac{13}{6})^2 + 182\tfrac{59}{126} = 0,$$

and the second

$$40S_1\kappa_1 - 26S_2\kappa_2 - 1 = \pm 11,$$

and the solutions are, with lens 1 leading,

$$\left.\begin{matrix} S_1\kappa_1 = 5{\cdot}841 \\ S_2\kappa_2 = 8{\cdot}524 \end{matrix}\right\} \text{ and } \left.\begin{matrix} S_1\kappa_1 = -1{\cdot}351 \\ S_2\kappa_2 = -2{\cdot}541 \end{matrix}\right\},$$

and with lens 2 leading,

$$\left.\begin{matrix} S_1\kappa_1 = 4{\cdot}232 \\ S_2\kappa_2 = 6{\cdot}896 \end{matrix}\right\} \text{ and } \left.\begin{matrix} S_1\kappa_1 = -2{\cdot}952 \\ S_2\kappa_2 = -4{\cdot}157 \end{matrix}\right\}.$$

Finally, cemented objectives built up of three lenses may be considered. From either of the formulae given the values

$$A = -\frac{43}{18}, \quad A' = \frac{101}{9}$$

may be found. The equation from which S has been eliminated may be used to find $1 - 2\theta$ directly. The general equation with the first lens divided is

$$\{(\gamma_0 - A')(1+\varpi)^2 + \beta_0^2(1+2\varpi)\}(1-2\theta)^2$$
$$-2(1+2\varpi)(2+\varpi)\frac{1+G}{1-G}\beta_0(1-2\theta)$$
$$+A'(1+\varpi)^2 - \left(\frac{1+G}{1-G}\right)^2 = 0,$$

and the curvature to be added to the standard form is

$$\frac{1}{2(1+\varpi)}\left\{(2+\varpi)\frac{1+G}{1-G} - \beta_0(1-2\theta)\right\},$$

the curvature of the end face of the standard form being of course

$$\pm\tfrac{1}{2}(j-\kappa) + (1-2\theta)(j_1k_2 - j_2k_1)/2k.$$

Applying these expressions to the solution of the present case, the values found are, with the first lens divided,

$$1 - 2\theta = {\cdot}5117,$$

with extreme curvatures,

$$1{\cdot}741 \text{ and } -0{\cdot}925,$$

and $$1 - 2\theta = -{\cdot}5545,$$

with extreme curvatures,

$$2{\cdot}528 \text{ and } -0{\cdot}138.$$

With the second lens divided the solutions are imaginary.

Any other problem in the calculation of thin objectives is solved by a method exactly comparable to that illustrated. For the discussion of the equations to be used in other problems reference must be made to other sources.

The problem undertaken is not theoretically complete. Any actual lens will not be "thin," but what may be termed a "close" lens, the separations between the surfaces being such as to give the required aperture with a suitable additional substance to enable the glass worker to secure surfaces of good figure. The curvatures obtained from the solution in which thicknesses have been neglected require therefore to be modified in consequence of the departure from correction due to the introduction of thicknesses. Consideration has also to be given to the character of the correction which it is possible to achieve, on which the mathematical conditions that should be obeyed must depend. In general it is found that the first order aberration must not be entirely removed, as the errors of higher orders tend to produce over-correction. The type of correction exhibited by a well-designed objective thus shows small positive aberration, which rises to a maximum and falls to zero for rays which enter near the margin of the aperture, and the procedure adopted must secure the satisfaction of this condition. It is found on investigation that for relative apertures such as are normally employed this condition is satisfied by making no alteration in the curvatures of the surfaces, with the exception of the small change in a shallow surface necessary for the attainment of good colour correction. Owing to this fortunate coincidence the calculation of telescope objectives by the algebraic method described is much to be preferred to the more laborious trigonometrical methods.

§ (12) SYSTEMS WITH MORE THAN TWO GLASSES.—A problem which arises much less frequently than any of those already discussed relates to the calculation of systems in which more than two different glasses are used. When there is one lens of each of n glasses they can be arranged in $n!$ orders affording $\tfrac{1}{2}n!$ cases to be investigated if a complete examination is to be made into the properties of the various systems. In accordance with what has been said of thin cemented systems in general, the most important problem is the determination of the values that γ_0 may take, and particularly the effect on this quantity of variations in the order. It is not difficult to show that when there are three separate glasses the extreme values of γ_0 are obtained by putting a lens of extreme index in the middle, whether the value is the highest or the lowest depending upon whether an odd or an even number of components differ in sign from the complete lens. When there are four components extreme values usually result by placing all the positive lenses together in the order of their indices, and all the negative lenses together also in order. Such complex systems usually arise from

attempts to reduce second order chromatic aberrations.[1]

§ (13) SYSTEMS IN WHICH CHROMATIC ABERRATION IS NOT IMPORTANT.—Systems are occasionally required for use in circumstances where chromatic differences may be neglected, and it is thus possible to construct them using only one kind of glass. Lenses so constructed afford good examples of one or two principles of importance, and they are of practical interest since they may be made to have very small outstanding aberrations for even exceptionally large relative apertures.

When a single lens is employed to form an image of an object placed so that the paraxial magnification is G, the spherical aberration vanishes when

$$\frac{1}{(1-\varpi)^2}+4(1+2\varpi)S^2-8(1+\varpi)S\frac{1+G}{1-G}+(3+2\varpi)\left(\frac{1+G}{1-G}\right)^2=0,$$

and when this cannot be made to vanish the left side may be put in the form

$$\frac{1}{(1-\varpi)^2}-\frac{1}{1+2\varpi}\left(\frac{1+G}{1-G}\right)^2+\frac{4}{1+2\varpi}\left\{(1+2\varpi)S-(1+\varpi)\frac{1+G}{1-G}\right\}^2,$$

which attains its minimum value when

$$S=\frac{1+\varpi}{1+2\varpi}\cdot\frac{1+G}{1-G}.$$

It is usually said that at this position the lens acts like a prism at minimum deviation, the air or glass angles between the ray and the two normals being equal. This is incorrect; for to the order of accuracy here required the ratio of the sine of the angle at the first surface to that at the second is

$$-\frac{2S-(1+G)/(1-G)+1/(1-\varpi)}{2S-(1+G)/(1-G)-1/(1-\varpi)},$$

and when S has the value for which the spherical aberration is a minimum this ratio becomes

$$\frac{2\mu+1-3G}{3-G(2\mu+1)},$$

which shows that the supposed law is only correct in the special case $G=-1$, for which the system is symmetrical. Since $(1+2\varpi)/(1-\varpi)^2$ exceeds unity for all positive values of ϖ less than 4, there is always positive spherical aberration for all values of $(1+G)/(1-G)$ between the limits ± 1, that is, for all real images of real objects. It is possible, however, to eliminate this aberration by substituting for the single lens a number of thin lenses of the same glass in contact. For such a combination (43) gives

$$\beta\kappa^2=2(1+\varpi)\Sigma S_m\kappa_m^2,$$

and (49)

$$\begin{aligned}\gamma\kappa^3=\frac{1}{(1-\varpi)^2}\Sigma\kappa_m^3&+4(1+2\varpi)\Sigma S_m^2\kappa_m^3\\&-8(1+\varpi)\Sigma S_m\kappa_m^2(\kappa_{1,m}-\kappa_{m,n})\\&+(3+2\varpi)\Sigma\kappa_m(\kappa_{1,m}-\kappa_{m,n})^2,\end{aligned}$$

so that the spherical aberration at magnification G is measured by

$$\begin{aligned}\frac{1}{\kappa^3}\Bigg[\frac{1}{(1-\varpi)^2}\Sigma\kappa_m^3&+\frac{4}{1+2\varpi}\Sigma\Bigg\{(1+2\varpi)S_m\kappa_m\\&-(1+\varpi)\left(\kappa_{1,m}-\kappa_{m,n}+\kappa\frac{1+G}{1-G}\right)\Bigg\}^2\kappa_m\\&-\frac{\kappa^3-\Sigma\kappa_m^3}{3(1+2\varpi)}-\frac{\kappa^3}{(1+2\varpi)}\left(\frac{1+G}{1-G}\right)^2\Bigg].\end{aligned}$$

Assuming that the powers of all the component lenses have the same sign as κ, the minimum value of this expression is

$$\frac{1}{3(1+2\varpi)}\left[\left(\frac{2+\varpi}{1-\varpi}\right)^2\frac{\Sigma\kappa_m^3}{\kappa^3}-1-3\left(\frac{1+G}{1-G}\right)^2\right],$$

and the first coefficient being large compared with the other terms, removal of the aberration will be best effected by making $\Sigma\kappa_m^3$ as small as possible compared with κ, that is, by making the power of every component equal. If the number of elements is given, say n, the aberration is removable for all values of ϖ below that which satisfies

$$\frac{1}{n^2}\left(\frac{2+\varpi}{1-\varpi}\right)^2-1-3\left(\frac{1+G}{1-G}\right)^2=0.$$

The smallest number of components for correction is evidently obtained for distant objects, and the greatest number is necessary when the object and image are equal in size. If $G=0$ is taken as a convenient reference case, twice as many components will be required for the same value of ϖ when $G=-1$ and approximately 1·4 times the number when it is about $-\frac{1}{11}$. For $G=0$ the lowest refractive index that may be employed is evidently

$$\mu=\frac{2n+1}{2(n-1)},$$

special values being $\mu>\frac{5}{2}$ for $n=2$, $\mu>\frac{7}{4}$ for $n=3$, $\mu>\frac{3}{2}$ for $n=4$, and $\mu>\frac{11}{8}$ for $n=5$. For the limiting index all the S's are positive and increasing from the first member of the series to the last, the system assuming the form of a series of meniscus lenses in contact on the axis with air gaps between them towards their edges, the curvature differences of the air gaps being equal.

It will usually be necessary for a lens of this kind to satisfy the sine condition in addition to being free from spherical aberration.

[1] *Trans. Opt. Soc.* xxii. 111.

Substituting in the expression for β the value of $S_m\kappa_m$ which results in minimum spherical aberration, it is found that

$$\beta=2\frac{(1+\varpi)^2}{1+2\varpi}\cdot\frac{1+G}{1-G}$$

or $$\beta-(2+\varpi)\frac{1+G}{1-G}+\frac{\varpi}{1+2\varpi}\,\frac{1+G}{1-G}=0,$$

and the sine condition is only fulfilled when the object and image are equal. Evidently this must be met by an increase in the minimum refractive index for a given number of components. Let $S_m\kappa_m$ be given the value

$$v_m+\frac{1+\varpi}{1+2\varpi}(\kappa_{1,m}-\kappa_{m,n})+\frac{2+\varpi}{2(1+\varpi)}\kappa\frac{1+G}{1-G},$$

where v_m is a variable whose value is at present undetermined. The sine condition is satisfied if

$$\Sigma v_m\kappa_m=0,$$

and the spherical aberration coefficient becomes

$$\frac{1}{3(1+2\varpi)}\left\{\left(\frac{2+\varpi}{1-\varpi}\right)^2\frac{\Sigma\kappa_m^3}{\kappa^3}-1\right\}-\frac{1}{(1+\varpi)^2}\left(\frac{1+G}{1-G}\right)^2$$
$$+4(1+2\varpi)\Sigma\frac{v_m^2\kappa_m}{\kappa^3}+\frac{4\varpi}{1+\varpi}\cdot\frac{1+G}{1-G}\Sigma\frac{v_m\kappa_m}{\kappa^2},$$

and the lowest value of the index will be obtained by making all the v's zero and all the powers equal. The equation from which the limit is to be found is

$$\frac{1}{n^2}\left(\frac{2+\varpi}{1-\varpi}\right)^2-1-\frac{3(1+2\varpi)}{(1+\varpi)^2}\left(\frac{1+G}{1-G}\right)^2=0,$$

which gives when $G=0$ and $n=4$ the approximate solution $\varpi=\cdot648$ or $\mu=1\cdot543$.

If the lens determined by this approximate solution has thicknesses inserted without change in the curvatures, the spherical aberration will be very slightly over-corrected, and the departure from the sine condition appreciably over-corrected. The latter is remedied by increasing all the curvatures by a common value, making the lenses more decidedly meniscus, but in so doing the spherical aberration will be over-corrected. This is remedied by a further increase in refractive index, solving for the minimum spherical aberration and suitable under-correction of the sine condition. For a relative aperture of about $f/1$ a suitable refractive index is approximately 1·6. The zonal variations in the spherical aberration and in the sine ratio for even so large an aperture as this will be found extremely small.

§ (14) More Complex Systems.—It is not possible in the space available for this article to enter on a discussion of the way in which the principles applied above in considering thin objectives may be extended so as to cover systems of complex construction for large apertures such as microscope objectives, or photographic lenses where large apertures are required to be combined with a large field of view. It must suffice to say that, by the aid of theorems which assume a very neat form, it is possible to determine the conditions which each lens should satisfy on the assumption that it may be regarded as a thin lens finitely separated from its neighbours, and that a definite treatment applied to this simplified lens will yield the correct data for the real lens. The importance of this procedure lies in its automatic evasion of attempts at the theoretically impossible, to which pursuit the designer without some such guide is very apt to devote a great part of his time. Indeed little experience of lens calculations is required to force home the conviction that almost every attractive scheme for the removal of aberrations involves direct conflict with Fermat's principle. Before concluding, it is, however, desirable to mention briefly a few general results which have many applications.

It was shown in equations (15) that the resolved equations governing the passage of light through the system are of the form

$$\mu_m M_m-\mu_{m-1}M_{m-1}+\eta_m K_m=0,$$
$$\eta_{m+1}-\eta_m-\mu_m M_m\tau_m\varpi_m=0.$$

Let another set of such quantities be distinguished by the introduction of accents. Then, whatever meaning these quantities may bear, the value of

$$\Sigma\eta_m(\mu'_m M'_m-\mu'_{m-1}M'_{m-1}+\eta'_m K'_m)$$
$$-\Sigma\mu_m M_m(\eta'_{m+1}-\eta'_m-\mu'_m M'_m\tau'_m\varpi'_m)$$
$$-\Sigma\eta'_m(\mu_m M_m-\mu_{m-1}M_{m-1}+\eta_m K_m)$$
$$+\Sigma\mu'_m M'_m(\eta_{m+1}-\eta_m-\mu_m M_m\tau_m\varpi_m)$$

is identically zero. In other words,

$$\sum_1^n\eta_m\eta'_m(K'_m-K_m)$$
$$+\sum_1^{n-1}\mu_m M_m\mu'_m M'_m(\tau'_m\varpi'_m-\tau_m\varpi_m)$$
$$=\eta'_n\mu_n M_n-\eta_n\mu'_n M'_n-\eta'_1\mu_0 M_0+\eta_1\mu'_0 M'_0,$$

or

$$\sum_1^n\eta_m\eta'_m(K'_m-K_m)$$
$$+\sum_0^n\mu_m M_m\mu'_m M'_m(\tau'_m\varpi'_m-\tau_m\varpi_m)$$
$$=y'_n\mu_n M_n-y_n\mu'_n M'_n-y'_0\mu_0 M_0+y_0\mu'_0 M'_0, \quad (61)$$

where y_0, y_n, y'_0, y'_n are arbitrary points in the external media on the two rays, distant τ_0, τ_n, τ'_0, τ'_n from the points in which the first and last surfaces are encountered.

These expressions give at once the conditions that paraxial rays relating to light of different colours should form images free from colour. Special results of importance are obtained by considering the case in which both rays are initially parallel to the axis, so that

$M_0 = M'_0 = 0$ and y_n and y'_n are made to vanish by selecting as the final end points the intersections of the ray with the axis. As the rays are paraxial $\tau_m = \tau'_m = t_m$, and since it may be assumed that the difference of index is small enough for the rays never to become appreciably separated if they are initially coincident, the second expression gives

$$\sum_1^n \eta_m{}^2 \delta\kappa_m + \sum_1^{n-1} \mu_m{}^2 M_m{}^2 t_m \delta\varpi_m + M_n{}^2 \delta v_n = 0,$$

where the last medium is non-dispersive and of unit index. It is permissible to divide throughout by $\eta_1{}^2$ and write for the η's and M's their values in terms of the direct paraxial ray, with the result that

$$\kappa^2 \delta v_n + \sum_1^n \left(\frac{\partial\kappa_{1,m}}{\partial\kappa_m}\right)^2 \delta\kappa_m + \sum_1^{n-1} t_m \kappa_{1,m}{}^2 \delta\varpi_m = 0$$

gives the change δv_n in the position of the second principal focus as the colour changes. The corresponding expression for the first principal focus may be written down by analogy. To find the variation of the power, assume $M_0 = M'_n = 0$. The right side of (61) is then $y_0 y'_n(K' - K)$. Dividing throughout by $y_0 y'_n$ and neglecting differences between the colours in the coefficients leads to

$$\delta\kappa = \sum_1^n \frac{\partial\kappa_{1,m}}{\partial\kappa_m} \frac{\partial\kappa_{m,n}}{\partial\kappa_m} \delta\kappa_m - \sum_1^{n-1} t_m \kappa_{1,m} \kappa_{m+1,n} \delta\varpi_m.$$

§ (15) Chromatic Aberration.—When the system is a thin lens the equations reduce to the single condition

$$\sum_1^n \delta\kappa_m = 0$$

for freedom from all chromatic aberrations for paraxial rays, as would be inferred from the fact that when κ is known the paraxial rays are all determined. For a discussion of the properties of glass as regards variation of index for colour, reference should be made to the article on "Optical Glass." For present purposes it will suffice to mention that the principal characteristic of any glass is given by a coefficient ν which gives the difference of power for the C and F lines of hydrogen in terms of that for the D sodium lines in the form

$$\kappa_F - \kappa_C = \frac{\kappa_D}{\nu},$$

and the rays for the C and F lines will thus be refracted alike if

$$\Sigma \frac{\kappa_D}{\nu} = 0.$$

When this condition is satisfied the outstanding chromatic aberrations are those generally considered most satisfactory for images to be examined visually. For photographic use it is usual to secure agreement between the D and G′ lines.

The condition for a thin doublet lens is automatically satisfied by giving κ_1 and κ_2 the values

$$\kappa_1 = \nu_1 \frac{\kappa}{\nu_1 - \nu_2},$$

$$\kappa_2 = -\nu_2 \frac{\kappa}{\nu_1 - \nu_2}.$$

When three glasses are employed it is generally expected to remove the second order differences of colour, and the solution of the problem is easy when once suitable glasses have been chosen. The properties of all glasses hitherto manufactured approximate very closely to a law which results in the lens having zero power when the appropriate conditions are satisfied. It is easy to see that a higher degree of correction is attained if the glasses vary in such a way that when the changes of index between two pairs of reference spectrum lines are chosen as variables, the points representing the glasses when these are plotted in perpendicular directions are collinear. For manufactured glasses, however, these partial ratios are practically linear functions of the ν's with the consequence stated above. A way out of the difficulty is afforded by the use of transparent crystalline materials, of which fluorite is much the most important. This substance exhibits no double refraction, and its representative point on the chart lies almost on the straight line about which normal glasses group themselves, while the linear relation between the dispersions and the ν values does not hold when fluorite is one medium and glasses are selected for the other two. By means of such a chart all suitable combinations of glasses may be obtained in a few minutes, and when the remaining conditions are specified the field of choice can quickly be reduced to one or two alternative combinations.[1]

§ (16) Aberration Formulae.—Equation (61) interpreted in the broadest way forms a sufficient basis for the construction of formulae for aberrations to any required order of accuracy. Such formulae may be arranged on many plans, but, though they have what many workers will regard as peculiar disadvantages, there is much to be said in favour of a development which remains entirely symmetrical in the variables for the initial and final media. An illustration of a symmetrical development will be afforded in the brief consideration given later to the application of Hamilton's method to optical problems. The preceding discussion of the properties of thin lenses also is symmetrical in character, and the three quantities in terms of which the aberrations have been expressed are capable of immediate application to the system used in the reversed

[1] *Trans. Opt. Soc.* xxii. 99.

direction with as much ease as in the original direction. This is a comparatively minor matter when only first order aberrations are under discussion, but it becomes extremely important when higher order effects are under consideration in order to secure the greatest economy of labour.

In a number of problems in which (61) might be employed it is advantageous to return to first principles. As an example, the formula giving the positions of the primary or tangential focal lines may be taken. Suppose a ray is refracted at the origin on a sphere which has its centre of curvature on the x axis, and assume that the ray lies in the plane $z=0$. Consider the length of the path from a point on the surface near the origin to the point $\rho\cos\phi$, $\rho\sin\phi$, 0. The point on the surface is approximately $\frac{1}{2}R(\eta^2+\zeta^2)$, η, ζ and the distance between the two points is

$$\rho-\eta\sin\phi+\frac{\eta^2}{2}\left(\frac{\cos^2\phi}{\rho}-R\cos\phi\right)+\frac{\zeta^2}{2}\left(\frac{1}{\rho}-R\cos\phi\right)+\ldots,$$

and thus the ray through η, ζ from $\rho\cos\phi$, $\rho\sin\phi$, 0 to $\rho'\cos\phi'$, $\rho'\sin\phi'$, 0 exceeds in optical path the ray through the origin by

$$-\eta(\mu'\sin\phi'-\mu\sin\phi)+\frac{\eta^2}{2}\left(\frac{\mu'\cos^2\phi'}{\rho'}-\frac{\mu\cos^2\phi}{\rho}-K\right)+\frac{\zeta^2}{2}\left(\frac{\mu'}{\rho'}-\frac{\mu}{\rho}-K\right)+\ldots$$

In the ordinary instrument there is no uniform change of path from point to point of the surface, so $\mu'\sin\phi'=\mu\sin\phi$, the ordinary law of refraction, is satisfied, which gives merely the direction in which the wavelets will reinforce one another. The following terms indicate the distances in these directions in which special concentrations will be found corresponding to the foci of geometrical optics. The meaning is obviously that considerable latitude may be given to ζ without producing any appreciable change of path in the positions given by the law hitherto considered exclusively, and similar latitude to η at positions given by the new law

$$\frac{\mu'\cos^2\phi'}{\rho'}-\frac{\mu\cos^2\phi}{\rho}=K. \quad . \quad (62)$$

Since the former law may be derived by considering a single ray alone without reference to neighbouring rays, it is evident that (62) represents the differential of that law, and it will be expected that relations derived from (62) will exhibit this form when compared with those obtained from the earlier law.

A simple application of this law of importance relates to rays passing near the axial point of a thin system of lenses. There are no changes in the angles of incidence between the two surfaces bounding any medium, since all are met where they are normal to the axis, and the equations for the individual surfaces are thus directly additive, giving, since

$$M_0=M_n, \quad N_0=N_n,$$

$$\frac{1}{\rho_n}-\frac{1}{\rho_0}=\frac{K}{1-\frac{1}{4}\{(M_0+M_n)^2+(N_0+N_n)^2\}},$$

so that the change is equivalent to replacing the ϖ in the expression for K, when $\eta=\zeta=0$ by $2+\varpi$. It at once follows that the relation between the curvatures of primary conjugate surfaces corresponding to (52) for the secondary surfaces is

$$\bar{s}-\bar{s}'-(3+\varpi)\kappa=0. \quad . \quad . \quad (63)$$

The interpretation of the two results may be expressed in a variety of ways; one of the simplest, which holds for systems in general and not solely for thin systems, is that the paraxial region of any image surface is most simply referred to a surface whose curvature is less than that of the object surface by $\varpi\kappa$, and that the relative distances of primary and secondary foci from this surface are in the ratio 3 to 1.

It may readily be seen that the defect known as coma, which is a manifestation of failure to satisfy the sine condition, shows a similar ratio of 3 to 1 for errors in and normal to the plane containing the principal ray. Careful consideration will show that simple laws which may at first appear to relate to the larger errors in fact must be interpreted in relation to the smaller, and the corresponding laws for the former will assume differential forms. The results already quoted will become evident in the discussion of Hamilton's method.

§ (17) A System of Thin Lenses.—It has been assumed in discussing the properties of thin lenses that reference to the unit surfaces provides a convenient means of distinguishing one ray from another. When a succession of separated lenses have to be considered, or a stop at a distance from the lens limits the aperture so that rays from different parts of the object meet the lens at different parts of its aperture, it is necessary to adopt a different reference system. The results already established on change of variables give aberration coefficients $\frac{1}{2}\delta_1$, $\frac{1}{2}\delta_2$, $\frac{1}{2}\{3\delta_3+\varpi(S-G)^2\}$, $\frac{1}{2}\{\delta_3+\varpi(S-G)^2\}$, $\frac{1}{2}\delta_4$, $\frac{1}{2}\delta_5$ for spherical aberration, coma, primary curvature, secondary curvature, distortion, and stop aberration respectively, where S is the magnification for the stop in the entire system, G the magnification for the image, and the

quantities $\delta_1, \delta_2 \ldots \delta_5$ are defined by the equations

$$4\delta_1(1-G)^{-4} = \gamma - 4\beta\mathfrak{G} + (3+2\varpi)\mathfrak{G}^2,$$

$$4\delta_2(1-G)^{-3}(1-S)^{-1} = \gamma - \beta(3\mathfrak{G}+\mathfrak{S}) + (1+\varpi)\mathfrak{G}^2 + (2+\varpi)\mathfrak{G}\mathfrak{S},$$

$$4\delta_3(1-G)^{-2}(1-S)^{-2} = \gamma - 2\beta(\mathfrak{G}+\mathfrak{S}) + 2(1+\varpi)\mathfrak{G}\mathfrak{S} + \mathfrak{S}^2,$$

$$4\delta_4(1-G)^{-1}(1-S)^{-3} = \gamma - \beta(\mathfrak{G}+3\mathfrak{S}) + \varpi\mathfrak{G}\mathfrak{S} + (3+\varpi)\mathfrak{S}^2,$$

$$4\delta_5(1-S)^{-4} = \gamma - 4\beta\mathfrak{S} + (3+2\varpi)\mathfrak{S}^2,$$

where $$\mathfrak{G} = \frac{1+G}{1-G}, \quad \mathfrak{S} = \frac{1+S}{1-S}.$$

The fact that the three middle expressions do not transform into one another by the interchange of G and S is of great importance, since it involves very severe restrictions on what may be achieved by systems built up from thin lenses. This property may be regarded as a direct consequence of Fermat's principle.

The expressions that have been obtained for β and γ show that the δ's for a complex system are consistent with the additive laws

$$(f\delta_r)_{1,n} = \Sigma(f\delta_r)_m G_{m+1,n}^{5-r} S_{m+1,n}^{r-1},$$

where f is the focal length of the part determined by the suffix outside the bracket, and $G_{m+1,n}$, $S_{m+1,n}$ denote the magnifications of the image and stop in the portions of the system following lens m; that is to say, they are the continued products of the subsequent magnifications at individual lens or surfaces. These additive laws hold generally, and may be established from first principles without a knowledge of the expressions from which the aberrations are to be numerically computed. As an example, spherical aberration may be taken. The section of the caustic resulting from the presence of this aberration must for the lowest order be of the form of a semi-cubical parabola

$$x^3 = y^2 f\delta,$$

where δ is a numerical coefficient measuring the amount of the aberration, and f is the focal length introduced in order that the coefficient δ may be of zero dimensions. If now a system is divided into two parts 1 and 2, in each of which aberration of this type is present, the coefficient for the complete lens will depend upon the coefficients for the two separate portions, since it must vanish if both of these are zero. If the first part is without aberration the linear coefficient $f\delta$ for the whole will obviously be identical with that for the second portion alone. If, on the other hand, the second part is free from aberration the final image will be the image of the caustic formed after the light has traversed the first part, and this image will be formed according to paraxial laws. Thus if G_2 is the transverse linear magnification for the second part of the system $y_2 = G_2 y_1$, $x_2 = G_2^2 x_1$, and

$$(f\delta_1)_{1,2} = \frac{x_2^3}{y_2^2} = \frac{(G_2^2 x_1)^3}{(G_2 y_1)^2} = G_2^4\frac{x_1^3}{y_1^2} = G_2^4(f\delta_1)_1.$$

Since the errors considered are first order effects, the law of addition is linear, and by combining the two cases the general law must be

$$(f\delta_1)_{1,2} = (f\delta_1)_1 G_2^4 + (f\delta_1)_2,$$

and by repeated application the result already given is established for $r=1$. It will be noted that when the system is divided by surfaces instead of by lenses, so that the refractive index is not necessarily unity at the points of division, the factors require modification.

§ (18) HAMILTON'S METHOD.—Brief consideration must now be given to the very elegant method of investigating problems in reflection and refraction described by Sir W. R. Hamilton before the Royal Irish Academy in a series of papers covering the years 1824 to 1832. Essentially the principle is the use of a potential function of certain variables the partial derivatives of which determine all remaining unknowns in terms of these variables. Theoretically the method is extremely powerful and its application in other fields has proved of extraordinary importance. It is thus particularly noteworthy that in its application in the field for which it was primarily designed it should be generally considered to have failed to justify expectations. One reason doubtless lies in the nature of the subject itself, which requires all problems to be investigated with a minuteness not called for or appreciable in other fields. Another contributory cause is perhaps that Hamilton himself, like most mathematicians, was more interested in the broad problems to which his discovery was applicable, and in deriving general results to which it led with great ease, than in the tedious task of constructing expressions which gave a numerical measure of the effects so readily investigated qualitatively, and that this task has proved a formidable one in less able hands. Whatever the true cause may be, the result remains that no notable use was made of the method in the first fifty years after its publication. Perhaps the best testimony to this failure is that it was largely forgotten that it was to these optical problems that potential methods were first applied, with the result that Bruns in Germany believed that he was breaking entirely new ground in so applying Hamiltonian tools, and published a very extensive and heavy investigation which, for the most part, constituted a duplication of Hamilton's original

work. To the potential function which he used for the greater part of his investigations Hamilton applied the name "Characteristic Function"; but use was also made of another function, with different variables and allied properties, which was designated the "Allied Characteristic Function." Bruns, with characteristic thoroughness, investigated all the functions which could be utilised for the purpose, and proposed for them the generic title of "Eikonal." It is convenient to retain Hamilton's name in the sense in which he used it, and to restrict "Eikonal" to a particular function which, like the characteristic function, is symmetrical in its variables, and takes for these variables the direction cosines of a ray instead of the co-ordinates of a point. In both cases the function has the dimensions of a length, and in the case of the characteristic function represents the length of the optical path between the points whose co-ordinates are taken as variables, and in the eikonal the length of the optical path between the feet of perpendiculars to the ray from two selected points in the object and image spaces respectively. Instead of introducing the full number of variables, since all that is required is the identification of the initial and final portions of a single ray, one of them in each space may be absent, and intersections with fixed planes will be derived.

Assuming that the system is symmetrical about an axis, it is convenient in the case of the characteristic function to adopt y, z and y', z' as variables, the axis of symmetry coinciding with the axes of x and x'. If then V is the optical length of the path between fixed planes expressed as a function of the points in which the ray intersects these planes, the direction cosines of the ray before and after traversing the system are given by

$$\mu M = -\frac{\partial V}{\partial y}, \quad \mu N = -\frac{\partial V}{\partial z},$$

$$\mu' M' = \frac{\partial V}{\partial y'}, \quad \mu' N' = \frac{\partial V}{\partial z'}.$$

Similarly with the eikonal E, if the optical path is expressed as a function of M, N, M′, N′, the reference points being on the axis, the co-ordinates of the points in which the ray meets the planes normal to the axis through these reference points are determined from

$$y = \frac{\partial E}{\partial(\mu M)}, \quad z = \frac{\partial E}{\partial(\mu N)},$$

$$y' = -\frac{\partial E}{\partial(\mu' M')}, \quad z' = -\frac{\partial E}{\partial(\mu' N')}.$$

Since the system is symmetrical about an axis, V will be a function of y^2+z^2, $yy'+zz'$, $y'^2+z'^2$ only, and E a function of M^2+N^2, $MM'+NN'$, $M'^2+N'^2$ only. Put $(1) = \mu^2(M^2+N^2)$, $(2) = \mu\mu'(MM'+NN')$, $(3) = \mu'^2(M'^2+N'^2)$. Then E is a function of (1), (2), (3), and these may be transformed into other variables as found convenient for discussing particular problems. Suppose that it is desired to consider the conditions for freedom from aberration for magnification G, the reference points being the axial points of the object and image planes. Let there be a stop for which the magnification is S. Introduce the variables I, II, III defined by

$$\left.\begin{aligned} &\mathrm{I} \quad (S-G)^2 = (1) - 2G(2) + G^2(3) \\ &\mathrm{II} \quad (S-G)^2 = (1) - (G+S)(2) + GS(3) \\ &\mathrm{III} \quad (S-G)^2 = (1) - 2S(2) + S^2(3) \end{aligned}\right\}, \qquad (64)$$

so that

$$\left.\begin{aligned} (1) &= S^2\mathrm{I} - 2GS\mathrm{II} + G^2\mathrm{III} \\ (2) &= S\mathrm{I} - (G+S)\mathrm{II} + G\mathrm{III} \\ (3) &= \mathrm{I} - 2\mathrm{II} + \mathrm{III} \end{aligned}\right\}; \qquad (65)$$

then, denoting differentiation by a suffix,

$$y(S-G)^2 = (\mu M - G\mu' M')(2E_{\mathrm{I}} + E_{\mathrm{II}}) + (\mu M - S\mu' M')(E_{\mathrm{II}} + 2E_{\mathrm{III}}),$$

$$y'(S-G)^2 = (\mu M - G\mu' M')(2GE_{\mathrm{I}} + SE_{\mathrm{II}}) + (\mu M - S\mu' M')(GE_{\mathrm{II}} + 2SE_{\mathrm{III}}), \qquad (66)$$

so that

$$(y' - Gy)(S-G) = (\mu M - G\mu' M')E_{\mathrm{II}} + 2(\mu M - S\mu' M')E_{\mathrm{III}},$$

and similarly

$$(z' - Gz)(S-G) = (\mu N - G\mu' N')E_{\mathrm{II}} + 2(\mu N - S\mu' N')E_{\mathrm{III}}.$$

Now if the image of the plane object falls on the plane and is free from aberration, $y' - Gy = z' - Gz = 0$ for all rays. Moreover, in general $M/N \neq M'/N'$, since this implies that the rays are restricted to the axial plane containing the object and image points. Consequently E_{II} and E_{III} must vanish identically; that is, E must be a function of I only, and all rays arising from the same object point must have identical values for $\mu M - G\mu' M'$ and $\mu N - G\mu' N'$. This is a generalised form of the well-known sine condition, and reference to (33) shows that it involves the result stated earlier, that K must have the same value for all rays arising from the same point of this object plane.

The sine condition as usually given relates only to rays arising from a point on the axis. Equation (66) shows that in this case $\mu M - G\mu' M'$ must be zero—E_{I} cannot vanish, for its constant term is the focal length of the system. The result may, therefore, be stated in the form that the ratio $\mu M/\mu' M'$ must be constant for all rays through the axial point and equal to the linear magnification for paraxial rays.

The connection between K and E is readily found from (32) and (66),

$$\frac{1}{K}=\frac{2G}{(S-G)^2}E_1=-E_{(2)} \text{ by (64)},$$

and it is easy to verify that this relation is always true. Thus $-E_2$ is the focal length for the ray determined by the values given to the variables. E_1 and E_3 serve to fix the positions of the principal foci on this ray. The relations between the two systems enable the results of calculation made by one of them to be readily stated in terms of the other, and in particular they show that phase relationship at and near the foci may be directly obtained from ray tracing by simple (usually graphical) integration. Notwithstanding the simplicity of direct calculations of phase differences, it will be found that the advantage lies with this graphical method. Incidentally it affords a convincing demonstration of the very small differences in the conclusions to which different theories lead for the location of the best focus in the presence of aberration, and thus justifies the recognised practice of usually disregarding the wave theory in calculating the details of construction of an optical system.

§ (19) The Cosine Condition.—Investigations have been made of the meaning to be attached to definite departures from the sine condition, and the problem is of great importance in economising in the volume of calculations. Some of the conclusions derived are invalidated by erroneous assumptions made in the course of the work, and it will not be superfluous to inquire into the problem here. It is not necessary to assume that the system is symmetrical in any sense, and any reference planes may be chosen for the object and image spaces.

Consider three neighbouring rays (*a*), (*b*), and (*c*) which have respectively the initial and final direction cosines

(*a*)	L,	M,	N;	$L'+\delta L'$,	$M'+\delta M'$,	$N'+\delta N'$:
(*b*)	L,	M,	N;	L',	M',	N':
(*c*)	$L+\delta L$,	$M+\delta M$,	$N+\delta N$;	L',	M',	N':

and which intersect the reference planes in the points

(*a*)	0,	y,	z;	..	..	..:
(*b*)	0,	$y+\delta y$,	$z+\delta z$;	0,	$y'+\delta y'$,	$z'+\delta z'$:
(*c*)	..	..	.. ;	0,	y'	z'.

Add to E the suffixes *a* and *c* when $M'+\delta M'$, $N'+\delta N'$ are to be substituted for M' and N', and $M+\delta M$, $N+\delta N$ for M and N respectively. Then

$$\mu\delta y=\frac{\partial E}{\partial M}-\frac{\partial E_a}{\partial M},$$

and expanding E_a by Taylor's theorem in terms of E and its derivates

$$\mu\delta y=-\frac{\partial^2 E}{\partial M\partial M'}\delta M'-\frac{\partial^2 E}{\partial M\partial N'}\delta N'$$
$$+ \text{ higher powers of } \delta M' \text{ and } \delta N'.$$

Similarly

$$\mu\delta z=-\frac{\partial^2 E}{\partial N\partial M'}\delta M'-\frac{\partial^2 E}{\partial N\partial N'}\delta N'+\ldots;$$

also

$$\mu'\delta y'=-\frac{\partial E}{\partial M'}+\frac{\partial E_c}{\partial M'}$$
$$=\frac{\partial^2 E}{\partial M\partial M'}\delta M+\frac{\partial^2 E}{\partial N\partial M'}\delta N+\ldots,$$

and

$$\mu'\delta z'=\frac{\partial^2 E}{\partial M\partial N'}\delta M+\frac{\partial^2 E}{\partial N\partial N'}\delta N+\ldots$$

Multiply these four expressions by δM, δN, $\delta M'$, $\delta N'$ and add. Then

$$\mu\delta y\delta M+\mu\delta z\delta N+\mu'\delta y'\delta M'+\mu'\delta z'\delta N'=0 \qquad (67)$$

to at least the third order in the small quantities δM, δN, $\delta M'$, $\delta N'$. This relation contains the general result to be established since the directions of the axes are quite arbitrary, but it may be clearer to express it in a somewhat different form.

If rays (*a*) and (*c*) satisfy a relation of the form

$$\cos\theta=p\cos\theta'+q, \qquad (68)$$

where θ and θ' are angles made with fixed straight lines in the object and image spaces respectively having direction cosines l, m, n and l', m', n' respectively, the expression of these two conditions in terms of the direction cosines gives

$$l\delta L+m\delta M+n\delta N+p(l'\delta L'+m'\delta M'+n'\delta N')=0,$$

Now a general point on ray (*a*) is

$$\rho L,\quad y+\rho M,\quad z+\rho N,$$

and if this ray is displaced without rotation through a distance d in the direction l, m, n a point on the displaced ray is

$$\rho L+dl,\quad y+\rho M+dm,\quad z+\rho N+dn,$$

and a particular point is

$$0,\quad y+\frac{d}{L}(Lm-Ml),\quad z+\frac{d}{L}(Ln-Nl),$$

and if this displaced ray is identical with (*b*)

$$\delta y=\frac{d}{L}(Lm-Ml),\quad \delta z=\frac{d}{L}(Ln-Nl).$$

Similarly if ray (*c*) coincides with (*b*) when displaced through a distance d' without rotation

$$\delta y'=\frac{d'}{L'}(L'm'-M'l'),\quad \delta z'=\frac{d'}{L'}(L'n'-N'l').$$

Substitute these values in (67). Then

$$\mu d(l\delta L+m\delta M+n\delta N)$$
$$+\mu'd'(l'\delta L'+m'\delta M'+n'\delta N')$$
$$=\frac{\mu dl}{L}(L\delta L+M\delta M+N\delta N)$$
$$+\frac{\mu'd'l'}{L'}(L'\delta L'+M'\delta M'+N'\delta N')$$
$$+\text{third order quantities in } \delta M, \delta N, \delta M', \delta N'.$$

It follows that if these quantities are small all rays selected by obedience to the condition (68) will, if displaced in the object space a small distance d parallel to the first direction, be displaced through the distance $p\cdot\mu d/\mu'$ parallel to the second direction in the image space. As the condition will in general

define an object and an image caustic, these caustics may be displaced without rotation or deformation in the given directions, provided the ratio of the displacements has the required value.

The cosine condition (68), which has been established without any assumption relative to the aberrations present, includes as particular cases the various theorems described previously. If the system is symmetrical about an axis, the rays from points at the same distance from the axis in a given object plane will be refracted similarly, and thus if $z=z'=0$, $(\delta z'/\delta z)=(y'/y)$. For such a case equation (33) may be applied, showing that $\mu M/\mu' M'$ is the magnification perpendicular to the plane containing the ray, and $\mu \delta M/\mu' \delta M'$ is by (67)[1] the magnification in that plane.

§ (20) Magnification for Displacement along the Axis.—Another case of importance relates to the magnification for displacement along the axis. If the axis itself is included as one of the rays of the group to be considered, q must have the value $1-p$, and the axial magnification is $\mu p/\mu'$, where $p=(1-\cos\theta)/(1-\cos\theta')=(\sin\frac{1}{2}\theta/\sin\frac{1}{2}\theta')^2$, and for paraxial rays this becomes $(\mu' G/\mu)^2$, where G is the transverse magnification. If, therefore, no change is to be made in the spherical aberration for a small axial displacement the condition to be satisfied is

$$\frac{\mu\sin(\theta/2)}{\mu'\sin(\theta'/2)}=G.$$

It has been found that when there is freedom from aberrations at magnification G, E is an arbitrary function of I. This evidently implies that there is one degree of freedom remaining in the way in which the aberrations of every order are corrected, and this freedom may be interpreted in terms of the spherical aberration in the image of the stop. If these aberrations are assigned in addition to the position of the stop the properties of the entire system are fully determined. The most important case is when $S=1$ and the stop is free from spherical aberration. In this case

$$E\kappa=-\frac{(1-G)^2}{G}\sqrt{1-I};$$

for if the reference planes are moved to the stop planes E becomes E′, where

$$E'\kappa=-\frac{(1-G)^2}{G}\sqrt{1-I}+\frac{1-G}{G}\sqrt{1-(1)}-(1-G)\sqrt{1-(3)},$$

and when $M=M'$, $N=N'$ this gives

$$E'=y=y'=z=z'=0$$

for all rays. It will be observed that there are here three points on the axis for which spherical aberration of all orders is removed—one for magnification G and two coincident points for magnification unity. The equation for freedom from spherical aberration of any order is necessarily of even order in the magnification, so there is at least one other point where the aberration of any assigned order disappears. In general there is no other position for which the aberration vanishes for all orders. The first order aberration, for example, vanishes for the magnification

$$-\frac{1-2G}{2-G},$$

and the corresponding value for $E\kappa$ is

$$-\frac{(1-G)^2}{G}\sqrt{1-I}+\frac{1-G^2}{(1-2G)G}\sqrt{1-(1)}+\frac{1-G^2}{2-G}\sqrt{1-(3)},$$

from which it readily follows that spherical aberration of higher orders is present.

§ (21) Standard Forms for Aberration Expansions.—The fact that entire freedom from aberrations for magnification G requires E to be a function of I only shows that all terms which have $(MN'-M'N)$ as a factor must vanish. This enables a number of conditions to be written down without reference to the magnification, and these conditions will be found to restrict severely the types of system that can satisfy the conditions. The condition for the first order aberrations, for instance, is $\varpi=0$, and this condition has been associated with the name of Petzval. The difficulty of satisfying this and other conditions simultaneously is illustrated by the general experience that in even the most highly corrected systems a compromise is necessary in consequence of which this condition is usually far from satisfied. The example given of a case in which E is expressed in a finite form suggests that in systems which are well corrected there should be no question about the convergency of E or of its derivates when expanded in a series of ascending powers of (1), (2), and (3). It follows that the evaluation of the coefficients of the terms in such an expansion should in such a system give a reliable measure of the outstanding aberrations. The converse, however, may in some instances not hold; it is quite conceivable that a system which has small values for the coefficients of the terms of low orders may not be satisfactory through the corresponding expansion for a part of the system being divergent. It is therefore important that systems of novel construction calculated by means of the expression for these coefficients should be checked in a way which does not assume the validity of such an expansion. Such a check is furnished by tracing selected rays through the system and comparing the results with those found from the earlier work.

[1] It should be particularly noted that for use in the ordinary notation the third and fourth terms of (67) must have their signs changed, because the differentials of the direction cosines belong to one ray for the object space and the other ray for the image space.

It is convenient to have a standard form for such expansions, and it is highly advantageous to keep it symmetrical in form. For this reason, instead of choosing as the reference planes a pair of object and image planes, the planes normal to the axis through the principal foci are selected. Apart from an additive constant, which is of no interest, E then takes the standard expanded form

$$E\kappa = -(2) - \tfrac{1}{8}[A'(1)^2 - 4B'(1)(2) + 4C(2)^2 + 2(C+\varpi)(1)(3) - 4B(2)(3) + A(3)^2] - \text{terms of higher orders.}$$

Evidently if the light is reversed in direction, to secure similar results it is only necessary to interchange A and A′, B and B′. From their definitions C and ϖ will be symmetrical with respect to the two directions. Assuming that the external media are of unit index, the value of E when the reference points are in the planes for magnification G is found by adding $-(1/G)\sqrt{1-(1)} - G\sqrt{1-(3)}$. Expanding and substituting from (65) gives

$$E\kappa = \frac{(S-G)^2}{2G}\mathrm{I} - \tfrac{1}{8}\Big[\delta_1\mathrm{III}^2 - 4\delta_2\mathrm{II\,III} + 4\delta_3\mathrm{II}^2 + 2\{\delta_3 + \varpi(S-G)^2\}\mathrm{I\,III} - 4\delta_4\mathrm{I\,II} + \Big\{\delta_5 - \frac{(S-G)(S^3-G)}{G}\Big\}\mathrm{I}^2\Big] \ldots,$$

where

$$\delta_1 = A - G(4B+1) + 2G^2(3C+\varpi) - G^3(4B'+1) + G^4A',$$

$$\delta_2 = A - G(3B+1) + G^2(3C+\varpi) - G^3B' - S\{B - G(3C+\varpi) + G^2(3B'+1) - G^3A'\},$$

$$\delta_3 = A - G(2B+1) + G^2C - 2S\{B - G(2C+\varpi) + G^2B'\} + S^2\{C - G(2B'+1) + G^2A'\},$$

$$\delta_4 = A - G(B+1) - S\{3B - G(3C+\varpi)\} + S^2\{3C + \varpi - 3GB'\} - S^3\{B'+1-GA'\}$$

$$\delta_5 = A - S(4B+1) + 2S^2(3C+\varpi) - S^3(4B'+1) + S^4A'.$$

Alternatively, substitution from (64) gives

$$A = G - G^3\frac{S^3-G}{(S-G)^3} + 2\varpi\frac{S^2G^2}{(S-G)^3} + \frac{(\delta_1, \delta_2, \delta_3, \delta_4, \delta_5)(S-G)^4}{(S-G)^4},$$

$$B = -G^2\frac{S^3-G}{(S-G)^3} + \varpi\frac{SG(S+G)}{(S-G)^2} + \frac{(\delta_1-\delta_2, \delta_2-\delta_3, \delta_3-\delta_4, \delta_4-\delta_5)(S-G)^3}{(S-G)^4},$$

$$C = -G\frac{S^3-G}{(S-G)^3} + 2\varpi\frac{SG}{(S-G)^2} + \frac{(\delta_1-2\delta_2+\delta_3, \delta_2-2\delta_3+\delta_4, \delta_3-2\delta_4+\delta_5)(S-G)^2}{(S-G)^4},$$

$$B' = -\frac{S^3-G}{(S-G)^3} + \varpi\frac{S+G}{(S-G)^2} + \frac{(\delta_1-3\delta_2+3\delta_3-\delta_4, \delta_2-3\delta_3+3\delta_4-\delta_5)(S-G)}{(S-G)^4},$$

$$A' = \frac{1}{G} - \frac{S^3-G}{(S-G)^3} + \varpi\frac{1}{(S-G)^2} + \frac{\delta_1 - 4\delta_2 + 6\delta_3 - 4\delta_4 + \delta_5}{(S-G)^4},$$

and the same method readily expresses the aberrations when S and G are given in terms of the aberrations for other values S′ and G′.

Comparison of δ_1 and δ_5 shows that the meaning of the latter with relation to the stop corresponds to the meaning of the former for the object. Differentiation shows that

$$M - GM' \doteqdot y'\kappa, \quad N - GN' \doteqdot z'\kappa$$

in accordance with what has been found in (32). The first term gives the well-known paraxial laws, and the remaining terms correspond to aberrations. Writing η' and ζ' for points in the final stop image, which will be given by

$$M - SM' = \eta'\kappa, \quad N - SN' = \zeta'\kappa,$$

the image defects are given approximately by

$$y' - Gy = -\frac{\kappa^2}{2(S-G)^3}[\delta_1\eta'(\eta'^2+\zeta'^2) - \delta_2\{2\eta'(\eta'y'+\zeta'z') + y'(\eta'^2+\zeta'^2)\} + \delta_3\{\eta'(y'^2+z'^2) + 2y'(\eta'y'+\zeta'z')\} + \varpi(S-G)^2\eta'(y'^2+z'^2) - \delta_4 y'(y'^2+z'^2)],$$

with a corresponding expression for $z' - Gz$. Assuming that a point in the object plane $z=0$ is under consideration, z' may be replaced by zero on the right, giving

$$y' - Gy = -\frac{\kappa^2}{2(S-G)^3}[\delta_1\eta'(\eta'^2+\zeta'^2) - \delta_2 y'(3\eta'^2+\zeta'^2) + \{3\delta_3 + \varpi(S-G)^2\}\eta' y'^2 - \delta_4 y'^3],$$

$$z' = -\frac{\kappa^2}{2(S-G)^3}[\delta_1\zeta'(\eta'^2+\zeta'^2) - \delta_2 2y'\eta'\zeta' + \{\delta_3 + \varpi(S-G)^2\}\zeta' y'^2],$$

from which the character of the various aberrations is readily seen. All are familiar with the exception of that involving δ_2, the coma aberration, which is generally regarded as a rather mysterious effect. The displacements are directly proportional to the distance of the image point from the axis and to the square of the distance from the axis at which the aperture is traversed. The introduction of polar co-ordinates at the stop shows the character of the defect more readily, the y and z displacements being then proportional to

$$y'(\eta'^2+\zeta'^2)(2+\cos 2\theta), \text{ and } y'(\eta'^2+\zeta'^2)\sin 2\theta$$

respectively. A detailed discussion of this aberration will be found in the text-books on advanced geometrical optics.

§ (22) Aberration Coefficients found by the Hamiltonian Method.—The comparison of the curvature terms with those found earlier shows that the characteristic relations for thin lenses in air are

$$A - 2B + C = 1, \quad B - 2C + B' = \varpi, \quad C - 2B' + A' = 1,$$

and further comparison with the terms in δ_1 and δ_2 gives for this case

$$\beta = B' - B, \quad \gamma = 4C + 2\varpi + 1.$$

The Hamiltonian methods are sufficient in themselves for the determination of the aberra-

tion coefficients, by building up those for a compound system in terms of the elements. If the system is divided at the foot of the perpendicular to the ray from an intermediate axial point, it follows from the definition of E as a length that

$$\mathrm{E}-\mathrm{E}_1-\mathrm{E}_2=0.$$

Moreover, if the ray meets the plane through this intermediate point in y, z, these are given by the equations

$$y=-\frac{\partial \mathrm{E}_1}{\partial(\mu \mathrm{M})}, \quad z=-\frac{\partial \mathrm{E}_1}{\partial(\mu \mathrm{N})},$$

as well as

$$y=\frac{\partial \mathrm{E}_2}{\partial(\mu \mathrm{M})}, \quad z=\frac{\partial \mathrm{E}_2}{\partial(\mu \mathrm{N})},$$

and therefore, since E is a function of other variables than M and N, which concern the intermediate medium alone,

$$\frac{\partial}{\partial(\mu \mathrm{M})}(\mathrm{E}-\mathrm{E}_1-\mathrm{E}_2)=\frac{\partial}{\partial(\mu \mathrm{N})}(\mathrm{E}-\mathrm{E}_1-\mathrm{E}_2)=0,$$

and these give two equations for μM and μN in terms of the external variables. A similar process may, if desired, be applied to the external media. The substitution of the values for μM and μN given by these equations in the equation for E solves the problem. The process is tedious rather than difficult, and one reason why other methods have been more successful in practice at once becomes apparent—the equations present themselves in a form requiring reduction, whereas other methods give them directly in their lowest terms.

The same process may be applied to the characteristic function, and indeed the forms of the two expressions are very similar, and when one is known the other can be written down at once. They each have special advantages as well as special disadvantages. The eikonal is particularly convenient in dealing with problems concerning thin lenses, but fails when the system becomes telescopic. If the eikonal is regarded as built upon the power κ, a symmetrical construction which remains finite for a telescope may be founded upon $\partial^2\kappa/\partial\kappa_1\partial\kappa_n$, but this breaks down in the case of a thin lens. The advantage rests with the system that has been followed here, as it is never essential to deal with a telescope as a unit, but a suitable division of the system may always be made in which the two parts are of finite focal length and the aberrations of which require to be suitably related.

A convenient system of equations for the calculation of the coefficients of the eikonal is

$$\mathrm{A}=\Sigma g^2 h, \qquad \mathrm{A}'=\Sigma g'^2 h',$$

$$\mathrm{B}=\Sigma g g' h, \qquad \mathrm{B}'=\Sigma g g' h',$$

$$\mathrm{C}=\Sigma g'^2 h=\Sigma g^2 h', \qquad \varpi=\frac{1}{\kappa}\Sigma\frac{\kappa_m}{\mu_{m-1}\mu_m},$$

where the summations extend over all surfaces, and

$$g_m=\mu_{m-1}\mathrm{R}_m\frac{\partial\kappa_{1,m}}{\partial\kappa_m}-\kappa_{1,m-1}=\mu_m\mathrm{R}_m\frac{\partial\kappa_{1,m}}{\partial\kappa_m}-\kappa_{1,m},$$

$$g'_m=\mu_{m-1}\mathrm{R}_m\frac{\partial\kappa_{m,n}}{\partial\kappa_m}+\kappa_{m,n}=\mu_m\mathrm{R}_m\frac{\partial\kappa_{m,n}}{\partial\kappa_m}+\kappa_{m+1,n},$$

$$h_m=\frac{\partial\kappa_{1,m}}{\partial\kappa_m}\left(\frac{\kappa_{1,m}}{\mu_m^2}-\frac{\kappa_{1,m-1}}{\mu_{m-1}^2}\right),$$

$$h'_m=\frac{\partial\kappa_{m,n}}{\partial\kappa_m}\left(\frac{\kappa_{m,n}}{\mu_{m-1}^2}-\frac{\kappa_{m+1,n}}{\mu_m^2}\right).$$

§ (23) Method of checking the Results.—In checking the reliability of the conclusions reached by the approximate methods that have been described, it is convenient to have the terms representing aberrational effects separated from those which are in accordance with paraxial laws. As a rule it is only necessary to consider rays which lie in a plane containing the axis, and these rays may be rapidly traced by means of the formulae

$$\sin\phi=\sin\psi+\mathfrak{h}\mathrm{R},$$

$$\mu'\sin\phi'=\mu\sin\phi,$$

$$\mathfrak{h}'-\mathfrak{h}=\frac{4\mathfrak{h}(\sin\phi-\sin\phi')(\sin\phi'+\sin\psi)}{\sin^2\psi_0'+(\cos\psi+\cos\phi+\cos\phi')^2} \quad 1,$$

$$\sin\psi'=\sin\psi_0'-(\mathfrak{h}'-\mathfrak{h})\mathrm{R},$$

and on transference to the next surface

$$\mathfrak{h}_{m+1}=\mathfrak{h}'_m+t_m\sin\psi_m,$$

where $\mathfrak{h}$ and $\mathfrak{h}'$ are the perpendiculars to the ray from the vertex of the surface before and after refraction, and $\sin\psi_0'$ is the approximate value of the sine of the inclination after refraction given by the paraxial law

$$\sin\psi_0'=\sin\psi+\sin\phi'-\sin\phi.$$

It will be noted that the aberration terms are those involving $\mathfrak{h}'-\mathfrak{h}$, and the terms in the numerator of the expression for this quantity are the first order aberration terms. The magnitude of the denominator in comparison with its paraxial value 8 gives the ratio of the terms of higher orders to the first order values. Rays traced through by this method indicate directly where departures from the approximate expressions occur and what measures should be taken to secure the most satisfactory compromise or, where possible, to secure thorough correction. The only tables needed are a single-page, four-figure sheet giving the cosines from the sines. It will be noted that the differences between the cosines and unity occur as a small correcting factor in the aberrational expression, and the four figures give approximately a degree of accuracy comparable with that obtainable from six- or seven-figure logarithms using the ordinary trigonometrical method of ray tracing.

A consideration which will appeal strongly to the computer who is working continuously at ray tracing is the reduced mental demand the use of this method involves. It has been devised particularly for use where calculating machines are available, and it is only under these conditions that its special advantage will be realised.

T. S.

OPTICAL CONSTANTS, TABLE OF, FOR TYPICAL OPTICAL GLASSES. See "Glass," § (23).

OPTICAL GLASS

§ (1) PROPERTIES OF OPTICAL GLASS.—The material most generally used for the construction of the prismatic and lenticular portions of optical instruments is glass. This is available in many varieties, all specially manufactured for the purpose from the purest materials obtainable, and so treated that the finished product is as transparent as possible for the whole visible spectrum and the contiguous spectral regions, is homogeneous, free from internal strain and from certain other defects. In certain types of glass the entire removal of some of the minor defects has not been found possible. For example, dense baryta crowns almost invariably contain throughout the whole mass of the melting a number of bubbles. If these are small and not too numerous they are of little consequence in instruments in which the employment of these glasses is of special importance, and the glass-maker contrives to cut out the larger bubbles and any pieces in which the bubbles are too numerous before moulding the remainder into plates or discs for the use of the lens-maker. Again, certain glasses which in other respects possess properties of great value are very liable to tarnish or even to decompose after prolonged exposure to the atmosphere, and their use is practically confined to combinations in which they can be cemented between two lenses of more durable glass. A few very dense flint glasses begin to absorb light strongly before the violet end of the spectrum is reached, and in considerable thicknesses they are practically opaque to blue light. Their use is consequently confined to the construction of very small lenses, such as the lenses of microscope objectives of high power, where the short length of the path of light within the glass renders its strong absorption almost innocuous.

Apart from the presence of objectionable qualities such as those just mentioned, particular types of glass are selected solely for their purely optical properties. The optical computer could desire the liberty to select arbitrarily the two principal properties of the glass he would use, the dispersion which controls the chromatic aberration, and the refractive index for a selected colour which determines the spherical errors of the instrument. Until new glasses were manufactured at Jena by Schott u. Gen. the choice was limited to glasses of a linear series. If μ is used to denote refractive index, and a suffix is added to distinguish the spectral line to which it relates, the dispersion is measured by the magnitude of ν where

$$\mu_F - \mu_C = \frac{(\mu_D - 1)}{\nu}. \qquad (1)$$

The older glasses obey a relation of the form

$$\frac{\alpha}{\mu_D} + \frac{\beta}{\nu} = 1, \qquad (2)$$

where α and β are constants having the same values for all the glasses.

Consider now an object glass made up of a number of thin lenses in contact, each kind of glass satisfying the above relation. Let R be the difference in the curvatures of a typical component, and write κ for R $(\mu - 1)$, adding a suffix when μ carries one. From equation (1)

$$\Sigma\kappa_F - \Sigma\kappa_C = \Sigma\frac{\kappa_D}{\nu}, \qquad (3)$$

showing that the C and F rays will only be similarly refracted if

$$\Sigma\frac{\kappa_D}{\nu} = 0, \qquad (4)$$

which is the usual condition for achromatism in a telescope objective. Multiplying both sides of (2) by κ_D,

$$\alpha\Sigma\frac{\kappa_D}{\mu_D} + \beta\Sigma\frac{\kappa_D}{\nu} = \Sigma\kappa_D. \qquad (5)$$

It is ordinarily essential for the condition (4) to be closely satisfied, so that the term in β disappears from (5). The quantity on the right is the power of the system, and the coefficient of α is the quantity which determines the curvature of the field. It follows that with such glasses there is no power to vary the curvature of the field of a thin objective.

The realisation of the limitations implied by the relation (2), together with another property of optical glasses to be mentioned presently, induced a number of experimenters to search for glasses outside the region to which known types belonged. Among these Vernon Harcourt and Stokes may be mentioned. Their investigations achieved only a partial success and led to no results of practical utility. It turned out that they just missed success, largely through the want of such technical advice as a glass-maker could afford. Abbe, working in conjunction with Schott, an experienced glass manufacturer, succeeded

in overcoming the difficulties of making several novel varieties of glass in about two years. The results of their work were of such importance that the Jena glassworks were founded for the manufacture of the new glasses. A first list of forty-four types of glass was published in 1886, of which nineteen represented glasses of novel optical position. Other lists have been issued since at various dates, and taking all the lists together glasses have been listed in the regions indicated in *Fig.* 1, which shows a very different state of

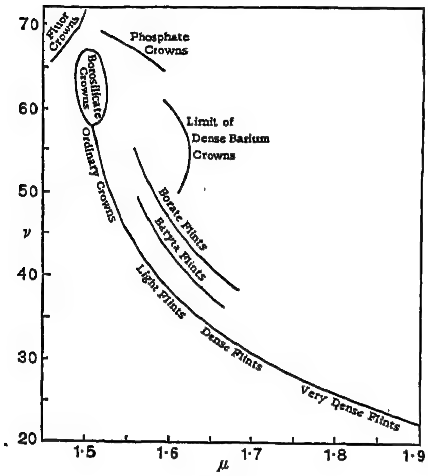

FIG. 1.

affairs from the hyperbolic line which represented the glasses obtainable earlier.

The most important of the new varieties have been:

Phosphate crowns	First introduced 1886
Barium phosphate crowns	
Boro-silicate crowns	
Dense barium crowns	
Borate flints	
Baryta light flints . .	First introduced 1888
Telescope crowns . . .	„ „ 1902
Telescope flints . . .	„ „ 1905
Fluor crowns	„ „ 1913

Of these glasses much the most remarkable in their properties were the phosphate glasses and borate flints of the first list. These have all been found to be unstable and have been withdrawn. In successive lists it will be noted that there has been a general tendency to continue to withdraw the more extreme glasses, and it may be inferred that stable glasses have not yet been made having extreme properties in desirable directions.

§ (2) IRRATIONALITY OF DISPERSION.—The production of glasses not constrained by the normal relation between refractive index and dispersion is the most notable permanent result of the work of the Jena glassworks. But though the importance of this achievement was not unappreciated, nevertheless it was not the prime motive which inspired the researches of Harcourt, Stokes, and Abbe. Much more attention was given in these investigations to the production of glasses with a considerable difference of dispersive power, but with a similar division of the dispersion for various parts of the spectrum. If two prisms are made from an ordinary crown and an ordinary flint so as to produce as closely as possible the same angular dispersion in the neighbourhood of the region of the spectrum to which the eye is most sensitive, it will be found that the crown prism will have the greater dispersion between this region and the red end of the spectrum, while the flint will produce the greater dispersion between this central region and the blue end of the spectrum. The consequence of this irrationality of dispersion is that a telescope objective, instead of bringing light of all visible wave-lengths sensibly to the same focus, has a minimum focal length for some wave-length which may be chosen by the designer, and for wave-lengths towards the ends of the spectrum the position of focus is so different that images in light of these colours will not be seen. Moreover, the longer the focal length the greater is the defect, so that it is particularly serious in all large refracting telescopes. The relatively advanced degree of development of astronomical instruments at an early stage in the evolution of optics led to early recognition of this fault, and thus it naturally called for the attention of those who sought to improve optical glass. The importance of the other direction in which freedom was desired, the removal of the restriction expressed by equation (2), was only recognised as of considerable importance with the development of photography.

From equations (1) and (3) it is evident that in a system for which C and F have a common focus, so that equation (4) is satisfied, the focus for some other line, say X, will coincide with C and F if all the glasses have the same value for

$$\frac{\mu_X - \mu_C}{\mu_F - \mu_C}.$$

A ready index of the suitability of two glasses for producing very perfect colour correction will thus be afforded by tabulating these ratios where X is made to agree in turn with a number of spectral lines. Such ratios are given in the lists issued by glass-makers, the usual ratios chosen being

$$\frac{\mu_D - \mu_{A'}}{\mu_F - \mu_C}, \quad \frac{\mu_F - \mu_D}{\mu_F - \mu_C}, \quad \frac{\mu_{G'} - \mu_F}{\mu_F - \mu_C}.$$

It is not easy, however, from an examination of these figures, which must be given to three decimal places to be of practical utility, to realise what has actually been achieved. An alternative method will therefore be adopted which will show the degree of uniformity clearly with the aid of the minimum number of figures. The method has the further merit of leading directly to a number of conclusions of considerable importance.

A rough examination of the figures of the glass lists will show that the change of distribution of the dispersion runs fairly uniformly with ν. We may, therefore, fit a formula of the type

$$\mu - \mu_D = (\mu_F - \mu_C)(a + b\nu)$$

to the glasses as a whole for the various spectral intervals, and tabulate the outstanding corrections which must be made to the calculated dispersions to equal those observed. It is preferable to apply this method to the actual differences of refractive index rather than to the calculated ratios, for the former are likely to be more accurate and the errors of the measurements are approximately constant in index differences. As a basis it is important to employ a list which includes many varieties of glass, both ordinary and new types, and the list should be critically examined for any internal evidence of unreliability in the figures. The various Jena glass lists, though not entirely free from error, will be found the most satisfactory for the purpose, and these lists have been utilised in preparing the following tables.

The formula for the refractive index of any given wave-length now becomes

$$\mu - \mu_D = a(\mu_F - \mu_C) + b(\mu_D - 1) + \epsilon \times 10^{-5}, \quad (6)$$

where a and b are functions of the wave-length only and ϵ is the divergence from normality. When the wave-length for the D line is substituted into the formulae for a and b they must both vanish. Moreover b has the same value for the C and F lines, and for these lines a has values differing by unity. It is found that the outstanding values of ϵ are small if the following values are adopted for these constants:

Line.	Wave-length.	a.	b.
A′	0·7682	– ·544	– ·00167
C	0·6563	– ·269	– ·00045
D	0·5893	0	0
F	0·4861	·731	– ·00045
G′	0·4341	1·404	– ·00223

It is important to notice the meaning to be attached to b in lenses composed of glasses having $\epsilon = 0$. By addition for the various glasses (6) gives

$$\Sigma\kappa = a(\Sigma\kappa_F - \Sigma\kappa_C) + (1 + b)\Sigma\kappa_D. \quad (7)$$

Thus in a system achromatised for C and F the power for any particular wave-length is $1 + b$ times that for the D line. Thus b measures the so-called secondary spectrum, and this is invariable for combinations of normal glasses forming a thin lens. It will be seen later that b assumes small positive values somewhat on the short wave-length side of the D line, so that the extreme variation of the focus is somewhat greater than the preceding figures suggest. By simple transformation the reference position may be chosen at any other part of the spectrum in place of the D line, and the precise type of chromatic correction may also be chosen arbitrarily, without altering the general character of the chromatic relations. The equation to the secondary spectrum can readily be found under any assigned conditions by expressing b as a function of the wave-length.

§ (3) Refractive Index and Wave-length.—Most attempts at fitting a formula to express the refractive index of glass as a function of the wave-length appear to have been based upon the study of a few glasses for which the indices have been observed for a large number of lines. Such a method is doubtless satisfactory for the particular glasses to which the formula is fitted, but it almost invariably happens that these formulae fail seriously when applied to normal glasses in general. The fact that a formula such as (6) expresses a relation which holds within narrow limits for such glasses indicates that a high degree of accuracy can be attained from a formula which involves only two distinct functions of the wave-length. To determine these functions let the term in $(\mu_D - 1)$ be eliminated from the equations, and to obtain a good distribution of the observed points let only $\mu_{A'}$, μ_C, μ_F, and $\mu_{G'}$ enter into the equation so obtained. The relation is evidently

$$\begin{aligned}(b_{G'} - b_F)(\mu_C - \mu_{A'}) - (b_C - b_{A'})(\mu_{G'} - \mu_F) \\ + \{(a_C - a_{A'})(b_{G'} - b_F) - (a_{G'} - a_F)(b_C - b_{A'})\} \\ (\mu_F - \mu_C) = 0,\end{aligned}$$

or, numerically,

$$178(\mu_C - \mu_{A'}) + 122(\mu_{G'} - \mu_F) = 131(\mu_F - \mu_C).$$

A shorter very approximate relation is

$$17(\mu_C - \mu_{A'}) + 11(\mu_{G'} - \mu_F) = 12(\mu_F - \mu_C).$$

Now the glasses have two quite distinct degrees of freedom, but all obey this relation. It follows that each function of the wave-

lengths must obey this relation separately. The great majority of the functions that may be proposed may be ruled out of court at once since this relation is not satisfied by them.

A class of functions which may be considered on account of their simplicity is that where the wavelength occurs to some power n. As n is given different values, the value assumed by

$$178\{(\cdot6563)^n-(\cdot7682)^n\}-131\{(\cdot4861)^n-(\cdot6563)^n\}+122\{(\cdot4341)^n-(\cdot4861)^n\}$$

or

$$122(\cdot4341)^n-253(\cdot4861)^n+309(\cdot6563)^n-178(\cdot7682)^n$$

may be plotted. It is found that the resulting curve (see *Fig.* 2) crosses the zero line for two values of n,[1] viz. $-0{\cdot}91$ and $-3{\cdot}40$. The corresponding formula for the refractive index is readily seen to be

$$\mu-\mu_D=\{\cdot226(\mu_F-\mu_C)+\cdot0062(\mu_D-1)\}\frac{\lambda^{-\cdot91}-\lambda_D^{-\cdot91}}{\lambda_F^{-\cdot91}-\lambda_C^{-\cdot91}}+\{\cdot774(\mu_F-\mu_C)-\cdot0062(\mu_D-1)\}\frac{\lambda^{-3\cdot4}-\lambda_D^{-3\cdot4}}{\lambda_F^{-3\cdot4}-\lambda_C^{-3\cdot4}},$$

and from this the equation to the secondary spectrum for any type of correction is deducible without difficulty. When C and F are brought together the minimum focus is found at wave-length $\lambda=0{\cdot}5558$ with $b=+0{\cdot}00008$, and when D and G′ are united as for photographic purposes, b takes the values

$b_{A'}=-\cdot00253$, $b_F=+\cdot00071$,

$b_C=-\cdot00088$, $b_{G'}=0$,

$b_D=0$, $b_{max.}=+\cdot00071$ at $\lambda=\cdot4972\mu$.

The formula found above shows (*Fig.* 3) that of those hitherto proposed Conrady's[2] second form

$$\mu=\mu_0+a\lambda^{-1}+b\lambda^{-\frac{7}{2}}$$

is that of most general utility when only two functions are employed. If the Cauchy form

$$\mu=\mu_0+a\lambda^{-2}+b\lambda^{-4}$$

were assumed, the relation

$$494(\mu_C-\mu_{A'})+245(\mu_{G'}-\mu_F)=300(\mu_F-\mu_C)$$

would be obeyed; it may be shown that no glass obeys this law, and the formula will therefore be unreliable when applied to the dispersion of glass. Other formulae may readily be found which will obey the actual law as accurately as that already determined, but in view of the simplicity of this result and the present degree of accuracy in refractometric observations there is little gain to be expected therefrom.

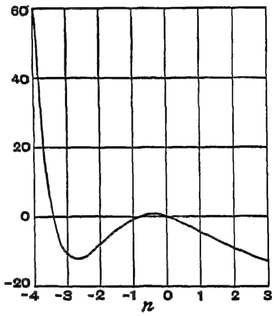

FIG. 2.

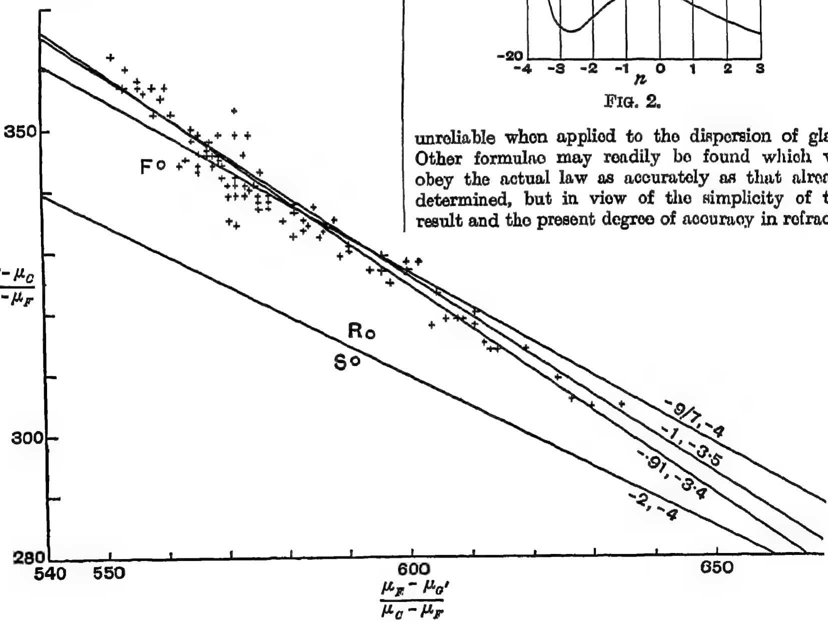

FIG. 3.

F = Fluorite. R = Rock salt. S = Sylvite.

[1] The solution $n=0$ is, of course, valueless.

[2] *Monthly Notices, R.A.S.* lxiv. 460.

§ (4) Table of Properties.—In the following tables the glasses, as usual, are arranged in the order of their ν values. The type number is given first—O. indicates that the ordinary procedure is followed in manufacture, S. that the glass is made in special pots on a small scale only. As the history of the glass is of interest, the date of introduction is given, and if the glass has since been withdrawn the date of withdrawal also.

For brevity the lists are denoted by letters, the dates being as follows:

1886	A	1902	D
1888	B	1905	E
1892	C	1913	F

Where two letters appear, the earlier indicates the list in which the glass is first mentioned, the latter the first list from which the glass is omitted. In the descriptions of the glasses the following contractions are used:

Ba.	Barium	h.	High
B.	Borate	l.	Low
BS.	Boro-silicate	L.	Light
Cr.	Crown	M.	Medium
d.	Dense	O.	Ordinary
D.	Densest	P.	Phosphate
Δ.	Dispersion	S.	Silicate
E.	Extra	T.	Telescope
F.	Fluor	UV.	Ultra-violet
Fl.	Flint	Z.	Zinc
G.	Glass

It should be noted in considering the values of the ϵ's that the dispersions are supposed to be correct to ± 2 units in the fifth decimal place. An error of this amount in the measured value of $\mu_F-\mu_C$ would introduce an error of 3 in the calculated value of $\mu_{G'}$, and as there might be an error in the measurement of $\mu_{G'}-\mu_D$ of 2, it is possible for an error of 5 units to appear in the last column without any actual deviation in the glass from normal behaviour. The figures suggest that errors only reach such a magnitude in one or two isolated cases, a check being obtained by comparing the behaviour of any glass with the normal properties of other glasses of the same type, and particularly with those of neighbouring optical position. If glasses of higher index than 1·7 be excepted in addition to those that have been withdrawn on account of their instability, there remain very few types whose departure from the normal distribution of the dispersion exceeds the experimental errors of the measurements. It may thus be said that, apart from unstable types, practically no success has been achieved in the manufacture of glass suitable for the elimination of secondary spectrum. For all stable glasses the dispersion formula already mentioned is sufficiently accurate, but for special glasses such as borate flints an additional term in the formula is necessary.

It is not unimportant to note what values are required in the ϵ's for two glasses to be used for a thin achromatic lens to enable the secondary spectrum to be eliminated. Let the outstanding ϵ's be divided into two portions, the one proportional to the medium dispersions of their glasses, the rest proportional to the refracting power but of opposite sign in the two glasses. The former portion may be neglected, since it simply gives a corrected value to a in formula (6). The indices may now be written in the form

$$\mu-1=(\mu_D-1)\left\{1+\frac{a}{\nu}+b+c\frac{\nu-\nu'}{\nu+\nu'}\right\},$$

$$\mu'-1=(\mu_D'-1)\left\{1+\frac{a}{\nu'}+b-c\frac{\nu-\nu'}{\nu+\nu'}\right\},$$

and therefore

$$\Sigma\kappa=(1+b+c)\Sigma\kappa_D$$

for an achromatic combination. There will be no secondary spectrum if $b+c=0$ for all colours. Since b is negative for the reference lines other than D, the ϵ's must be positive for the crown lens and negative for the flint. Taking 1·55 as a mean value for both indices, the ϵ's of each lens must depart from the normal to the following extents for the ν values shown to bring the focus for the lines indicated to the same position as that for the D line:

ν.	ν'.	$\epsilon_{A'}$.	$\epsilon_C=\epsilon_F$.	$\epsilon_{G'}$.
70	30	37	10	50
65	35	28	7	37
60	40	18	5	25
55	45	9	2	12

Since there are no crown glasses available which are above normal even as much as is indicated in the last rows of figures, the greater part of the correction will have to be borne by the low values of the flint glass. These figures indicate clearly that a ν difference of approximately 10 was the extent of the achievement reached for objectives without secondary spectrum even with unstable glasses,

The following table gives the mean values of results obtained by various observers (Landolt-Börnstein Tables, made at the Reichsanstalt (*Z. f. Instrumentenkunde*, 1920, xl. 94); they are for a temperature of 20° C. and refer rock salt and sylvite are for a temperature of 18° C. For particulars with regard to the positions of infra-red

and that appreciable reduction with present glasses can only be obtained by the use of abnormally steep curves. They further indicate the character of the chromatic focal relation to be expected in objectives corrected for secondary spectrum. In the outer parts of the spectrum there will be a tendency to approximate more closely to the normal type. Thus there is a general flattening of the focal curve, with four points in which the selected plane is crossed, not three as is usually stated. objective that can be made. The alternative is to have recourse to lenses of more complex structure in which an essential part in the correction is played by the separations of the components. That correction may be achieved in this way is readily seen. For consider a system built up of a number of thin achromatic lenses of ordinary glasses, separated from one another. Each of these produces a similar secondary spectrum, that is to say they behave as lenses all of the same kind of glass with

The failure of the attempt to manufacture stable glasses which will enable the secondary spectrum to be eliminated leads to the conclusion that, apart from new discoveries, two methods remain open for the construction of apochromatic objectives. The one consists in the employment of natural crystals of the cubic system for at least one component of the lens. Fluorite has been generally employed, and it is easy to see from the values of its dispersion given elsewhere that by its aid such objectives can be built. This method imposes severe limitations on the size of very small dispersion. If now the components are given the separations which would enable simple lenses all of the same glass and of the right powers to be chromatically corrected to the first order, it is evident that the condition for the removal of the secondary spectrum with the achromatic lenses is satisfied. That systems using only one glass may be chromatically corrected is well known, but they are of limited utility. A discussion of the procedure to be followed in applying either of these methods lies outside the scope of this article.

References.—A great deal of information is to be found in various journals on optical glass. Much of the work that has been done on Jena glasses in particular has been collected by Hovestadt, whose book has been translated into English by Professor and Miss A. Everett, and published under the title *Jena Glass*, and reference to this book is recommended for further information. For recent work, reference should be made to the *Journal of the Society of Glass Technology*, both for special articles and for information on material published elsewhere.

Table II. gives the results of a series of measurements on typical specimens of optical glass manufactured by Schott & Gen., Jena (H. Th. Simon, *Ann. d. Phys. u. Chem.*, 1894, liii. 555).

The results of measurements on the temperature coefficients of refractive index in the case of transparent crystals vary considerably. The values obtained by a number of observers at various mean temperatures are given in Table III. (Landolt-Bornstein Tables, 4th ed., 1912, p. 976).

The "flow temperature" given in Table IV. is the minimum temperature at which the glass is in a fluid state. It depends on the duration of the heating process and on the size of the specimen. The following values are for specimens in the form of cubes, the length of the side of which is 25 mm. The results refer to specimens of optical glass manufactured by the Sendlinger Optische Werke, Zehlendorf, near Berlin. In the first column the figures refer to the refractive indices and ν values of the glasses. Thus 510/634 shows that the specimen has a refractive index (for sodium D) of 1·510 and a ν value of 63·4 (F. Weidert and G. Berndt, *Z. f. tech. Phys.*, 1920, No. 6).

OPTICAL GLASS, MANUFACTURE OF. See "Glass," § (17).

OPTICAL IMAGE: ITS DEFECTS. See "Optical Parts, The Working of," § (3) (i.).

OPTICAL PARTS, THE WORKING OF

§ (1) INTRODUCTION.—For the production of an optical instrument the collaboration of the designer, the computor, and the optical worker is essential. Particulars of the function of the proposed instrument and the conditions to be fulfilled having been determined, the designer is able to prepare a general scheme of the mechanical and optical arrangement. So far as the optical portion is concerned, this involves a general knowledge of the limitations of computation and the accuracy attainable in the practical working of the parts.

Where possible, the designer avoids the introduction of extreme angular apertures that might necessitate the use of very special types of glass or increase the computational difficulties. But the tendency must always be towards the imposition of increasingly drastic demands, and frequently for one or more details of the optical system the designer must finally rely upon the utmost skill of the computor. Close collaboration between the computor and the workshop is also essential. Thus, for example, it may be desirable to use particular types of glass that happen to be in stock or standard test plates and tools.

It is the function of the optical worker, with whom this article is mostly concerned, to form the parts to the specified dimensions, to polish the surfaces, to examine the performance of the finished work, and when possible, to compensate the defects whether of surface or substance.

§ (2) METHODS.—As to the methods employed in the workshop, much depends upon the character of the work. Large astronomical objectives for which the demand is extremely small are invariably produced singly and involve the exercise of very special craftsmanship.

One renowned manufacturer[1] has stated as regards design that object-glasses cannot be made on paper. The empirical method of producing such parts consists in the computation of the objective by means of the simplest formulae with a view principally to the elimination of chromatism, and the determination of the desired focal length, and then in the removal of residual aberrations, and more particularly spherical aberration, by mechanical local retouching based upon optical examinations of the images formed by different zones and portions of the objective. From the point of view of the perfection of the objective this empirical method appears to be justified by the excellence of the results attained. Other makers of large astronomical object-glasses[2] advocate the alternative method. By rigid computation they determine the curves, thicknesses, separations, and apertures of the parts, and in the workshop they endeavour to attain the desired degrees of freedom from the several aberrations by the least possible departures from the calculated data. Local retouching, however, can hardly be avoided in the production of large optical parts. Peripheral or central zones of one or more of the surfaces may have to be retouched in order to produce an aspherical surface for the compensation of spherical aberration. Regular cylindrical retouching may be necessary for the correction of astigmatism. Surface imperfections, defects of homogeneity, defective annealing, constraint during working processes, and thermal effects may all involve irregular retouching.

But the organisation of most optical workshops is arranged principally for the production of moderately small lenses and prisms, of which comparatively large quantities have usually to be produced, as, for example, in the manufacture of binoculars and cameras. For reasons of cost, retouching of such parts is not permissible, and indeed rarely necessary, if the materials are well selected. They must be produced within limits specified by the

[1] H. Grubb, "The Production and Testing of Telescope Objectives and Mirrors," *Nature*, 1886, xxxiv. 85.

[2] S. Czapski, *Zeits. f. Instk.*, 1887, vii. 101.

designer and computor, and defective elements are rejected. Trial and error methods play but little part in such an organisation. Each step is based upon precise measurements.

There is an intermediate class of multiple work involving parts the size and cost of which are such as to make a certain amount of retouching necessary, although such retouching must always be regarded as undesirable.

At the present time the technique of the optician is in advance of that of the glass-maker. By machinery it is possible to produce surfaces that may be regarded as optically perfect. A prism, such as is used at the ends of a rangefinder, having perfect optical surfaces will not necessarily give a well-defined image, owing to small imperfections of the glass, such as defective annealing or homogeneity. The larger the piece the greater is the difficulty in obtaining glass that is sufficiently homogeneous to suit the requirements of the optician.

In such work it is customary to form and polish the pieces by machine, to test the perfection of the definition of the parts, and, if necessary, of their individual surfaces. Those that fail to pass and that exhibit certain types of imperfect definition may be saved by hand retouching, or, in the more regular cases, by machine. Of the remaining defective pieces, some may require re-annealing. The others must be finally rejected unless they can be utilised in instruments of lower power or inferior quality.

There is another class of work, such, for example, as condenser lenses and to some extent spectacle lenses, in which no great accuracy either of form or surface is required, and which will not be further considered.

It will be evident from the above general remarks that the production of high-quality optical parts cannot be reduced entirely to purely mechanical operations. A certain amount of hand work is involved, not only because of the need for the irregular touching of surfaces, but also for the production of certain delicate and accurate details for which suitable machinery has not yet been elaborated.

In the most highly organised workshops there may therefore still be seen in operation the early hand processes elaborated by such pioneer workers as Huyghens, Hooke, Newton, Father Cherubin, Herschel, and Molyneux.

§ (3) THE OPTICAL IMAGE. (i.) *Its Defects.*—Whether for the purpose of final or work-in-progress inspection, or for retouching, it is necessary to analyse the definition of the image produced by the optical part or system in question, and to diagnose the probable defects with a view to their possible correction.

It is not sufficient to make the broad statement that the definition is bad, because it may be possible to compensate the defect in the case of large and costly parts without much additional expense. Suppose the optical part to be examined is a thick parallel plate of glass whose transmission surfaces have been optically worked and may be regarded as being unquestionably true, and suppose the part is placed in the parallel beam before the objective of a telescope which is directed upon a collimator or test image comprising small holes or lines. If the glass is perfect, its insertion in the path of the light should not affect the appearance of the collimator image. If, to obtain a sharp image, a readjustment of the telescope eyepiece is necessary, the parallel plate has a focus error. It is equivalent in its action to a very weak lens. Examination by means of the interferometer may reveal a regular change of optical density from the centre outwards as represented by the circular bands of *Fig.* 1 (*a*). The defect in question may be due to imperfect annealing, or a regular defect of homogeneity. Double refraction resulting from imperfect annealing of the glass may be tested by inserting a half-wave plate and observing the extent to which the bands are displaced as the half-wave plate is rotated.

If the defect is due to internal stresses, the glass should be re-annealed, but if the substance itself is at fault the definition may be corrected by making one of the surfaces spherical. In the case of a prism a transmission face would be chosen for the operation in preference to a reflecting surface, since oblique reflection at a curved surface necessarily introduces astigmatism, which again might require to be compensated by working one of the transmission faces to a suitably oriented cylindrical form.

If the image appears sharply defined but oval shaped, the defect is one of astigmatism. The interferometer appearance of the glass may be as indicated in *Fig.* 1 (*b*). A cylindrical surface suitably oriented will suffice to compensate the defect, but if it is the glass that is strained it should be re-annealed.

Instead of a single clearly defined image a complex multiple image may be produced. This defect is due to heterogeneity of the glass, the structure of which when viewed by means of the interferometer may appear as in *Fig.* 1 (*c*). Such a structure might result from imperfect solution of the constituents, the nucleus of a sphere, in a soda lime glass, for instance, being quartz, having an ordinary refractive index of 1·54, and the various layers being silicates of gradually diminishing refractive index, approximating to about 1·5, which is the index for sodium silicate. Each sphere acts as a small aperture lens and forms a separate part of the multiple image. Local retouching may sometimes suffice for

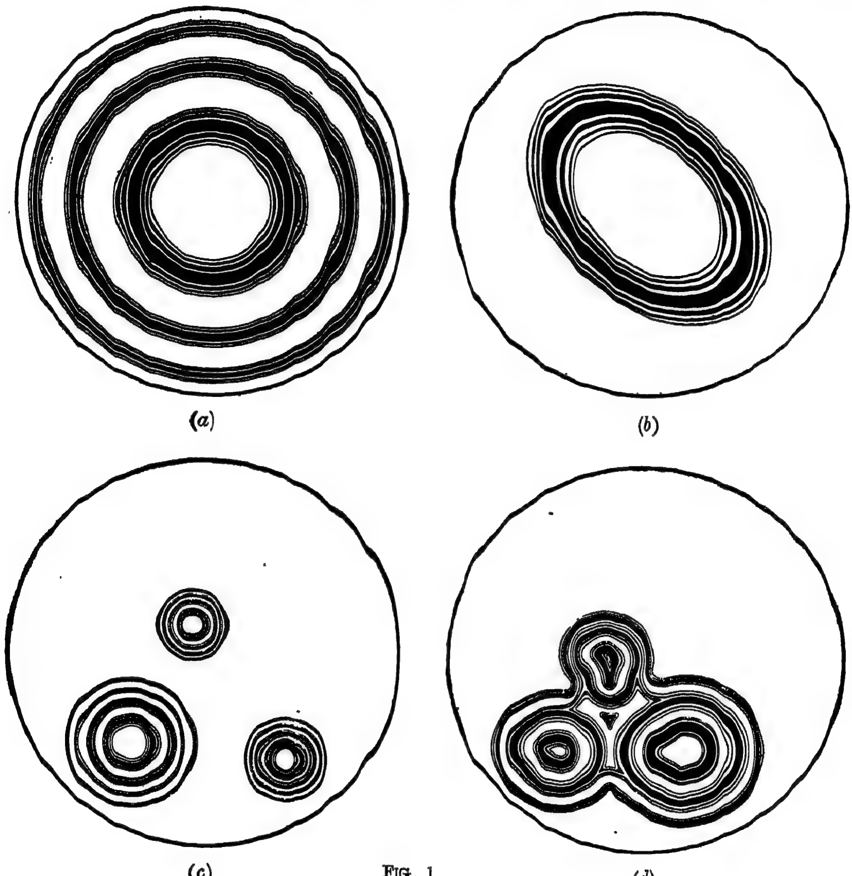
the compensation of these multiple image defects.

If the spheres are distorted and merge into one another as indicated by the interferometer appearance in *Fig.* 1 (*d*), the image produced will be indefinite or "fuzzy." Retouching in such a case is usually impracticable and the part must accordingly be finally rejected.

These several defects may appear singly or in combination and in various degrees. Thus, for example, in practice pure astigmatism is seldom found in optically parallel plates of thick glass. Usually the appearance of the image is attributable to lenticular and astigmatic defects which may be compensated by working one surface to a suitable cylindrical and the other to a spherical form.

It should be remembered that in the estimation of the various types of definition it is necessary that the inspector should know to what extent the errors are attributable to the defects of his eye, or to the apparatus employed, which should involve the smallest possible number of optical parts.

Veins, if not numerous, and if unaccompanied by other defects, have no serious effect upon the definition. A vein is usually an extremely fine thread of glass richer in silicate of alumina than the surrounding substance. Each vein is equivalent to a long astigmatic lens of extremely short focus, and the separate image formed by it is usually so diffused as to be invisible. But if the test object is a fine line, then by a movement of the eye the image may be momentarily occulted by the passage of the vein in front of it. A number of parallel veins may give rise to a rippling appearance of the image, and be sufficient cause for the rejection of the part. Often, however, the veins in glass are an indication of defective homogeneity, and in the best work the use of such glass should be avoided.



(*a*) (*b*)

(*c*) FIG. 1. (*d*)

(ii.) *Spherical Aberration.*—For the investigation of spherical aberration errors

Foucault's[1] original knife-edge method is still frequently employed, especially in the case of large object-glasses. If the eye of the observer is placed close to the focal point of the object-glass and receives all the rays falling upon it from a star or its equivalent, the whole aperture of the object-glass will appear illuminated. If then the focus is cut transversely by means of a knife edge, which should be mounted upon a fine operating screw, the whole aperture will become dark at the instant the knife edge passes the axis, if the objective is ideally perfect. If all the rays from the objective do not pass through the ideal focus, a number of rays will escape past the edge and still reach the eye, and the aperture will be partially illuminated, the distribution of the light affording an indication of the extent and distribution of the aberration. In the direct focussing method[2] the eye receives the focal image, formed by the objective, of a natural or artificial star, which appears as a system of diffraction rings surrounding a central spot of light. By examining the image out of focus on the near and far sides, the nature of the spherical aberration either over the whole surface or over zones may be deduced from the change in the distribution and character of the rings. Irregular defects of the surfaces or of the glass may be indicated by distortion of the rings. Thus an oval-shaped system would denote astigmatism. Chromatic aberrations may also be investigated by using homogeneous light of various wave-lengths. These two methods, and particularly the former, give qualitative results rather than quantitative. The latter method in the hands of a skilled observer is more precise and the appearances may be more directly interpreted.

Special forms of Michelson's Interferometer[3] are now frequently employed for the examination of prisms and lenses, and even of complex optical systems, although the interpretation of the results is then difficult. When a simple prism or object-glass is examined in this way the surface will appear uniformly illuminated if the piece under test causes no relative retardation of any portion of a plane wave front, assuming, of course, that the optical parts of the interferometer itself have been accurately compensated.

A concentric ring appearance would indicate curvature of one or more of the surfaces or a regular variation of the material. Irregularities of surfaces or substance would be indicated by a distortion of the system of rings.

The interferometer does not discriminate between retardations attributable to the glass and to the surfaces, except those due to defective annealing, which may be detected by observing the shift of the rings as a half-wave plate inserted before the eye is rotated. It is the resultant retardation that is indicated by the interferometer, and by the use of the interferometer alone it is not possible to allocate the component defects to the particular elements. But in practice it is sufficient to compensate the resultant defect by retouching one of the surfaces, and for this purpose a contour of the ring system as seen by the observer is painted upon the surface selected for the retouching operation. By polishing away the high portions and repeating the observations a comparatively uniform distribution may ultimately be obtained, and the definition be thereby greatly improved. Only large prisms and objectives can be subjected to an expensive process of this kind. For the production of aspherical surfaces the method is particularly valuable.

(iii.) *Chromatic Aberration.* — Chromatic aberrations may be investigated by the Vogel[4] method, provided the aperture is not so small that a large shift of the eyepiece is necessary to detect a difference of focus. It is also necessary that the chromatic effects due to the eye and the eyepiece or other parts involved should be previously determined.

In the eyepiece there is mounted a direct vision prism which forms a spectrum of the star image formed in the field of view through the intermediary of the part to be tested. If the correction is perfect, the spectrum, when the eyepiece is focussed, will appear as a thin line of uniform width, but if there is any chromatic aberration of particular colours the corresponding portions of the spectrum will be broader than the remaining parts. A measurement of the aberrational defects may then be obtained by observing the shift of the eyepiece necessary to reduce the various widths to a minimum amount. This method indicates only the general chromatic defect. It can hardly discriminate between zones, and if the aperture is reduced by stopping out the peripheral portions, the usefulness of the method is diminished.

Precise measurements of the various aberrations are obtainable even in the case of objectives of small aperture by the Abbe Focimeter method.[5]

But probably the most complete and precise investigation of the spherical and chromatic aberrations of any optical part is obtainable

[1] Foucault's method is discussed in the handbook *On the Adjustment and Testing of Telescope Objectives*, by T. Cooke & Sons, 1896.

by the Hartmann method [1] by means of which the final positions of particular rays are located in a manner comparable with the trigonometrical computation of the paths of rays. Symmetrically arranged holes in a diaphragm determine the portions of the optical part to be traversed by the fine bundles of rays which are finally received upon photographic plates situated at symmetrical positions before and after the focal plane. From the spacing of the images on the photographic plates in comparison with the spacing of the holes in the diaphragm the aberrations can be determined. Separate observations with light of different colours are made for the determination of chromatic aberration. The original method of examining the optical performance of an objective by means of selected rays is described by Father Cherubin,[2] who also demonstrates the effects of defective centring and emphasises the importance of accuracy in this respect.

From a consideration of the light intensity at a focal point Lord Rayleigh [3] has stated that "in general we may say that aberration is unimportant when it nowhere (or, at any rate, over a relatively small area only) exceeds a small fraction of the wave-length (λ). Thus in estimating the intensity at a focal point where in the absence of aberrations all the secondary waves would have exactly the same phase, we see that an aberration nowhere exceeding $\frac{1}{4}\lambda$ can have but little effect," and again, "An important practical question is the amount of error admissible in optical surfaces. In the case of a mirror reflecting at nearly perpendicular incidence there should be no deviation from truth (over an appreciable area) of more than $\frac{1}{8}\lambda$. For glass, $\mu - 1 = \frac{1}{2}$ nearly; and hence the admissible error in a refracting surface of that material is four times as great." This estimated value of Lord Rayleigh of the permissible phase difference is generally confirmed by practical experience.

§ (4) Test Plates.—Test plates are very commonly used for the examination of the surfaces not only during the progress of the work, but also in the final testing, with a view to the allocation of any observed defects of definition.

Sir Isaac Newton [4] has dealt very exhaustively with the colours of thin plates, which had previously been observed, but not completely described by other workers. Although it is evident from Newton's description that he realised that these colours afforded an indication of minute irregularities of thickness of the intervening layer, it is not so clear that it was his practice to test the surface being operated upon in comparison with a test plate having a very perfect optically flat surface.

These test plates which are the most valuable of the practical optician's appliances are usually made of quartz. But for reasons of economy glass test plates which from time to time must be compared with the standard quartz plates are employed. Quartz has the primary advantage of hardness. The frequent cleaning of the test surface that is essential soon impairs the definition in the case of a glass plate, and even in the case of quartz a good worker handles the surfaces with the greatest care.

For flat work the parallel quartz plate, having an approximate thickness of about one-fifth its diameter, is polished on both sides and worked as perfectly flat as possible on at least one side. When the test plate surface is placed upon the surface to be tested, if the latter is the larger and the more rigid, a thin layer of air is enclosed between them. Diffused white light which is reflected from the two surfaces of the air film gives rise to interference colours which may be viewed by a suitably placed eye. If monochromatic light is used numerous fine interference lines are visible, indicating minute variations that cannot be detected when using white light. Since the temperatures of the work and of the test plate will most probably be unequal, several systems of Newton's rings more or less distinct will be visible. As the temperatures equalise the rings will broaden, and in the course of 5 to 30 minutes, or more according to the volume of the parts, if the surface is perfect, a uniform straw yellow appearance may be obtained by skilful manipulation of the plate. If the surface is regularly curved concentric rings will be seen, and the greater the curvature the closer will be the spacing of the rings, provided the surfaces are clean and dry and the test plate is properly handled. Distorted rings or bands indicate irregularity of the surface relatively to the test plate. If when the test plate is gently pressed eccentrically by means of a pointed piece of wood, and not the finger, the centre of the rings moves towards the point of application; the surface under test is convex. It is very important that the adjacent surfaces of the work and the test plate should not only be thoroughly clean and free from the minutest specks of dust, but that they should also be free from any trace of moisture, the capillary action of which would locally distort the pieces and give a false indication.

For the best quality of work great skill is necessary in the use of a test plate, the indications of which require careful interpretation. Flat surfaces may be finally tested by an analysis of the reflected image in the manner described in § (2). The reflection test is the more reliable, but the test plate has the merit of great convenience, and for the greater part of the work the optician is called upon to perform it is thoroughly reliable and invaluable. For curved work one surface of the test plate is worked to the appropriate curve and the other surface is made flat. The radius of the curved test surface is measured by means of a spherometer or the radius or focus may be determined optically. It will be understood that the primary function of the test plate is not to obtain absolute measurements, but to determine the extent and nature of the difference between the worked surface and the test plate. To indicate the permissible amount of irregular distortion is hardly possible. If there is any noticeable irregularity the surface should be reworked. Slight regular ellipticity may be permissible when the astigmatisms of two transmission faces are normal to one another. Curvature to the extent of one and a half to two complete rings is generally regarded as being just permissible. It might be thought that such a statement would require extensive qualification according to the size of the part, its function, and its position in the optical system, particularly as regards its distance from a focal plane. Practical experience, however, shows that this limit of two rings, which accords with the practice of at least one large German firm,[1] covers a very wide range of work. Factory conditions render it practically impossible to adjust the limits to suit the requirements of individual parts. The tendency is towards the adoption of approximately one general and high standard of optical quality.

§ (5) Optical Processes.—For practical reasons it is customary to divide the process of working optical surfaces into three stages: (1) The forming stage in which the size and shape of the part is accurately determined; (2) the smoothing stage; and (3) the polishing stage.

Stages (1) and (2) involve the use of abrasives and these operations are accordingly performed in rooms quite separate from the polishing departments, where fine media only are employed. But it must not be assumed that the polished appearance of the surface as distinct from regularity of surface is a phenomenon that only takes place as a result of the polishing process. Actually a certain amount of polish is associated with the use of the roughest abrasive.

[1] W. Zschokke, *Festschrift*, Firma C. P. Goerz, p. 140.

It is only within comparatively recent years that the molecular regularity of polished surfaces has received recognition. The earlier conception is very clearly expressed by Sir Isaac Newton [2] in the following words:

"For in polishing glass with sand, putty, or tripoly, it is not to be imagined that these substances can, by grating and fretting the glass, bring all its least particles to an accurate polish, so that all their surfaces shall be truly plain or truly spherical and look all the same way so as together to compose one even surface. The smaller the particles of those substances are the smaller will be the scratches by which they continually fret and wear away the glass until it be polished, but be they never so small they can wear away the glass no otherwise than by grating and scratching it and breaking the protuberances, and, therefore, polish it no otherwise than by bringing its roughness to a very fine grain so that the scratches and frettings of the surface become too small to be visible."

There is no indication here that Newton regarded the surfaces as being molecularly regular or comparable with the surface of a liquid.

Subsequent writers have not hesitated to accept without question and to repeat the statement of so authoritative an observer as Newton. Thus, for example, Coddington,[3] Sir J. F. W. Herschel,[4] and Sir David Brewster [5] use practically the words of Newton when describing a polished surface.

If polishing were merely a continuation of the grating and fretting of the surface protuberances it should be possible to observe a continuous sequence of appearances from coarse conchoidal fractures to a grain of ultramicroscopic character. But if the operation of polishing a smoothed surface is performed under the microscope it will be seen that numerous patches of perfect polish akin to the still surface of a liquid are formed almost instantly, and that these patches exhibit no intermediate structure other than accidental scratches and kindred defects.

Lord Rayleigh [6] in a lecture on "Polish" appears to have been the first to describe their appearance. He states that, "In view of these phenomena we recognise it is something of an accident that polishing processes as distinct from grinding are needed at all, and we may be tempted to infer that there is no

essential difference between the operations. This appears to have been the opinion of Herschel (as expressed in the *Enc. Met.*, art. 'Light,'[1] pp. 447 to 830), whom we may regard as one of the first authorities on such a subject. But although perhaps no sure conclusion can be demonstrated, the balance of evidence appears to point in the opposite direction." . . . "Under those conditions which preclude more than a moderate pressure it seems probable that no grits are formed by the breaking out of fragments but that the material is worn away almost molecularly." . . . And later he states: "But so much discontinuity as compared with the grinding action has to be admitted in any case that one is inevitably led to the conclusion that in all probability the operation is a molecular one and that no coherent fragments containing a large number of molecules are broken out. If this were so there would be much less difference than Herschel thought between the surfaces of a polished solid and of a liquid."

Although the molecular character of the polishing operation and the similarity of the surface produced to that of a liquid are quite definitely expressed, and although Lord Rayleigh has referred in other of his papers to the remarkable pool-like appearance of elementary polished patches of a glass surface, it is not quite clear whether he regarded the result as being due to the removal of the substance molecule by molecule as distinct from the removal of minute aggregates of molecules or as being due to a molecular rearrangement or flow of the surface molecules as in the case of a liquid.

This latter conception is attributable very largely, if not entirely, to Sir George Beilby, who has developed it in a series of papers[2] dealing principally with metal surfaces, the tenacity of which is such that the surface amorphous layer is capable of bridging over surface cavities even when these are not completely filled with debris. It is very doubtful if any such bridging over of even minute cavities occurs in glass owing to the small cohesion of the silicates as compared with that of the metals.[3]

According to the molecular flow[4] theory of polishing, the forces exercised by the polisher upon the surface molecules of the glass suffice to overcome the cohesive forces binding them together, with the result that the molecules rearrange themselves uniformly under the action of their surface tension forces. Thus it would appear that the grain of a polished surface, being molecular, is much finer than is actually required for the regular reflection of even the shortest visual rays at normal incidence.

Polished layers may be produced in several ways although in all cases the action is fundamentally the same. Fire-glazed surfaces result from the thermal agitation and consequent flow of the surface molecules. Chemical forces produce a similar result. Provided precautions are taken to prevent the accumulation of fluoride crystals, very perfect light-reflecting glass surfaces may be produced by the action of hydrofluoric acid.[5]

When a piece of glass is fractured the forces at the cleavage edge so profoundly disturb the molecules that they are able to flow and form the characteristic polished appearance of a fractured surface.

It is hardly possible to fracture a piece of glass so suddenly that its surface is not polished. Under the microscope a rough ground surface is seen to consist of numerous conchoidal depressions the surfaces of which are all light reflecting, and which may indeed be made to act as so many separate lenses of poor quality.[6] Closer examination will disclose a rounding of all the ridges where the conchoidal surfaces intersect that can only be attributable to viscous flow. The ridges have a characteristic yellow-green colour whether the glass is flint or crown. Where these ridges intersect one another elementary polished patches are found, and if an attempt were made to polish a rough ground surface of this type, it would be seen that these elementary patches would be extended until they joined one another with the ultimate formation of a continuous polished surface.

§ (6) Abrasion.—In order that the workshop processes may be more fully understood, the features characteristic of abrasion and polishing must be considered in detail.

Suppose a small steel ball is pressed upon the polished surface of a glass cube the transverse faces of which are also polished so that the stresses introduced may be viewed by means of a polariscope.[7] When the pressure

[1] Herschel's description is practically a repetition of Newton's earlier observations.

[7] J. W. French, "Percussion Figures in Isotropic Solids," *Nature*, Nov. 20, 1919, p. 312.

is very light the appearance between the crossed Nicols is as in *Fig.* 2. The central black cone has an angle of about 20°, which appears to be practically independent of the pressure. The cone of strain *b*, *b* has an angle of about 90°. Some surface light is visible at *d*, *d*. At low pressures the dark cones *c* and *a* merge softly into *b*. As the pressure is increased the interfaces become more intensely defined, but the angles do not alter appreciably. Further gentle increase of pressure causes the surface layer to rupture as in *Fig.* 3, which is a photo-micrograph of an etched polished surface repeatedly ruptured by gentle impact. If the Nicols are paralleled black rays will be seen proceeding from the edge of the crack as in *Fig.* 4, their direction indicating that the crack is normal to the surface. The character of *Fig.* 2 is not appreciably altered.

A new phenomenon makes its appearance when the pressure is again increased. Immediately under the ball there appears as in *Fig.* 5 a sphere pierced by the filament of the cone *a*, and having a black outline tinged with red on the outside. The interior is filled with green-blue light; otherwise the general appearance of *Fig.* 2 is unaltered. If now the Nicols are paralleled, it will be seen that the well-known type of conical fracture [1] has been produced as indicated in *Fig.* 6. The coloured sphere of *Fig.* 5 is a certain indication of the existence of a cone fracture. Examination with the Nicols in an intermediate position shows that the cone fracture which follows the surface of *b* is tangential to the sphere which covers it. If the pressure is again increased the crushing point is soon reached. The glass under the ball collapses almost explosively, a distinct click being audible, and the ball sinks deeply through the surface. At the moment of this collapse, the cone of light *b* broadens out owing to the extension of the area of pressure. The cone fracture also may extend horizontally like the brim of a hat, thus definitely terminating the depth below the surface, and the space within the cone becomes cleft by one or by two fracture planes normal to one another and having their line of intersection on the axis of the dark cone *a*, as in *Fig.* 7. The diametral planes may be extended to the brim as in *Fig.* 8. Under crossed Nicols two new small coloured spheres indicative of subsidiary planes may be observed as in *Fig.* 9.

Now the grains of an abrasive such as carborundum are nodular in parts and hard and

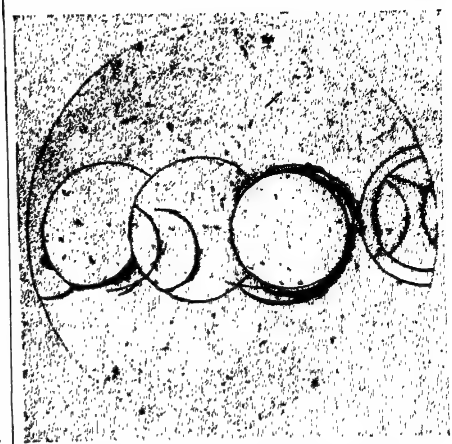

FIG. 3.—Surface etched after rupturing. Magnification 40 diameters.

akin to the steel balls used in the experiment. But a rough ground or smoothed glass plate exhibits practically no cone fractures, notwithstanding the vast number of impacts that must have occurred in the operation. Only if the tool carrying the abrasive is lowered sharply on to the glass surface will a number of cone fractures probably be formed.

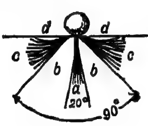

FIG. 2.

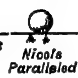

FIG 4.

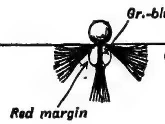

FIG. 5.

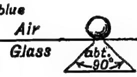

FIG. 6.

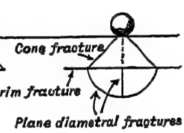

FIG. 7.

From this it seems evident that the grinding of glass is not the result of any such normal pressure of the grains, and another explanation must be obtained. In the experiments with the steel ball as described above the forces were symmetrical about the vertical axis. When the pressure is applied near the edge of the surface, the new appearance corresponding with the stage illustrated in *Fig.* 2 will be as illustrated in *Fig.* 10, from which it will be

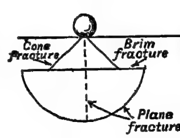

FIG. 8.

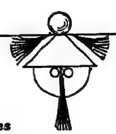

FIG. 9.

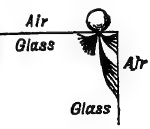

FIG. 10.

[1] "L'Éclatement," Ch. de Fréminville, *Revue de Métallurgie*, Sept. 1914, sect. vii. p. 66.

seen that the central cone is now deviated towards the side. Its axis along which fracture finally takes place follows the characteristic conchoidal section. It is presumably the impact of the abrasive grains on the edges of cavities that produces the conchoidal splintering of a ground surface as indicated in *Fig.* 11.

As it is the transverse movement of the tool relatively to the glass that forces the hard grains against the edges of the cavities, it is to be expected that the rate of grinding will depend upon the speed of movement of the tool relatively to the work, and also upon the pressure exerted by the grains. This is confirmed, so far as the effect of relative speed is concerned, by the results of carborundum abrasive tests which indicate that the weight of glass removed is directly proportional to the relative speed,[1] the other conditions being maintained constant. To eliminate the effect of loss of cut fresh abrasive must be applied at intervals of about one minute, and precautions must be taken to ensure constancy of the general conditions throughout the tests.

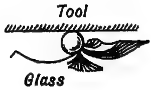

FIG. 11.

From an examination of the previous *Fig.* 11, it will be seen that the larger the grain the deeper, in general, will be the point of impact and the larger the splinters removed. The rate of grinding is therefore dependent also upon the size of the grain. Thus by reducing the coarseness of the abrasive at each stage of the grinding operation, a surface of any desired degree of fineness may be obtained; and indeed the surface may be highly polished by means of the same material as is used for the rough grinding, provided a sufficiently fine grain of a suitable character is obtainable. Prior to the time of Antheaulme[2] it was the practice of the earlier opticians[3] to make the polishing process merely a continuation of the grinding stage, the sand first used being ground down sufficiently in the operation to serve as a polishing medium in the later stages.

Highly polished optical surfaces have also been produced by the use of very fine grades of carborundum. As much more suitable polishing media than fine carborundum are available, this experiment is mainly of interest as emphasising that there is no strict line of demarcation between abrasion and polishing. The removal of material and the production of the amorphous polished layer occur simultaneously, although to different extents. Thus in the coarsest grinding there is removal of material and only very slight surface flow along the ridges between the concavities of the surface, since the cleavage flow over the depressed surfaces of the conchoidal fractures does not contribute except in the last stage to the final surface.[4] As the abrasive becomes finer the splinters decrease in size and the material removed diminishes, while the amount of surface flow over the network of ridges increases.

If in the grinding process the flat grinding tool is so hard that it rides over the grains, the impacts would be more normal to the surface and undesirable cone-fracturing would occur. The finer the abrasive the harder may be the smoothing tool. Lead, zinc, copper, aluminium, brass, and cast iron have all been used for various kinds of work and various abrasives, but fine-grained cast iron and brass, free from surface defects, are most generally, and indeed almost universally, employed. Steel is too hard for even the finest grades of abrasive.

After the surface has been ground to the necessary degree of fineness, polishing may be commenced, the purpose of the process being to promote the greatest possible amount of surface flow while avoiding the conchoidal splintering characteristic of the grinding process.

A very small amount of material is removed during the polishing action, but the nature of the abrasion, if it can be so termed, is characteristically different from that during grinding. Minute grooves are ploughed through the amorphous surface layer, and small portions of the amorphous substance become disengaged by the action of the polisher and are removed. These fragments may be recovered by dissolving away the rouge and resinous substances. The residue has a sparkling snow-like appearance and consists of extremely minute unresolvable particles cemented loosely together possibly by surface fusion along their edges.

§ (7) POLISHING.—A clear distinction must be drawn between a polished surface and one that is at the same time optically regular. This will be more easily understood by considering the action of a cloth polisher as compared with that of a pitch polisher.

Suppose in *Fig.* 12, A is the fine ground surface greatly magnified composed of flat elementary areas with numerous conchoidal depressions. A surface of this kind is said to be grey, the appearance being due to irregular reflection or scattering of the light. B is a layer of soft cloth or felt cemented to the regular surface of the metal runner C, which may be of aluminium, brass, or iron. Over the flat areas of A the drag, and consequently the reduction of the general level, will be greatest. Over the surfaces of the

[1] "More Notes on Glass Grinding and Polishing," J. W. French, *Trans. Opt. Soc.*, Jan. 1917, xviii.

[2] *Histoire des mathématiques*, Montucla, vol. iii. part v. book ii. p. 498.

[3] Renati Descartes *Opera Philosophica*, "Dioptricis," 1656, cap. x.; Johannes Zahn, *Oculus Artificialis Telediopticus*, 1702.

[4] "Some Notes on Glass Grinding and Polishing," J. W. French, *Trans. Opt. Soc.*, Nov. 1916, xvii. No. 2.

depressed areas into which the felt partially sinks there will be a certain amount of drag and polishing action, combined with the removal of material not only from the flat portions but to some extent from the depressions also. There will be a general rounding off of the irregularities, but, as is confirmed by practice, the irregularities cannot be eliminated by the use of a soft polisher, although a small amount of original greyness is rendered less conspicuous to ordinary vision, and a false appearance of complete uniformity and polish may be produced more quickly by means of a soft polisher. Suppose a harder type of polisher such as a pitch polisher is used. When using the same polishing medium, such as rouge, the amount of drag and polishing action over the flat portions will be greater than when using cloth, and, further, as the

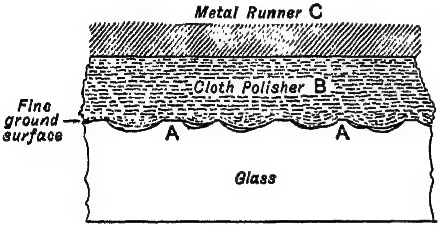

FIG. 12.

pitch will not sink into the depressions to the same extent, the rounding and particularly the removal of material from the depressed portions will be less.

When using a hard polisher a uniform polished surface free from all greyness is obtained by the removal of the surface material stage by stage until the surface is reduced below the level of the deepest conchoidal depression.[1]

Under the action of the polisher, according to the flow theory, the disturbance of the surface molecules is such that they are able to rearrange themselves or flow with the consequent formation of a polished amorphous layer. Minute aggregations of the rouge or other medium plough away the surface layer, and it is conceivable that there may be also some swaging action, material being removed from the higher portions and welded upon the adjacent depressed areas. As the amorphous material is removed in this way the underlying molecules are acted upon by the polisher, and the process is repeated layer by layer as indicated in *Fig.* 13.

If rouge is employed in the last stage it is generally possible by special illumination of the surface to detect an open network of these fine grooves; but if no medium other than a very fine film of water is used for the final polishing operation, the presence of grooves will hardly be observable. When a surface of this kind is etched with hydrofluoric acid a network of grooves will reappear,[2] and it has

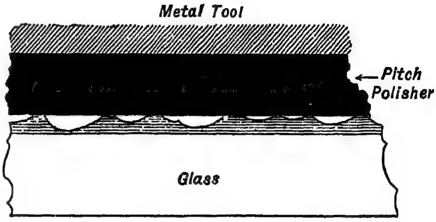

FIG. 13.

been assumed that just as in the case of metals the original grooves have been bridged over by the amorphous layer and are uncovered when the surface layer is dissolved away. Numerous experiments, however, seem to indicate that the cohesion of the amorphous silicates is too small to permit of the bridging of the finest surface cracks that can be produced.[3] That grooves produced during the rouge-polishing stage become filled up during the final water-polishing stage may, however, be accepted. Thus it is probable that the groove A in the surface layer becomes filled up possibly in stages at each stroke in the manner indicated in *Fig.* 14. On the assumption that the expenditure of energy upon a substance tends in general to reduce its chemical stability, it is to be expected that the material filling the grooves would be rapidly acted upon and that the grooves produced by

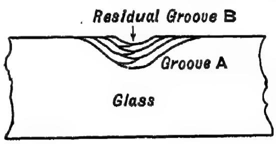

FIG. 14.

etching are really reproductions of the original grooves. The course of the original grooves will in any case be indicated by a very fine groove B, which would be extended by the acid to form a deeper groove occupying the place of the original one.

The various stages in the grinding and polishing of a glass surface may be summarised briefly as follows:

1. The removal of material by the breaking away of splinters, the size of which is reduced in stages by the use of finer grades of abrasive.

[1] "Polishing of Glass Surfaces," Lord Rayleigh, *Proc. Opt. Convention*, 1905, i. 75.

[2] "Interference Bands and their Applications," Lord Rayleigh, Royal Inst., March 24, 1893.

[3] "Some Notes on Glass Grinding and Polishing," J. W. French, *Trans. Opt. Soc.*, Nov. 1916, xvii. No. 2.

2. The production of an amorphous or surface flow layer and the gradual removal of these layers by grooving as distinct from the splintering of the first stage, the removal of material being effected by means of a very fine abrasive or polishing material such as minute aggregates of particles of rouge.

3. The elimination of the grooves produced in stage 2 by the use of a continuous medium such as a film of water in place of the discontinuous medium such as rouge, there being during this stage the maximum production of surface flow and practically no removal of the surface layer material and no splintering action whatever.

§ (8) Polishing Materials.—An abrasive to be effective must possess several well-defined characteristics. The grains, which must be hard, should have an irregular form presenting many strong edges or rounded points that will transmit the impact forces to the glass to be abraded. When the grains break down the fragments should be of the original form in order that the action on a finer scale may be continued. An abrasive that breaks down into lamellar fragments is said to lose its cut. Diamond, splinters of which are illustrated in *Fig.* 15, is the most effective of abrasives, but owing to its cost it can only be used for special operations such as the slitting of glass where the quantities are small.

Carborundum (SiC) is a compound of carbon

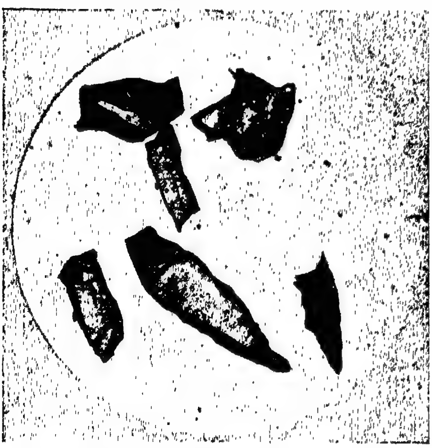

Fig. 15.—Diamond Splinters. Magnification 15 diameters.

and silica, resulting from the fusion of carbonaceous materials such as coke or charcoal with sand in the electric furnace at a temperature of about 2000° C. Its hardness on Mohs scale is about 9, diamond being 10. From *Fig.* 16 it will be seen that the grains are of the desired irregular shape, which is retained as they break down.

Other important abrasives are obtained by the combination of alumina and silica in the electric furnace, such, for example, as corundum, alundum, and aloxite. They are

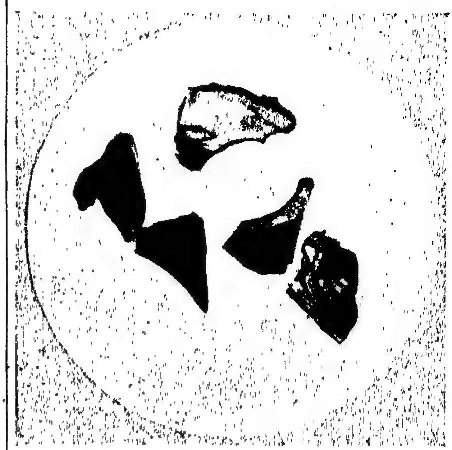

Fig. 16.—Carborundum. Magnification 40 diameters.

most commonly employed in the form of grinding wheels. As loose abrasives they are not so effective as carborundum.

Emery is a natural form of artificial corundum, being a silicate of alumina containing, however, oxides of iron and other impurities irregularly distributed. It breaks down more readily than carborundum and loses its cut. The loss of cut is only temporary, however, as after washing the material can be used as a finer grade of emery.

Sand is sometimes used for rough abrasion, more particularly in establishments where no facilities exist for the washing and recovery of the more expensive types of abrasive. Its grains are frequently rounded and water-worn as indicated in *Fig.* 17, and it readily breaks down and loses its cut.

Separation of an abrasive into the various grades of fineness is generally done by a process of settling and levigation. Thus three-minute emery is the material obtained from the liquid that is decanted after a settling period of three minutes. For carborundum it is necessary to use sieves of various finenesses in conjunction with settling, except in the finest stages, for which sufficiently fine sieves are unprocurable.[1]

A comparison of the abrasive powers of carborundum, emery, and sand of approximately equal size of grain is obtainable from *Fig.* 18, which also shows how in the case of each abrasive the rate of abrasion is directly proportional to the pressure when fresh abrasive is supplied continuously.

If the abrasive is not frequently renewed,

[1] "The Grading of Carborundum for Optical Purposes," J. W. French, *Trans. Opt. Soc.*, Oct. 1917.

the rate of grinding would not increase regularly with the load owing to the loss of

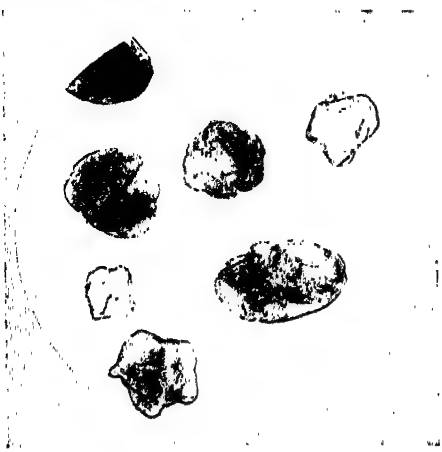

FIG. 17.—Sand. Magnification 40 diameters.

cut and a certain clogging action, especially at the higher pressures. This is illustrated in *Fig.* 19, from which it will be seen that when using No. 3 carborundum having an average grain diameter of 0·1 mm. the rate of abrasion is directly proportional to the load when fresh

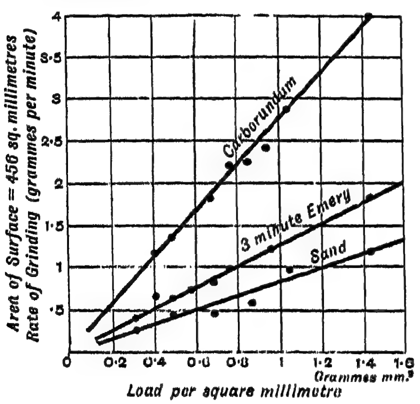

FIG. 18.

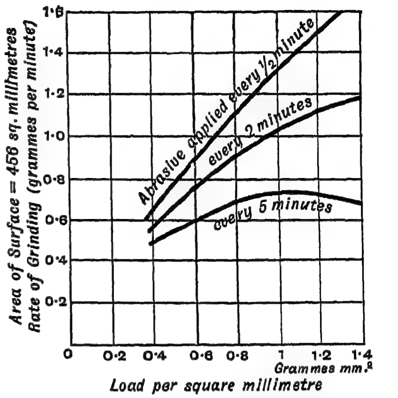
material is applied every half minute, whereas there is actually a reduction of the rate at high loads when the intervals between the applications are of five minutes' duration.

The series of curves in *Fig.* 20 shows how the rate of abrasion varies with the size of the grains and the load on the tool. Fresh abrasive was applied every half minute, and it will be seen that for the coarsest No. 1 carborundum having a grain diameter of approximately 0·2 mm. the abrasion is directly proportional to the load. In the case of the carborundum grades 3, 4, and 5 the curve bends at the higher loads suggesting the need for more frequent renewal of the abrasive, due possibly to clogging arising from an admixture of glass powder in these intermediate grades.

A similar series of abrasive curves for 3 minute, 15 minute, and 40 minute emery is



No. 3 Grade (washed) Carborundum (0·1 mm. diam.)

FIG. 19.

illustrated in *Fig.* 21. Between the 3 and 15 minute curves there is a considerable interval which corresponds, however, with the grain dimensions, which are 0·13 mm. and 0·01 mm. respectively.

From the various diagrams it will be evident

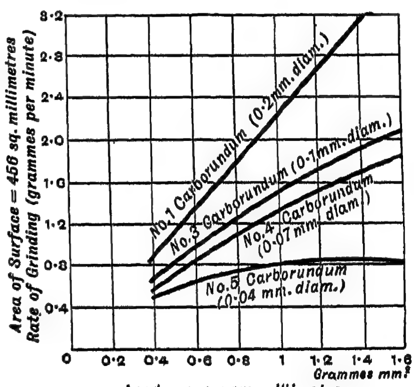


FIG. 20.

that the rate of abrasion of a particular type of glass depends upon:

The nature of the abrasive.

Its grade of fineness.

The load upon the tool.

The relative speed and to some extent the frequency of renewal.

The material of the tool itself, which has some bearing on the rate of abrasion, is

practically determined by the type of abrasive, the materials of widest application being fine-grained cast iron and brass.

Rates of abrasion afford a general but not definite idea of the quality of a ground surface, because the same weight of material may be removed by the production of large shallow splinters or by smaller and correspondingly deeper ones. In the grinding process it is sought to produce a surface of uniform texture free from isolated deep pits which often determine the thickness that must be finally removed. A record of the texture may be obtained by observing the reflecting power of the ground surface.[1] If the surface is viewed so obliquely that the irregularities are foreshortened to such an extent that even the longest red rays are reflected, a perfect white image of, say, an incandescent filament may be seen reflected from the surface. The image

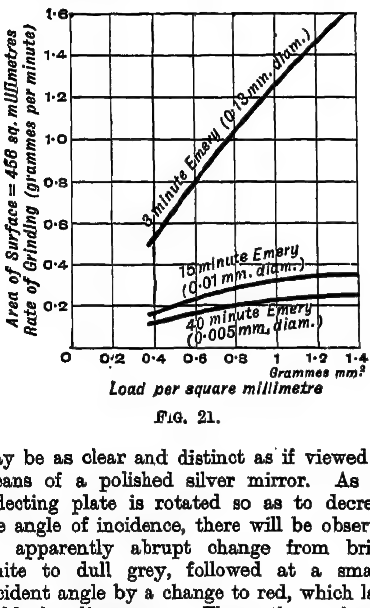

FIG. 21.

may be as clear and distinct as if viewed by means of a polished silver mirror. As the reflecting plate is rotated so as to decrease the angle of incidence, there will be observed an apparently abrupt change from bright white to dull grey, followed at a smaller incident angle by a change to red, which later suddenly disappears. These three changes take place sufficiently abruptly to provide a general record of the surface. Thus in the case of a piece of hard crown glass, ground with 3 minute emery, the respective angles of incidence, the readings of which can be repeated to within half a degree, were 80°, 78°, and 75°. For similar glass ground with an abrasive wheel, the corresponding figures were 66°, 61°, and 46°, thus indicating a much finer texture. In *Fig.* 22, which gives a comparison of the surfaces produced by a series of carborundum abrasives, abscissae represent the size of the respective grains, and ordinates the cosecants of the angle between the surface and the line of sight. This is equivalent to the projection of the texture in a plane normal to the line of sight, thus enabling the irregularities to be compared directly with the lengths of the waves regularly reflected. As is to be ex-

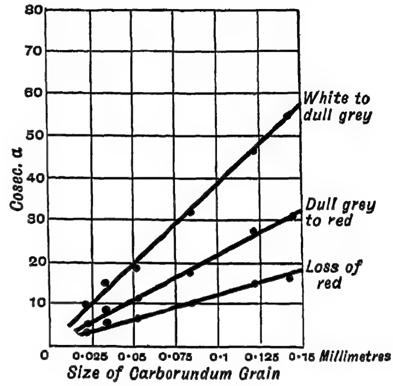

FIG. 22.

pected from the previous abrasion diagrams the curves are straight lines, the projected dimensions of the texture being directly proportional to the size of the grain when the other conditions such as load and speed are maintained constant throughout.

Fig. 23 shows the corresponding results obtained when using the three grades of emery commonly employed, namely 3 minute, 15 minute, and 40 minute emery. If the conditions can be controlled with sufficient accuracy, similar straight line curves may be obtained for most abrasives, but in the case of such abrasives as powdered glass which break down readily and lose their cut, the conditions cannot

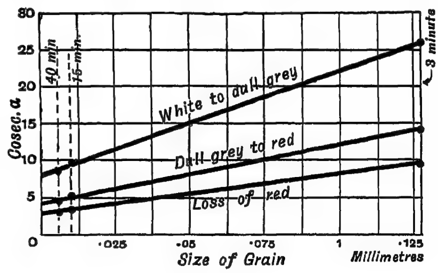

FIG. 23.

be easily controlled and the curves generally fall away towards the coarser grades.

Smoothing operations in the case of a single piece may be regarded as a continuation of the rougher grinding processes, their purpose being to reduce as much as possible the amount of material that has to be removed in the polishing process, but when a number of pieces after

[1] "More Notes on Glass Grinding and Polishing," J. W. French, *Trans. Opt. Soc.*, 1917 (Jan.), vol. xviii.

being formed are mounted in one block so that they may be polished together, the smoothing process preparatory to polishing is necessary in order to reduce any irregularity of the surface levels due to slight errors in the laying down of the pieces.

Whether the surface desired is plane or curved the final form of the piece must be produced before the polishing operation is commenced. Any important alteration of the form is impracticable during the polishing process, the functions of which are the formation of the brilliant amorphous light reflecting surface layer, and the production of a true figure, that is, the correction of minute errors of form not exceeding one or two wave-lengths over the whole surface. Greater errors of form must be corrected by a repetition of the smoothing or fine grinding operation.

Almost any substance in a fine enough state of division, and provided its grains are not lamellar in form or soluble in the liquid employed or liable to weld upon the surface of the glass, may be used as a polishing medium. Thus glass can be polished readily with fine charcoal, but hardly at all with graphite.

But in practice the choice may be limited to a very few substances, the principal of which is rouge, that is oxide of iron (Fe_2O_3). Many substances are slow in their polishing action. Putty powder, that is tin oxide (SnO_2), which at one time was extensively used, is now excluded for reasons of health.

Manganese dioxide (MnO_2), although an excellent medium, is very black and is difficult to remove from the hands and clothing; from the point of view of general cleanliness its use is often avoided. Other media again cannot be obtained in a consistently uniform condition, and although the variety of substances is great, there are really few that have all the advantages of rouge, which is so extensively used, except for the very cheapest kinds of optical work. Comparisons of the polishing media can only be made if the conditions are carefully standardised, and particularly if the texture of the original smoothed surface is the same in all cases. The rate of polishing, so far as polishing is determined by the removal of material until the bottoms of the deepest depressions are reached, depends upon the following:

The original state of the smoothed surface.

The character of the polishing-tool surface, which may be, for example, of cloth, pitch, wax, or paper.

The polishing medium.

The lubricant.

The load.

The relative speed of the tool and the surface operated upon.

The typical chart, *Fig.* 24, shows how the time of polishing and the rate of removal of glass are affected by the load on the tool. In this particular instance the rate of removal of material varied directly with the pressure, the tool being covered with a mixture of 95 per cent of beeswax and resin and 5 per cent pitch.

It is not possible to make any definite comparison of the numerous substances that may be used as polishing media, because the results are greatly influenced by the conditions. Substances that are only moderately good when a pitch polisher is used may be much more effective when the polisher is of a different type, such as cloth.

To obtain consistent results it is also very necessary to control the conditions, the most important being the original state of the smoothed surface to be operated upon.

Table I. shows the times of polishing when using a variety of typical polishing materials under the particular conditions specified. In all cases the original surface was smoothed with fine carborundum having an average grain diameter of about 1/200 mm., the reflection values of the surface being 80° grey, 73·5° red, and 64° loss of red. Pitch polishers were used throughout.

TABLE I

Machine type, reciprocating arm.
Revs. of spindle, 78 r.p.m.
Speed of arm, 190 strokes per minute.
Length of stroke, 1·25″.
Diam. of worked surface, 3″.
Diameter of polisher, 3″.
Load on polisher, ½ lb. per sq. inch.

Medium.	Polishing Time.	Quality.
	Hours.	
Precipitated rouge	3	Good polish.
Commercial rouge	4	
Glassite	4·1	
Very fine carborundum	8	Fair.
Putty powder (SnO_2)	11	Surface cut and not good.
Precipitated silica (SiO_2)	12	Surface not good.
Precipitated chromium oxide (Cr_2O_3)	14	
Precipitated alumina (Al_2O_3)	14	
Precipitated ferrous carbonate	16	Very slightly grey.
Precipitated hydrous MnO_2	22	

Putty powder and the various precipitated media are better suited to cloth polishers than to pitch polishers, but the

superiority of the first three media is still marked when used on cloth.

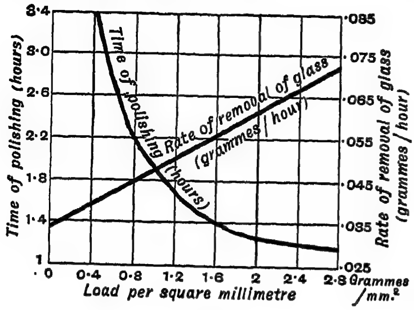

FIG. 24.

Very many substances have been used as a covering layer for the polishing tool to hold the polishing medium.

Huyghens [1] polished his glasses upon the metal tool itself, using a specially prepared mixture of Tripoli as a medium, which was reduced to a firmer and finer state by wiping away the marginal portions from time to time.

To Sir Isaac Newton [2] is attributable at least the suggestion that a pitch layer might be used for the polishing operation. In his *Opticks* he states that: "An object glass of a fourteen foot telescope made by one of our London artificers I once mended considerably by grinding it on pitch with putty and leaning very easily on it in the grinding, lest the putty should scratch it. Whether this way may not do well enough for polishing these reflecting glasses I have not yet tried."

It is quite clear from a previous paragraph [3] that Newton actually used pitch for both the grinding and the polishing of metal reflectors, for in the same work he states: "Then I put fresh putty upon the pitch and ground it again till it had done making a noise, and afterwards ground the object metal upon it as before, and this work I repeated until the metal was polished, grinding it the last time with all my strength together for a good while, and frequently breathing upon the pitch to keep it moist without laying on any more fresh putty." The application of water alone in the final stage is of particular interest as being an important detail of present-day practice.

Father Cherubin [4] lined his polishing tools with a variety of materials of fine and uniform texture. More particularly he refers to the use of very fine thin leather, fine English fustian, fine Holland or any fine linen, silk taffety or satin. He describes at great length the process of lining the tools with paper and the method of removing little lumps or irregularities, but the previous use of paper is attributable to Antheaulme,[5] who used the grinding tool itself when lined with paper as the polishing tool, the medium employed being Venetian Tripoli.

At the present day pitch, wax compounds and cloth are the materials most commonly used. Comparisons of a variety of materials when using a particular polishing medium can be obtained from Table II., which shows

TABLE II

SURFACE LAYERS OF POLISHING TOOLS

Material worked, glass—hard crown.
Surface smoothed with fine carborundum, diam. of grain about 1/200 mm.
Spindle speed, 124 to 130 r.p.m.
Arm speed, 100.
Stroke, 1·25″.
Polishing medium, rouge and water.
Load on polisher, ½ lb. per sq. inch.

Polisher.	Time of Polishing.	Remarks.
	Hours.	
90% pitch with 10% beeswax and resin	1·5	Good surface.
Very hard pitch	1·75	Fair surface, pitch hardness 0·5 at 37° C.
Beeswax and resin with 10% pitch	1·75	Good surface.
Pitch 70% with 30% rubber compound	2	" "
Pitch 70% with 30% rouge .	2	Fair surface.
Soft pitch	2·75	Good surface, pitch hardness 16 at 38° C.
Ebonite with 10% pitch . .	3·5	Polished, but cut, contact obtained with difficulty.
New cloth	4·5	Good surface.
Well-singed cloth . . .	6	Poor surface, cut.
Cork	6	Fair surface, slightly cut owing to bad contact.
Wood, deal	6	Cuts, owing to difficulty of obtaining good contact.
Brown paper, impregnated with beeswax and resin	6	Fair surface.
Very thick felt	12	Surface grey and mottled.

the time required to polish a piece of crown glass smoothed in all cases to the same standard. For the purposes of comparison comparatively slow speeds and loads were employed. From the previous diagrams it will be understood that the time of polishing would be reduced by increasing these factors, and the relative positions of the various materials might be slightly modified by the use of another polishing medium such as putty powder.

Since the time of Newton, over two hundred years ago, hand-polishing methods as practised to some extent in most high-class workshops have remained unaltered, except possibly in

production of an optically flat surface; if two are ground together the respective surfaces will become convex and correspondingly concave, the tendency in practice being for the upper tool to become concave. If one of these tools, say the convex No. 1, is then ground with No. 3 tool, the latter will become correspondingly concave, more or less like No. 2. If then the two concave tools Nos. 2 and 3 are ground together, their concavities

FIG. 25.—Hand Working.

so far as the materials employed are more uniform in quality.

§ (9) POLISHING TOOLS.—Some idea of the essentials of the actual flat or prism surface polishing operations may be obtained from *Fig.* 25. The pedestal (1), which must be rigid, has at its upper end a standard nose-piece upon which the tools may be screwed. Under the work bench there will be observed two flat tools (2) and (3) of close-grained and well-annealed cast iron, and on the bench another (5) lying face downwards with a wooden operating knob screwed into the boss. On the pedestal is mounted the tool or runner (4) as it is called, which has a uniform flat surface layer of pitch, and on the bench there is a similar runner (11), the pitch surface of which is exposed to view.

Three plane tools are necessary for the

will both be reduced. By grinding No. 1 on No. 2, then No. 1 on No. 3, and No. 2 on No. 3 in this way, and repeating the sequence of operations as long as may be necessary, all three tools become optically flat and may be kept in this condition by an occasional repetition of the process.

Sir Joseph Whitworth's name is generally associated with this method, which he applied to the production of standard surface tables, but although the principle may not previously have been clearly expressed, the method appears to have been known to the earlier opticians.

The work is ground or smoothed upon one of the metal tools, fine grades of carborundum or emery being used as the abrasive medium. It is essential that the surface should be ground and smoothed to the desired curvature

or flatness, as the time of polishing depends upon the perfection of the smoothing operations. Removal of material during the polishing process occurs very slowly, and it is then impracticable to effect an alteration of the shape other than a change of the figure involving a removal of material to a depth of a few wave-lengths.

For the polishing process the surface of the metal runner, which itself need only be approximately true, is covered with a layer of pitch about 12 mm. thick, the runner being heated gently to ensure good adherence. The pitch surface is then moulded by one of the flat tools that has been heated just sufficiently to soften the pitch upon which it is pressed. When the pitch is cold, the whole surface is divided into small squares by deep grooves which may be cut more cleanly under water when the pitch is of a brittle type. Over the pitch surface there is then stretched a piece of open texture muslin which is squeezed into the pitch by means of the hot flat tool, and is then peeled off, leaving its network impression on the surface.

While the deep grooves help to preserve the flatness by breaking the continuity of the layer and thus preventing the centre parts from being squeezed towards the periphery, their principal function as well as that of the fine network is to destroy the suction that would hinder the free movement of the work over the moist pitch surface.

The grooves also serve to retain any excess material that otherwise might collect and produce sleeks, that is, minute furrows on the surface of the work, or even cuts.

After the pitch surface has been prepared in the manner described, it is rubbed with one of the optically flat metal tools until it also is optically flat. Rouge and water are commonly used as the working medium, not only in the preparation of the pitch surface but also in the operation of polishing the work.

By means of the soft brush (7) fine, well-levigated rouge and water from the pot (9) are laid in streaks on the pitch surface of the tool (4), and the harder brush (6) is employed to spread the medium uniformly over the whole surface upon which the part to be worked is laid, the sponge (8) being used throughout the operations to wash away excess material from around the edge of the tool.

The operator, whose attitude is illustrated in *Fig.* 25, controls the work around its periphery by means of the fingers and thumbs, and, while gently pressing it into contact with the pitch surface, he moves it to and fro. At frequent intervals, after a few such repeated strokes, the work is given a wide-sweeping movement over the pitch surface and is occasionally rotated. At intervals the operator also steps round the pedestal, or, alternatively, the lower tool may be slowly rotated.

The purpose of these movements is to avoid any regular repetition of strokes that would tend to local wear of the tool or work, and the production of irregular surfaces. If the to-and-fro movements in one direction were repeated for too long a time, a broad depression would be formed on the tool surface, the optical flatness of which would accordingly be destroyed.

From time to time the pitch surface is reworked or formed by means of the metal tool (5), the flatness of which is preserved by occasional working with the tools 2 and 3. Towards the end of the process water only is used as a polishing medium and the operation is continued until the water is almost entirely dried up, which is evidenced by a characteristic squeaking noise. In this way the greatest possible viscous flow of the surface molecules is obtained owing to the close contact between the work and the polishing tool.

Surface defects such as sleeks are detected by examining the surface with a low-power lens, the necessary illumination being obtained from the lamp (10). Defects of flatness are detected by means of the test plate (12), which is placed on the surface of the work lying upon a black cloth. It is essential that the temperature of the parts should be allowed to equalise before attempting to form a definite decision as to the character of the surface under test, and before using the test plate the parts should be thoroughly cleaned with a linen cloth or selvyt (13), and also freed from dust by means of the soft brush (14).

At night it is convenient to use mercury-vapour lamplight, which is approximately homogeneous and produces black interference rings that may be very readily observed.

Much skill is necessary to obtain the correct figure or form of the polished surface within the limits essential to the production of well-defined images, and each operator has his own particular method of controlling the figure, which indeed to some extent depends upon individual characteristics such as the temperature of his hands. Two methods are frequently employed. In handwork, with the tool below the glass which has the smaller area, if the surface becomes concave the stroke should be reduced within the limits of the polisher. If the surface becomes convex the stroke should be widened until the defect is corrected. On machine work, with the tool having now the smaller area above the work, these operations should be reversed, a wide stroke, and especially one that overlaps the polishing tool, being employed to reduce any concavity of the surface of the work.

In the case of large surfaces, such as are usual in machine multiple work, the position of the polishing tool may be so altered that it acts more around the periphery or over the centre, as may be desired to correct the figure.

The second method consists in ringing the tool, that is, in broadening the furrows or scraping the tool surfaces, and thus reducing the effective polishing area at the centre or towards the edge, according to the requirements.

Thus, suppose a block of concave lenses is too shallow. To correct the figure it is necessary to remove material from the centre. This may be done by lengthening the stroke of the block so that at the ends of the travel it overlaps the polishing tool, with the result that for a portion of the time the outer parts, as compared with the centre, are not acted upon and are not reduced to the same extent; or the outer portion of the polishing tool may be reduced by scraping, or the effective surface reduced by ringing, so as to increase the relative effect of the centre parts.

A polisher that has been used for a considerable time often becomes glazed and loses its effect, so far as the removal of glass is concerned, but not as regards the actual polishing action if the contact is good. It has been suggested that the glaze which may be readily scraped away is a more or less continuous layer of glass.[1]

Particular results are also obtained by a proper selection of the polishing layer.

In the case of pitch, which should be a good quality of Burgundy pitch, the hardness must be varied by more or less prolonged boiling to suit the temperature, and to some extent the nature, of the glass and work.

Thus, unless the workshop temperature can be kept constant, which is not easy so far as the reduction of the maximum summer temperature is concerned, a hard, well-boiled pitch must be used in summer and a softer pitch in winter.

Some operators prefer the use of wax instead of pitch, and particularly for the polishing of curved work.

From *Fig.* 26 it will be seen that there are characteristic differences attributable largely to differences in the viscosities of the materials. Abscissae represent temperatures and ordinates the rates of penetration of a steel disc under a constant load. Whereas the pitch yields, even at the low temperatures, very little change occurs in the beeswax-resin composition until a temperature of about 27° C. is reached, when the viscosity rapidly changes. As the normal temperature of working rarely exceeds 22° C., it will be evident that wax layers are not so susceptible to fluctuations of temperature as pitch layers. Wax therefore retains its shape better than pitch, but its form is not so easily manipulated when a modification of

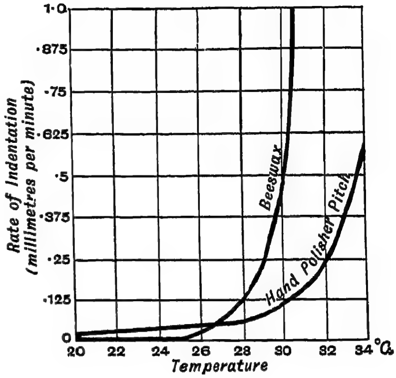

FIG. 26.

the figure is desired, and the difficulty of obtaining good contact is greater.

§ (10) POLISHING PROCESSES.—Only the very highest qualities of optical work or small quantities of individual parts are made by skilled hand methods. For the production of parts in large quantities considerations of cost make the use of machinery essential. Although highly specialised machinery has been evolved for the manufacture of particular products, such as spectacle lenses,[2] there are certain well-defined methods and types of machinery, a description of which alone will suffice to indicate the fundamental principles.

The machine processes may be divided, as in the case of hand work, into the three groups:

(*a*) Forming or roughing.
(*b*) Smoothing.
(*c*) Polishing.

Frequently the raw glass is supplied in the form of plates which are cut to the approximate shape by means of saws, as illustrated in *Fig.* 27. These saws are thin sheet-metal discs of a soft character. Iron armature stampings are very suitable for the purpose. The edge of the saw is notched and charged with diamond dust mixed with oil to the consistency of a fine paste. In Germany it is common practice to cut deep radial peripheral slots about a millimetre broad and to fill these with lead, which holds the diamond dust more effectively.

The work, which may be a pile of plates held within the jaws of an adjustable holder, is pulled by a weight against the cutting edge, the movement being controlled by the withdrawal of a screwed abutment.

[1] "The Surface Layer of an Optical Polishing Tool," J. W. French, *Proc. Opt. Soc.*, 1920, xxv. No. 3.

[2] *Schule der Optik*, Gleichen und Klein, 1914, practical section by Klein.

Turpentine as a lubricant gives the best results, but it has the disadvantage of being costly. Petrol is very suitable. Water with a small admixture of soda to prevent rusting of steel parts, although less effective, is commonly used.

An average peripheral speed of the saw is about 1200 feet per minute.

Labour and expense in cutting may be saved by the use of glass that has been moulded to approximately the correct shape and size, enough excess material only being allowed to ensure that when all the irregularities of the surface have been ground away the sizes will not be too small.

When the quantities involved are not large, the actual forming of the work to the required linear dimensions and shape within usually

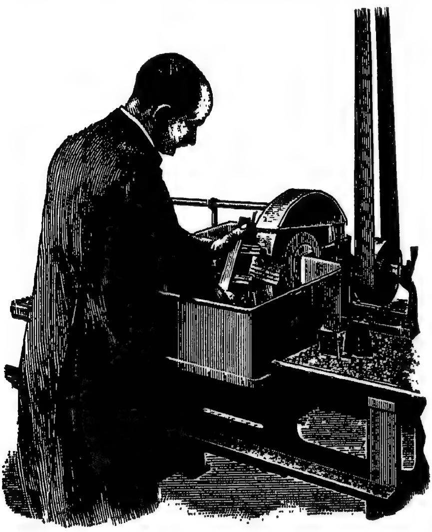

FIG. 27.—Disc Sawing Machine.

an angular limit of $\pm$ three minutes is sometimes done by hand, as indicated in *Fig.* 28, the angles being tested by means of simple adjustable gauges[1] or, in the case of lenses, by disc gauges turned to the appropriate radius. For the roughest grinding, sand or coarse carborundum or emery may be used, the sand being cheapest but slowest in action. If a plant for the washing and grading of the abrasive is installed,[2] the use of a single type of abrasive such as carborundum, a coarse and cheap grade of which only need be purchased, is both economical and convenient.

When two abrasives such as carborundum and emery are employed for the coarser and finer grinding processes respectively, great care must be exercised to avoid contamination of the emery with the harder carborundum. The large cast-iron grinding disc in *Fig.* 28, which

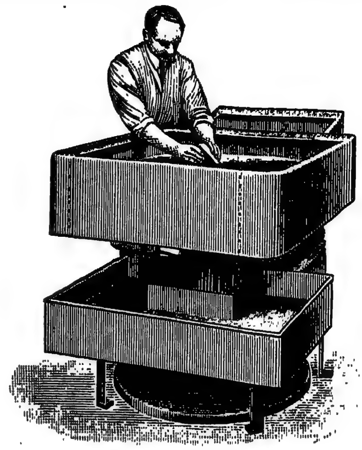

FIG. 28.—Rough Grinding Machine.

runs at a speed of about 250 revs. per minute, serves the double purpose of breaking down the coarser abrasive preparatory to fine grading and of forming the heavier work.

In the case of multiple work the cost of labour generally necessitates the adoption of grinding

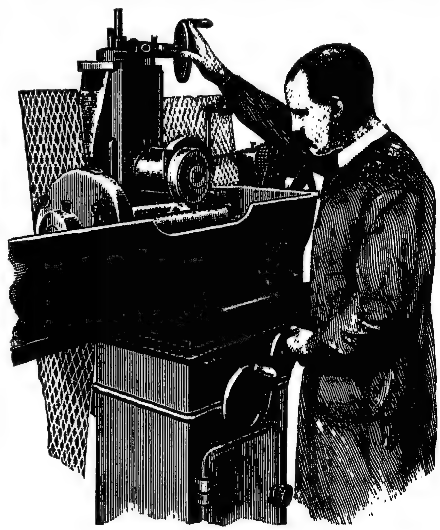

FIG. 29.—Glass Milling Machine.

machinery, one type of which is illustrated in *Fig.* 29. A number of parts are mounted upon an adjustable holder on the table of the machine, the holder being so arranged that it can be accurately angled in accordance with the indications of a scale. The table

[1] *Handbuch der praktischen Optik*, by Halle, 1913.
[2] "The Grading of Carborundum for Optical Purposes," *Trans. Opt. Soc.*, Oct. 1917.

runs the work longitudinally under the grinding wheel, and at the end of each stroke its motion is automatically reversed, the grinding being done during both strokes. At the end of each stroke the table is also fed transversely, automatically or by hand. Either a heavy cut of about 1 mm. with a slow table speed or a light cut of $\frac{1}{50}$ mm. with a fast cutting speed of 10 feet per minute may be used, but generally it is desirable to avoid the heavy forces incidental to a heavy cut.

The grinding wheel, which is fed down by hand as required, is a fine-grade carborundum type, such as 220 J, running at a peripheral speed of about 500 feet per minute.

An ample supply of lubricant, such as water, is essential to avoid all danger of the formation of minute heat cracks.

Milling cutters in the form of cylinders of copper, the surfaces of which are grooved longitudinally and charged with diamond dust, have been used by some of the more important German opticians, but such cutters now appear to have been generally abandoned, except for certain minor operations, in favour of carborundum wheels.

Glass milling, as compared with surface grinding, has the disadvantage of being comparatively slow and therefore relatively costly. This will be evident when it is considered that there is only line contact between the wheel and the surface of the work, which for the great part of the time is therefore not being acted upon, whereas in the case of surface grinding, material is being removed continuously from every part of the surface.

Surface grinding is usually done by means of a cast-iron disc with loose abrasive, and the parts to be operated upon are mounted in accurate multiple jigs, the expense of which can only be contemplated when the number of pieces to be manufactured is large.

As the work must be formed practically within the final inspection limits, it is necessary that the machine should be capable of working to an angular limit of about 2 minutes and a dimensional limit of about $\frac{1}{10}$ mm. to $\frac{1}{40}$ mm.

After the individual parts have been formed to the exact shape they are submitted to the smoothing processes preparatory to being polished. For this purpose the faces to be polished are placed in contact with an optically worked tool, *Fig.* 30, the surface of which has been thoroughly cleaned and slightly oiled. Care must be taken to ensure that the layer of oil between the surfaces of the work and the tool is not too thick, as otherwise a very slight pressure on one end of the piece may suffice to introduce an angular error of a minute. With a little practice such errors, even in the case of faces of a few centimetres length, may be avoided.

Over the tool there is then placed a circular framework, into which is poured a layer of plaster of Paris of about 3 mm. thickness. After the plaster has solidified the frame is filled with a special cement whose volume remains practically constant after solidification.

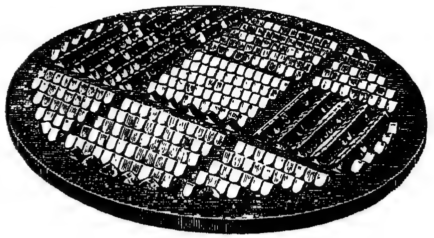

FIG. 30.—Block of Prism.

Plaster of Paris and cements that contain free lime have the disadvantage that, owing to crystalline changes in the solid condition, the volume after solidification increases for many months, the growth being comparatively rapid during the first few weeks.

In such a case, owing to this expansion, the smoothed surface of a cemented block of prisms tends to warp to an extent that may unduly prolong the polishing time, or even necessitate re-smoothing.

Plaster of Paris mixtures are suitable for blocks of 25 cm. diameter, and can be used for blocks of 50 cm. diameter if there is no delay between the smoothing and polishing processes and if the latter is completed rapidly and in one operation. For large blocks of 1 metre diameter, such as is illustrated in *Fig.* 31, special cements are essential.

The frame with the solidified cement containing the prisms is stripped from the oiled

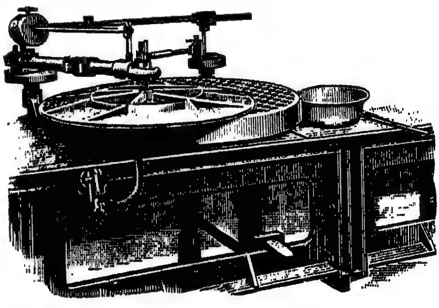

FIG. 31.—Smoothing or Polishing Machine for Blocks 1 metre diameter.

surface of the plate, and when turned over the thin layer of plaster of Paris can be removed, leaving the surfaces of the prisms projecting from the layer of cement, the face of which is cleaned and varnished to make it thoroughly waterproof and to prevent fragments from breaking loose and interfering with the work

of polishing. The thin layer of plaster of Paris has no appreciable ill-effect, as its thickness and time of action are both small.

For the actual smoothing operation a machine of the general type, originally devised by Lord Rosse,[1] indicated in *Fig.* 31, is employed, but although the principle involved is generally the same in all cases, the arrangements vary considerably.

In a machine tool for the working of metals or the forming of glass, such as is indicated in *Fig.* 29, the plane in which the work moves and the axis about which the tool rotates are both definitely fixed. The accuracy of the work is accordingly dependent upon the accuracy of the machine.

As the accuracy requisite for the polishing of an optically good surface is nearly ten times as great as is obtainable with the best type of machine tool, it is necessary for the manufacture of optical work to adopt the floating tool principle previously referred to in connection with the preparation of flat grinding tools.

In *Fig.* 31 it will be seen that the flat grinding tool rests freely upon the surface of the work, the diameter of which is about 20 per cent greater than that of the tool,[2] and that it is moved by a central pin resting in the hollow socket of the tool. For the actual movement of the tool various mechanisms have been introduced, but that indicated in the illustration is the most common.

All the arrangements[3] are particularly designed to sweep the tool over the surface in a continually and widely varying path that only repeats itself after a great number of strokes, and further, to provide simple adjustments whereby the action of the tool may be distributed more or less over the central or outer zones of the work for the purpose of regulating the form or figure.

Behind the machine there are situated two vertical shafts each carrying at its head a crank-pin the distance of which from the centre of rotation is adjustable. One crank drives the end of the main driving arm through the intermediary of a gimbal connection that enables the arm to be raised when necessary quite clear of the tool. The other crank similarly drives a radius bar coupled to the driving arm. As the throws of the crank are independently variable and as the point of connection of the radius bar with the driving arm is adjustable, a large variation in the path of the tool is obtainable. It is important that the revolutions of the crank spindles should not be a whole multiple of the work spindle revolutions. A hunting tooth should be introduced in the gearing, otherwise a portion of the surface will take longer to smooth or polish, thus increasing the time of the operation. By adjusting the length of the radius bar the tool may be made to act more over the periphery of the work, and the length of the stroke may be altered by a variation of the amount of throw of both cranks. These adjustments are necessary for the control of the form or figure of the work.

To determine by calculation the distribution of the grinding or polishing action over the surface of the work is very difficult and laborious. As was previously stated, the action is practically directly proportional to the relative speed of the tool and the work. When the tool is concentric with the rotating work, both rotate together, and there is no relative movement or grinding action unless a partial brake is applied to the tool. As the tool passes from the centre towards the periphery its velocity changes, and there is then relative motion of the tool and work and consequently abrasion. This rotation is always in the same sense as that of the work, but it necessarily varies throughout the cycle, although the momentum of a heavy tool acquired when in the concentric position tends to make the rotation more uniform.

The action at any particular point depends upon the time the part is acted upon by the tool, and this varies with the relative positions of the tool and the work, as the stroke is generally such that the tool sometimes overlaps the work at continually varying positions and by varying amounts.

The action is also proportional to the load, and this is not constant as the area of the tool in contact with the work varies in the overlapping positions.

From these considerations it will be evident that the problem of determining the distribution of the action even under the simplest conditions is a very complex one.

The object of the smoothing process is to remove irregularities of the total surface arising principally from small errors in the laying down or assembling of the individual parts and minor distortions of the mass, and to remove any accidental small holes or cuts introduced by the coarser abrasive during forming. If the initial work has been well done the amount of material to be removed is small, but as the rate of removal of material during the smoothing operation, when fine emery or carborundum is used as an abrasive, is much more rapid than during the polishing stage when rouge is employed, the importance of good smoothing will be evident.

The polishing process is practically a continuation of the smoothing, the same methods and type of machine being employed; but a polishing medium such as rouge is used in the first instance instead of an abrasive, and a pitch, wax, or cloth polisher instead

[1] Lord Rosse's *Telescopes*, 1884, and *Phil. Trans.*, 1840.
[2] *Deutsche mech. Zeit.*, 1909, ix. 81.
[3] *Handbuch der praktischen Optik*, Halle, 1913.

of a metal tool. As in the hand-polishing process previously described, water only is used as a polishing medium in the final stages of the operations.

§ (11) POLISHING MACHINE.—Another type of machine capable of polishing a block about 1·5 metres in diameter is indicated in *Fig.* 32,

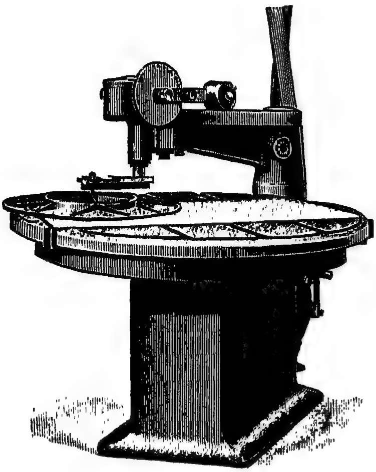

FIG. 32.—Smoothing or Polishing Machine for Blocks 1·5 metres diameter.

and the working of a concave block of large diameter lenses is illustrated in *Fig.* 33.

Two methods may be employed for the

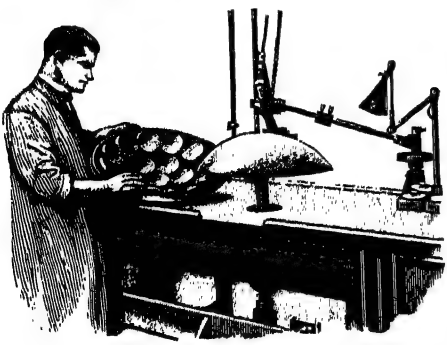

FIG. 33.—Block of Concave Lenses.

production of curved work such as the elements of an objective or an eyepiece.

In the first method, which is not extensively adopted on account of the accurate jigs that are involved, the lens blanks are ground to the final diameter to within a limit of about minus 1/20 mm. Several piles of discs cemented together preparatory to being ground to the correct diameter are shown in *Fig.* 34, which also illustrates the carborundum wheel edging machine.

The edged blanks after being separated and cleaned are mounted in the tool indicated in

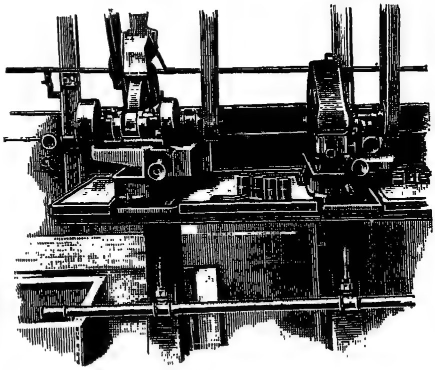

FIG. 34.—Automatic Edging Machine.

Fig. 33, and the curve is then ground true with the periphery, provided the jig and workmanship are sufficiently accurate.

In the more common method, the unedged and partially-shaped blanks are secured individually with pitch within the holder. They are then ground and polished in the usual manner, and after being removed and cleaned

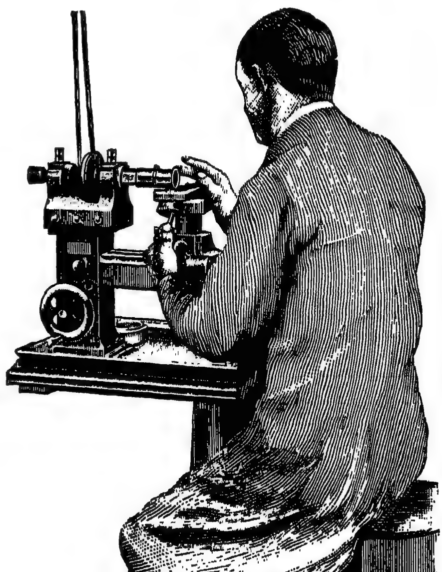

FIG. 35.—Hand Centring and Edging Machine

the periphery of the lens, if circular, is ground true with the optical axis of the lens.

This operation is indicated in *Fig.* 35. The

lens to be edged is slightly heated and cemented to the nose of the hollow spindle of a small lathe head. While the cement is soft the position of the lens is adjusted until the two reflections of a light or other object from the front and back surfaces of the lens[1] do not rotate when the spindle is slowly revolved. This occurs when the optical axis of the lens coincides with the axis of rotation. The cement is then allowed to harden, and the grinding of the periphery true with the axis of rotation, and therefore with the optical axis of the lens, is performed by pressing a brass plate against the edge while using emery or carborundum as an abrasive.

Various types of machines are employed for special operations and more particularly for the production of spectacle lenses,[2]

Astigmatic lenses are produced on machines in which a cylindrical tool is made to oscillate about the axis of the cylinder, the work itself being prevented from rotating. For the multiple production of toric lenses in which the two axes of curvature are approximately at right angles to each other, the lenses are worked upon cylinders of the appropriate radius and ground by means of tools whose cross-sections correspond with the curvatures.

Single and special toric lenses are ground individually upon small special machines, but in an article such as this, which is concerned more with general principles than with the mechanical appliances, it is not possible to describe in detail the numerous types of machine that are employed for spectacle work. The most complete information on this particular subject is obtainable from the catalogues of the optical machine tool makers or from the practical handbooks already referred to.

J. W. F.

Optical Path Difference: the difference in the total optical path travelled by rays of light which pass through an optical system at different distances from the axis. See "Microscope, Optics of the," §§ (7) and (8); also "Light, Rectilinear Propagation of."

OPTICAL ROTATION AND THE POLARIMETER

The rotation of the plane of polarisation was first observed in the year 1811 by Arago in quartz plates. Further, Biot, and also Seebeck, discovered the optical activity of some organic substances, oil of turpentine, and solutions of sugar and of tartaric acid.

Biot established the nature of the phenomenon and its laws in a long series of important papers which extend over a period of forty-seven years (1813 to 1860).

Fresnel published the theory of the properties of quartz and introduced the term "circular polarisation" in 1831.

W. Herschel and J. Herschel recognised the significance of certain faces on the quartz crystal for predicting the direction of the optical rotation.

An epoch-making discovery was Pasteur's in 1848. He proved in the case of tartaric and racemic acids that one and the same active substance may occur in two forms, with opposite rotatory power, as well as in an inactive modification.

Pasteur stated that substances which are optically active as crystals or in solution crystallise in hemihedral forms, *i.e.* the crystal and its mirror cannot be superposed. (Pasteur's rule is not reversible, hemihedral crystals do not always rotate polarised light) (1).

Pasteur thought that the optical activity might be caused by a lack of symmetry of the entire molecule. He imagined that the atoms might be arranged in the form of an irregular tetrahedron or of a screw.

No progress of theoretical importance was made until 1874, when Van t'Hoff and Le Bel, independently of each other, put forward the celebrated theory that the optical rotation of organic compounds is due to the presence of an asymmetric carbon atom. They each assumed that the four valencies of the carbon atom are directed to the points of a regular tetrahedron. If each of these valencies is attached to a different atom or radicle it is seen that two non-superposable tetrahedra result, and these are the left- and right-handed forms of the active substance

Thus the polarimeter has played as celebrated a role in the development of theoretical organic chemistry as its essential parts, the nicol prism and the quartz plate, have done in theoretical optics.

The rapid progress of synthetical organic chemistry in the later decades of the nineteenth century led to the study of a large number of new compounds which rotated polarised light.

One of the most celebrated of the prolonged researches connected with the polarimeter was Emil Fischer's on the constitution of the sugars, in which the interpretation of optical activity played a prominent part.

The discovery of compounds whose optical activity was due to the asymmetry of a nitrogen atom was followed by the brilliant work of Pope on optically active tin, etc., compounds.

Theoretically, optical rotation could arise from asymmetric valencies of elements other than carbon. These predictions have been realised. We are now acquainted with sub-

[1] *Dioptricks* 1692; Molyneux, chap. iv. of *Mechanick-Dioptricks*, p. 220.
[2] *Schule der Optik*, Gleichen und Klein, 1914, Praktischer Teil.

stances whose rotation is due to asymmetric nitrogen, tin, sulphur, selenium, phosphorus, silicon, chromium, and cobalt (2), English investigators, Pope, Peachey, Smiles, Neville and Kipping being chiefly concerned with the first six elements, while Werner was successful in obtaining the active compounds of chromium and cobalt.

Besides these inquiries of fundamental importance, the polarimeter was employed in a classical piece of research by Wilhelmy in 1850. He measured the rate of inversion of cane sugar and put forward the first correct mathematical treatment of the velocity of a chemical reaction. The extraordinary convenience of analysing a solution by optical means without altering its composition was the motive for employing the instrument.

Much work has been carried out on rotatory dispersion, but the interesting results obtained still await theoretical explanation. Technical use was made of rotatory dispersion in 1910 by M. E. Darmois, who found that the proportions of alpha and beta Pinene in rectified oil of turpentine could be determined by measuring the rotatory dispersion (3).

Magnetic rotation of the plane of polarisation, discovered by Faraday, was the subject of prolonged research by W. H. Perkin, senior, who showed that it was a property depending mainly on constitution, although there are some additive relationships.

While the study of rotatory dispersion prevented a too narrow interpretation being placed on the results with sodium light, a study of the influence of the solvents showed that not only the amount but also even the sign of the optical rotation could vary when the same substance was dissolved in different solvents.

Arising out of this purely scientific work is an interesting analytical method. The quantitative estimation of benzene in cyclohexane is difficult and troublesome, but by taking advantage of the fact that benzene is almost without influence on the rotation of ethyl tartrate, whilst cyclohexane exerts a considerable depressing influence, the proportions of the two substances present in a mixture may be estimated within about 3 per cent by the simple determination of the rotatory power of a mixture with a fixed proportion of the ester (4).

The influence of the solvent is also clearly shown in an important paper by F. H. Carr and W. C. Reynolds (5) on the rotatory power of alkaloids. They found, *inter alia*, that hydrastine has a strong dextro-rotation in 50 per cent alcohol, while it is inactive in 95 per cent alcohol, and laevo-rotatory in absolute alcohol. These observations suggest that indirect determinations of inactive substances may often be possible, by measuring their influence on the rotation of an admixed active substance. It has been known for a long while that boric acid and also acetone and other substances have a powerful effect on the rotation of tartaric acid. For the two substances mentioned, there are excellent chemical methods available; where this is not the case a polarimetric method might well be looked for.

Although a distinction may be broadly made between essential oils, which are optically active, and mineral and fatty oils, which are optically inert, the exceptions are of great importance. Castor oil is the only common vegetable oil which exhibits a distinct though slightly variable rotation. Mineral oils were thought for some years to be optically inactive, but further study has proved that they possess a small rotatory power, and this fact has supported one of the theories of the origin of petroleum.

The temperature correction may be of great importance for the analysis of a mixture, thus a mixture of dextrose (+) and invert sugar (+ and −, the latter predominating) may be analysed at 87° C., when the rotation of invert sugar becomes 0.

Starches can be determined by the polarimeter by Ewen's method and its later modifications; thus the products of another important industry may be controlled by this instrument.

The relation between concentration and specific rotatory power has been determined for a number of substances with a very high degree of accuracy, notably cane sugar, galatose, cocaine, lactose, maltose, glucose, camphor, nicotine. "Synthetic camphor" can be distinguished from natural camphor, and adulteration of inactive oils (such as almost all the fatty oils) with rosin or rosin oil is easily detected.

The left- and right-handed forms of active substances, *e.g.* sugars, can be separated by the action of micro-organisms, such as yeast and moulds which preferentially destroy one of the isomers. The isomers differ also in their behaviour with digestive enzymes of the animal body.

The explanation generally adopted is that the enzymes of fermentation and digestion are themselves asymmetric and attach themselves to one optical isomer, in virtue of spatial arrangements which have been compared to the fitting of a key in a lock.

"The first step in what may prove to be an inquiry of considerable significance in biology is marked by the preparation of *d*- and *l*-forms of simple dyes containing an asymmetric system. The work has not proceeded far, but evidence has already been obtained that these optical isomerides are selectively absorbed by wool, and the prospect is thus opened out that they may ultimately be used in the

staining of sections so as to reveal more completely the chemical constitutions of tissues. This field of research has not been explored by the chemist, and there is ample scope for future developments of great importance" (6).

PERIMETER OR SCOTOMETER: an ophthalmic instrument used to measure the field of vision from the macula to the peripheral parts of the retina, and to plot out the portions of the retina which are totally or partially atrophied. See "Ophthalmic Optical Apparatus," § (5).

PERISCOPES

§ (1) PRINCIPLE OF PERISCOPES.—As the name denotes, periscopes are optical instruments in which the general course of the rays, instead of being confined approximately to the neighbourhood of a single straight line, is deflected once or more into new directions with the aim of giving an observer a view from a position in which it is inconvenient to place his head. Among the best known examples are various forms of trench periscope, which consist essentially of small telescopes with reflectors at the top and bottom, or even of a small tube only to which mirrors have been attached at each end, so that the ray paths tend to conform to the shape of a crude letter Z. By the aid of such an instrument the observer is enabled to see what takes place, say, on the far side of a parapet behind which he himself is protected from bullets. Essentially similar in their general aim are the periscopes used on submarine boats to take observations above the sea while the vessel remains submerged. These naval instruments are more complex than those used on land, and as they provide

good illustrations of all the features which are found in periscopes generally, it will be convenient to consider the submarine periscope as the typical instrument of this class.

§ (2) Reflecting Systems.—Although periscopes have the bent ray path as their most obvious characteristic, optically this feature is of no importance. Any refracting telescope can be converted into a periscope by the insertion of mirrors in suitable positions without the necessity for any modification in the construction of the lenses. If reflecting prisms are substituted for mirrors the necessary changes in the system are very slight in character, and may be allowed for in the original design by supposing symmetrical blocks of glass of suitable thickness to be present, as no optical difference would then exist between the instrument with a straight ray course and that in which the light path suffers deviations. The reflecting and refracting systems are independent also in another sense, for though the size and the accuracy of surface necessary in the mirrors may vary greatly with their positions relative to the lenses, yet those positions are unimportant as far as the type of imagery yielded by the complete instrument is concerned. For instance, if a certain combination of mirrors and a telescope produces an upright image of a clock face with the hours increasing on a right-handed rotation, no image either inverted or with left-handed rotation will be produced by transferring the whole reflecting system so that it is entirely external to the telescope, and either precedes or follows it. To decide therefore what mirror systems are of value for the construction of periscopes, it is only necessary to consider whether the telescope to be employed is of the inverting or of the erecting type.

The commonest reflecting system consists essentially of two plane reflecting surfaces parallel to one another (*Fig.* 1). Light successively reflected at these two surfaces emerges parallel to its original direction, being merely laterally displaced by an amount proportional to the separation of the mirrors and to the sine of the angle of incidence. A clock face examined by light reflected from such mirrors presents the same appearance as when viewed direct. Such a system of mirrors in conjunction with an erecting telescope gives a correct view of the scene examined when the observer faces the direction of sight. Another simple system consists of two plane mirrors at right angles to one another (*Fig.* 2). Since the deviation produced in any ray is twice the angle between the outward drawn normals to the mirrors, the observer must have his back towards the direction of sight, and from this it follows that an image will appear correct to the observer when it is upright, but inverted left for right in space relative to the object. Now the two mirrors by themselves, if placed one above the other with their lines of intersection horizontal, will obviously produce inversion in the vertical but not in the horizontal direction; Since an inverting telescope inverts in both directions, the combination of these two mirrors with an inverting telescope will yield images of the type required (*Fig.* 3). If a correct view is required with an erecting telescope when the observer has his back to the direction from which light reaches the instrument, the reflecting system must be of a type which returns an image of correct appearance to the observer when used alone. The best known system of this kind consists of three plane mirrors mutually at right angles to one another, and many others only slightly less simple may be devised. A periscope of the reversed vision type may therefore be constructed with a plane upper mirror deflecting the light downwards through an erecting telescope at the lower end of which is a "roof" prism or two mirrors forming a roof, the edge of which is normal to the first mirror (*Fig.* 4). Roof prisms would be utilised very widely in optical instruments for their valuable properties were it not that the high degree of accuracy required in the angle between the two reflecting surfaces to avoid double images makes their manufacture very costly. In many cases this difficulty can be avoided at the cost of compactness by displacing the

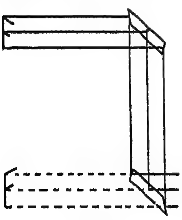

Fig. 1.

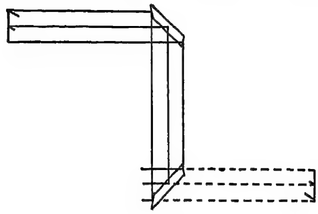

Fig. 2.

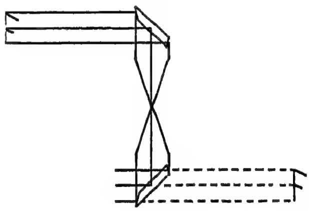

Fig. 3.

roof combination laterally, so that the light always meets the surfaces in the same order. Another case in which a roof combination

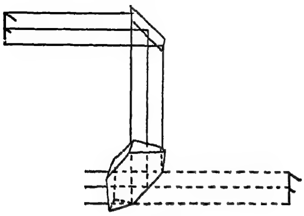

FIG. 4.

may be used is when an inverting telescope is employed with the observer facing the view. If the roof prism replace the lower plane prism of *Fig.* 1, the lateral inversion it causes compensates the inversion of the telescope in the horizontal plane, but the vertical inversion is uncorrected. The substitution at the upper end of the periscope of two mirrors inclined to one another in the vertical plane at an angle of 45° for the single mirror is a possible method of completing the rectification of the image (*Fig.* 5). An alternative of much importance consists in the introduction of an inverting isosceles prism. With this combination an erect image may be secured conveniently whatever the angle between the line of sight and the direction of observation

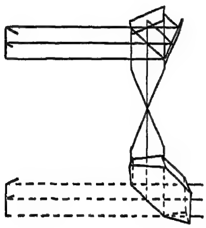

FIG. 5.

may be. The best known instrument of this kind has an upper isosceles right-angled prism, a lower roof prism, and an isosceles inverting prism placed along the vertical axis of the telescope, so mounted that it rotates through half the relative displacement of the upper and lower prisms. This arrangement is illustrated in *Fig.* 6.

In submarine periscopes it is considered important that the directions of sight and of observation should be identical, and as the use of roof reflectors is not free from difficulties erecting telescopes become necessary.

§ (3) FIELD OF VIEW AND ILLUMINATION.—From the point of view of light deflection then the periscope offers no new problem at all for consideration. Optically its special characteristic is that, when the extent of the field of view required and the amount of light necessary from each part of the field are considered, the instrument is of such unusual length that special forms of construction are essential to enable these particular features to be realised in an acceptable manner.

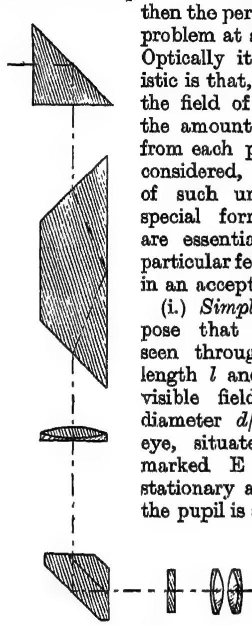

FIG. 6.

(i.) *Simple Periscopes.*—Suppose that a distant view is seen through a long tube of length l and diameter d. The visible field has an angular diameter d/l if the observer's eye, situated in the position marked E in the figures, is stationary and the diameter of the pupil is small in comparison with d (*Fig.* 7). If a lens of diameter d and focal length $l/6$ is placed in the tube at one-third its length from the observer's end, an inverted image of the distant view of angular diameter $3d/l$ will be seen at the principal focus of the lens which is at a distance $l/6$ from the observer's eye (*Fig.* 8). As

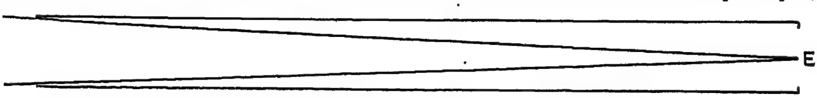

FIG. 7.

far as the field of view is concerned the eye is virtually placed at e, the image of E formed by the lens. As exception is taken to a system such as the above, which necessitates focussing

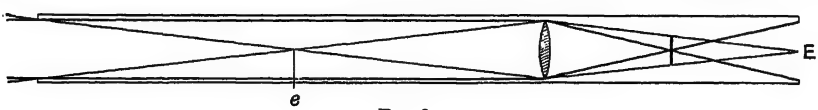

FIG. 8.

the eye on a fixed near plane, the single lens must be replaced by a telescopic system. The simplest consists of two single lenses of equal focal length with their separation double the focal length of either. If these are placed

at the ends of the tube the field of view is the same as for the vacant tube, but the image is inverted (*Fig.* 9). If the lenses are now reduced in focal length and are appropriately placed in symmetrical positions in the tube, the field can be increased up to four times its original value when the lens separation is $\frac{1}{2}l$ (*Fig.* 10). If the symmetrical arrangement is abandoned, the most favourable disposition with two equal lenses is reached when the focal length is $l/5$, the distance of the first lens from the object end of the tube being $2l/5$, which is also the distance between the lenses (*Fig.* 11). The image of the eye is then half-way between the front of the tube and the leading lens, and it is easy to see that a variation of the system in one direction results in a reduction of the field below $5d/l$ through the failure of the rays required to meet the aperture of the first lens, and a variation in the other direction leads to the obstruction of rays between the object and the virtual position of the eye by the front of the tube. To take an actual example, if the tube is thirty feet in length and six inches in diameter, the natural field of view is about one degree, and the best with two lenses is about five degrees. Fields of this magnitude fall far short of those required in submarine periscopes, and the inverted image is also objectionable. The addition of further lenses enables both defects to be removed.

A particularly simple form of erecting telescope consists of three equal lenses spaced at equal intervals, the separations being three times the focal length of the individual lenses. If such a system were inserted in the tube and occupied its entire length, the eye would be virtually placed a distance $\frac{1}{2}l$ in front of the tube, and the field of view would be $2d/l$ (*Fig.* 12). As the outer lenses are made to approach the central lens and the focal lengths of all suitably reduced, the field of view increases, reaching the best value $7d/l$ when the separations and the distance from the front of the tube to the first lens are each $2l/7$ (*Fig.* 13). This is not the only form of telescope of unit magnifying power which can be constructed of three equal lenses uniformly spaced, for evidently in *Figs.* 9 to 11 a third lens of any power could be inserted half-way between the lenses shown in the plane of the real image without disturbing the telescopic character of the image. The effect of such a lens is merely to alter the extent of the field of view. The

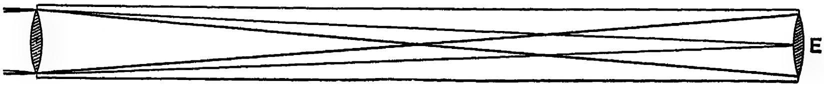

FIG. 9.

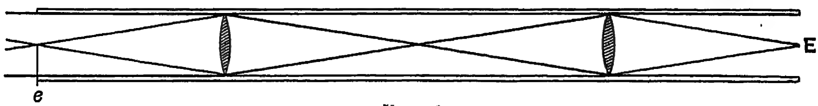

FIG. 10.

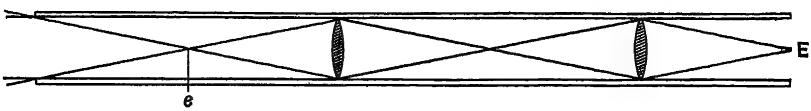

FIG. 11.

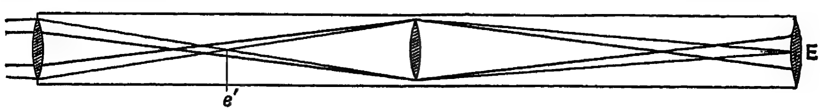

FIG. 12.

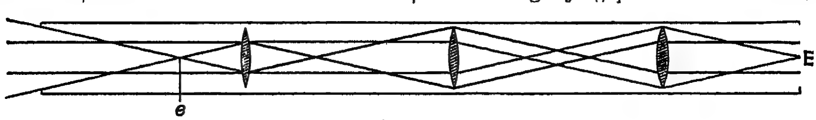

FIG. 13.

insertion of the lens in this system, however, does not influence the inversion of the image, so that the one system of three lenses presents an upright and the other an inverted image.

(ii.) *Six-lens Periscopes.*—When a greater number of lenses is used there is a choice of many different separations when the spacing is uniform and the lenses are of equal focal length. Consider, for example, a system with six lenses. Two telescopes each having three lenses if combined will produce a six-lens telescope with an upright image, whether the image is upright or inverted with three lenses. On the principle of combining two telescopes together it is obvious that with twelve lenses all these separations would give erect images. In addition, with twelve lenses there would be six separations resulting in inverting telescopes.

The five forms of telescope each containing six lenses are illustrated in *Figs.* 14 to 18 and the number of inversions is different in every case, the number for each separation being given in brackets in the above table. Other things being equal, the form in which f is large in comparison with t is the most desirable, since this implies lenses with slight curvatures.

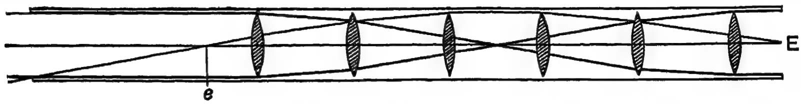

FIG. 14.

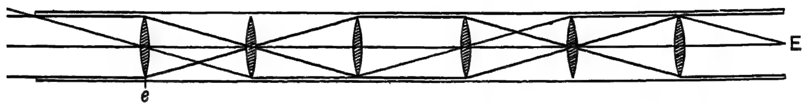

FIG. 15.

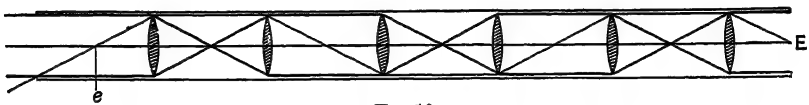

FIG. 16.

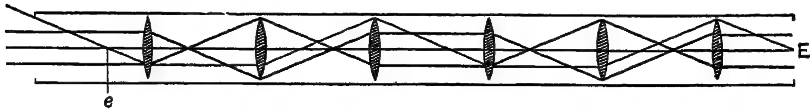

FIG. 17.

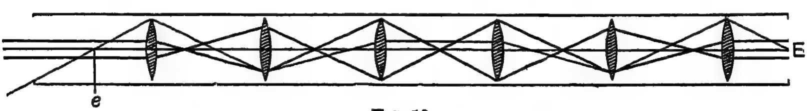

FIG. 18.

Three telescopes of two lenses each will evidently combine to form an inverting six-lens telescope. In addition there are two new forms, both inverting, which cannot be divided into separate telescopes. Thus, with six lenses each of focal length f the separations t may have the values given in the following table:

TABLE I

Inverting Telescopes.	Erecting Telescopes.
$t=(2-\sqrt{3})f$ (1)	$t=f$ (2)
$t=2f$ (3)	$t=3f$ (4)
$t=(2+\sqrt{3})f$ (5)	

But it is by no means the case that other things are equal, for the systems differ from one another in the extent of the field of view, in the brightness of the image at the centre of the field, and in the way in which the brightness varies from point to point of the field. The system with one inversion, illustrated in *Fig.* 14, is the most desirable as regards the curvatures of the lenses, but since the virtual eye position is the farthest of the series from the leading end of the tube, this form is the least satisfactory for the extent of the field of view. The systems with three and five inversions, illustrated in *Figs.* 16 and 18 respectively, are those with the largest fields of view, the two being on an equality. Not far behind them is the system with four inversions shown in *Fig.* 17.

(iii.) *Illumination.*—In order to consider the illumination at the centre of the field of view, the extreme rays of an incident beam parallel to the axis are represented in the diagrams by thicker lines than those used to indicate the extent of the field of view. The systems with one, two, and three inversions are on an equality, and transmit to the rear of the tube beams of light which on entrance and exit completely fill its diameter. When the number of inversions is increased to four, and still more when there are five, the width of the useful axial incident beam is much reduced, and the last two forms are not nearly as satisfactory as those which precede them for central illumination. It would thus appear that the greatest advantages rest with the form shown in *Fig.* 16, but when the illumination in the outer parts of the field of view is considered, it is seen that this form has distinctly undesirable features. The forms with four and five inversions alone show no decided change in illumination, as the origin of the beam of incident rays departs from the axis of the tube, but beyond certain angles the brightness of the image is diminished through light striking the interior of the tube as in the other forms. At the extreme angular field the intensity of the light falls to zero with the forms of *Figs.* 14, 16, and 18, but is finite with the remaining forms.

Figs. 14 to 18 are special cases of their kinds, as the extreme rays which determine the fields of view have been assumed to follow paths similar to those of rays which limit the axial beam of parallel rays. Other results as regards the field of view or the variation in illumination are obtained by assuming that the entire system of lenses is displaced along the tube, the eye remaining at the end of the tube. It will suffice to consider two other cases, in which the lenses of the two erecting telescopes are displaced towards the eye. *Fig.* 19 represents the same system as *Fig.* 15, but all the lenses have been moved towards the eye through a distance equal to half their focal length. The field of view is evidently the same as before, but the amount of light transmitted at the extreme angle is now less than before. Again, in *Fig.* 20 a system similar to that shown in *Fig.* 17, but with rather longer focal lengths for the lenses, has been displaced towards the eye through a distance equal to half the focal length of each lens. The field of view is now increased to an equality with those of the systems with three and five inversions, but, as in these other cases, the illumination at the edge of the increased field falls to zero. It is clear that a much more detailed analysis is necessary to determine exactly where the balance of advantage falls.

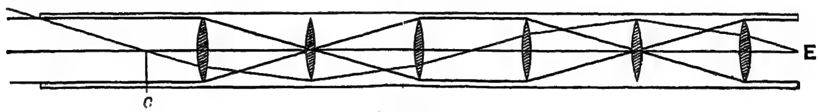

FIG. 19.

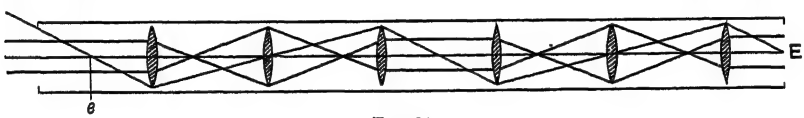

FIG. 20.

§ (4) THEORETICAL CONSIDERATION.—The diagrams just considered show that the field of view is enlarged by causing any ray of light, instead of travelling straight along the tube, to be deviated by a series of lenses from side to side. The number of lenses to an oscillation is arbitrary, and when the number of lenses to an oscillation is large, as in *Fig.* 14, the ray path resembles a sine curve. If there are n lenses to the telescope, each of power κ, the separation of successive lenses being t, the power of the complete system $\kappa_{1,n}$ is derived from

$$\begin{aligned}\kappa_{1,n} = \kappa_1 + \kappa_2 + &\ \ldots\ + \kappa_n \\ &- \kappa_1 t_1 \kappa_2 - \kappa_1(t_1 + t_2)\kappa_3 \ \ldots \\ &- \kappa_1(t_1 + t_2 + \ \ldots\ + t_{n-1})\kappa_n \\ &- \kappa_2 t_2 \kappa_3 - \kappa_2(t_2 + t_3)\kappa_4 \ \ldots \\ &+ \kappa_1 t_1 \kappa_2 t_2 \kappa_3 + \ \ldots,\end{aligned}$$

as is well known. On putting all the κ's and t's equal to one another, the coefficients depend on the numerical value of the sums of continued products obtained by dividing at $r-1$ points a line whose length varies from r to n into r parts each of a length represented by an integer. The result is

$$\begin{aligned}\kappa_{1,n} = n\kappa - \frac{(n+1)n(n-1)}{3!}\kappa^2 t \\ + \frac{(n+2)(n+1)n(n-1)(n-2)}{5!}\kappa^3 t^2 \ \ldots \\ + (-1)^r \frac{(n+r)!}{(n-r-1)!(2r+1)!}\kappa^{r+1} t^r \ \ldots,\end{aligned}$$

so that the system is telescopic if κt is made equal to one of the roots of the equation

$$\Sigma_r(-1)^r\frac{(n+r)!}{(n-r-1)!(2r+1)!}x^r=0,$$

and, like the ray path, this equation, if written in the form

$$\Sigma_r(-1)^r\frac{n(n^2-1^2)(n^2-2^2)(n^2-3^2)\dots(n^2-r^2)}{(2r+1)!}x^r=0,$$

is distinctly reminiscent of circular functions. This suggests that the circular functions will occur prominently in the theory of systems of lenses suitable for the transmission of light down a tube of constant diameter, and it is readily seen that if the four Gaussian constants are suitable circular functions the system may have such properties as those found in the systems already illustrated. If these constants are denoted for brevity by A, B, C, D, where

$$A=\kappa_{1,n},\ B=\frac{\partial\kappa_{1,n}}{\partial\kappa_1},\ C=\frac{\partial\kappa_{1,n}}{\partial\kappa_n},\ D=\frac{\partial^2\kappa_{1,n}}{\partial\kappa_1\partial\kappa_n},$$

the relation $BC-AD=1$ suggests cosine expressions for B and C and sine expressions for A and D. Moreover, the essential equations for the combination of two systems are

$$\left.\begin{aligned}A_{1,2}&=A_1B_2+A_2C_1\\B_{1,2}&=B_1B_2+A_2D_1\\C_{1,2}&=A_1D_2+C_1C_2\\D_{1,2}&=B_1D_2+C_2D_1\end{aligned}\right\}, \quad . \quad . \quad (1)$$

where the quantities are reckoned for a common terminal point to the two systems. For the distances x, x' from the selected terminal points of a pair of conjugate points satisfy the relation

$$Axx'+Bx'-Cx-D=0,$$

where x and x' are positive when measured from the terminal points in the direction in which light travels through the system. Thus, in this case, if x and x' refer to a first system which is to be combined with a second system for which the distances are represented by x' and x'', the two values obtained for x' must be identical, so that

$$\frac{C_1x+D_1}{A_1x+B_1}=-\frac{B_2x''-D_2}{A_2x''-C_2},$$

or

$$(A_1B_2+A_2C_1)xx''+(B_1B_2+A_2D_1)x''-(A_1D_2+C_1C_2)x-(B_1D_2+C_2D_1)=0,$$

and this must be equivalent to

$$A_{1,2}xx''+B_{1,2}x''-C_{1,2}x-D_{1,2}=0.$$

Also

$$\begin{aligned}(B_1B_2+A_2D_1)(A_1D_2+C_1C_2)&\\-(A_1B_2+A_2C_1)(B_1D_2+C_2D_1)&\\=(B_1C_1-A_1D_1)(B_2C_2-A_2D_2)&\\=1=B_{1,2}C_{1,2}-A_{1,2}D_{1,2},&\end{aligned}$$

so that

$$\begin{aligned}A_1B_2+A_2C_1&=\pm A_{1,2},\\B_1B_2+A_2D_1&=\pm B_{1,2},\\A_1D_2+C_1C_2&=\pm C_{1,2},\\B_1D_2+C_2D_1&=\pm D_{1,2},\end{aligned}$$

and by considering a special case, such as a thin lens in which $B_2=C_1=1$, $A_{1,2}=A_1+A_2$, or a lens in which A_2 is gradually increased from zero so that $A_{1,2}$ has the same sign as A_1, it is seen that the upper sign must be adopted. If now l denotes a length it may be supposed that A_1, B_1, C_1 are defined by the angles α_1, β_1, γ_1, where

$$A_1=\frac{\sin\alpha_1}{l},\ B_1=\frac{\cos(\alpha_1-\beta_1)}{\cos\beta_1},\ C_1=\frac{\cos(\alpha_1-\gamma_1)}{\cos\gamma_1},\ (2)$$

and it then follows from the identity $BC-AD=1$ that

$$D_1=-\frac{l\sin(\alpha_1-\beta_1-\gamma_1)}{\cos\beta_1\cos\gamma_1}. \quad . \quad (2a)$$

If now two systems with the same l are combined the addition equations give

$$A_{1,2}=\frac{\sin(\alpha_1+\alpha_2)}{l}+\frac{\sin\alpha_1\sin\alpha_2}{l}(\tan\beta_2+\tan\gamma_1),$$

$$B_{1,2}=\frac{\cos(\alpha_1+\alpha_2-\beta_1)}{\cos\beta_1}+\frac{\cos(\alpha_1-\beta_1)\sin\alpha_2}{\cos\beta_1}(\tan\beta_2+\tan\gamma_1),$$

$$C_{1,2}=\frac{\cos(\alpha_1+\alpha_2-\gamma_2)}{\cos\gamma_2}+\frac{\sin\alpha_1\cos(\alpha_2-\gamma_2)}{\cos\gamma_2}(\tan\beta_2+\tan\gamma_1),$$

$$D_{1,2}=-\frac{l\sin(\alpha_1+\alpha_2-\beta_1-\gamma_2)}{\cos\beta_1\cos\gamma_2}+\frac{l\cos(\alpha_1-\beta_1)(\cos\alpha_2-\gamma_2)}{\cos\beta_1\cos\gamma_2}(\tan\beta_2+\tan\gamma_1),$$

and the combined system has expressions for the Gaussian constants of the same form as the components if

$$\tan\beta_2+\tan\gamma_1=0,$$

that is, if $\qquad \beta_2+\gamma_1=0.$

The α of the compound system is then the sum of the α's of its components, while its β and γ are respectively β_1 and γ_2, that is, the external angles associated with its components. Moreover, if a single lens is considered referred to its unit points as terminal points, A is arbitrary, B and C are both unity, and, if the lens is thin, D is zero. Since α cannot be zero without making A zero, it follows that for such a lens

$$\alpha-\beta=\beta,\ \alpha-\gamma=\gamma,$$

or $\qquad \beta=\gamma=\tfrac{1}{2}\alpha.$

The preceding equation for $A_{1,2}$ may be interpreted in terms of each component lens referred to its own principal points; if t is the separation of the internal principal points of the two components this gives

$$\frac{\sin(\alpha_1+\alpha_2)}{l}=\frac{\sin\alpha_1}{l}+\frac{\sin\alpha_2}{l}-t\,.\,\frac{\sin\alpha_1}{l}\,.\,\frac{\sin\alpha_2}{l},$$

or $$t=l(\tan\tfrac{1}{2}\alpha_1+\tan\tfrac{1}{2}\alpha_2).$$

It follows that in a system of n lenses in which the power of the rth lens is

$$\kappa_r=\frac{\sin\alpha_r}{l}, \qquad . \quad . \quad . \quad (3)$$

and the separation between the rth and $(r+1)$th lenses is

$$t_r=l(\tan\tfrac{1}{2}\alpha_r+\tan\tfrac{1}{2}\alpha_{r+1}), \qquad . \quad . \quad (4)$$

the four Gaussian constants referred to the external principal points of the extreme components are given by

$$\left.\begin{aligned}
A&=\frac{\sin\alpha}{l}\\
B&=\frac{\cos(\alpha-\frac{1}{2}\alpha_1)}{\cos\frac{1}{2}\alpha_1}\\
C&=\frac{\cos(\alpha-\frac{1}{2}\alpha_n)}{\cos\frac{1}{2}\alpha_n}\\
D&=-\frac{l\sin(\alpha-\frac{1}{2}\alpha_1-\frac{1}{2}\alpha_n)}{\cos\frac{1}{2}\alpha_1\cos\frac{1}{2}\alpha_n}
\end{aligned}\right\}, \qquad . \quad (5)$$

where

$$\alpha=\alpha_1+\alpha_2+\ .\ .\ .\ +\alpha_n.$$

If α is a multiple of π the system is evidently a telescope of unit power, inverting if the multiple is odd, erecting if it is even.

§ (5) Geometrical Theory.—Equations (3) and (4) show that the properties of the special kind of system which has been considered have a parallel in polygons described about a circle. If radii are drawn (*Fig.* 21) making

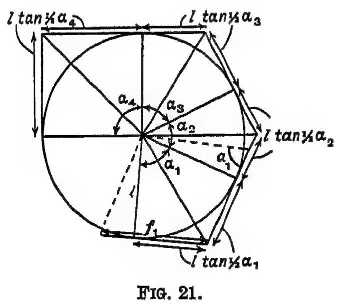

Fig. 21.

with one another successive angles $\alpha_1, \alpha_2, \alpha_3 \ldots$, the sides of the polygon which touch the circle where these radii meet the circumference will represent the lengths of the sections into which the lenses divide the periscope if the radius of the circle is l. The focal lengths of the lenses are represented by the sides of a rhombus having two sides along successive sides of the polygon and the centre of the circle as the opposite vertex. By constructing polygons in this way the properties of any system are investigated more simply than by drawing detailed diagrams such as *Figs.* 14 to 20.

It is convenient to extend this construction and replace the polygon by a right prism of uniform height. The justification for the use to be made of this extension follows from the best known properties of simple lenses. Referring to *Fig.* 22, let O be a point equidistant

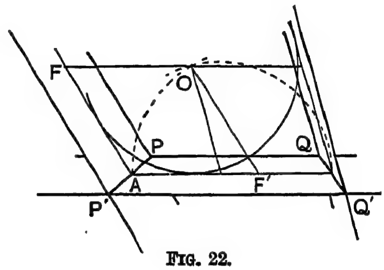

Fig. 22.

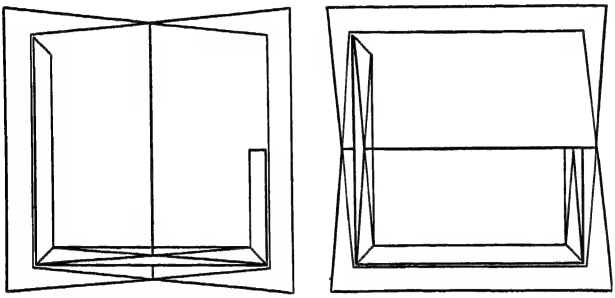
from two planes which intersect in the straight line PP′. Suppose that A is the foot of the perpendicular to PP′ from O, and that FA, AF′ lie each in one of the two planes, OFAF′ being a rhombus in the plane normal to PP′. If the two planes FPP′, F′PP′ are regarded as axial sections of the object space and image space for a thin lens with F, F′ as its principal foci and PP′ for its coincident unit planes, any object point is connected to its image point by a straight line which passes through O. The angle which the planes make with one another is immaterial, and if the image plane is rotated about PP′ the locus of O is a circle described about F as centre. Similarly, if the image plane is fixed and the object plane is revolved about PP′, O will move along a circular path with its centre at F′. If a second lens is introduced which meets the first image plane in QQ′, the effect of the second refraction may be determined through the intermediary of the first image plane by projecting through a suitable point O′ on to a third plane which contains the straight line QQ′. If the second plane is kept fixed and the first and third are rotated, O and O′ describe coplanar circles when the two lenses have a common axis, and under suitable conditions these circles intersect, and projection from this common centre gives all the correspondences that exist. In the cases considered here these conditions are satisfied, and also further projection from the same centre is possible, and the effect of many successive refractions may thus be exhibited in this particularly simple way.

The height of the prism corresponds to the diameter of the tube, that is, to the diameter of the lenses, so that the paths of rays may be depicted on the surface of the prism. It is at once evident that, since projection through the centre gives all correspondences after any number of refractions, the complete path of any ray through the entire system is determined by the intersection of a plane through the centre of the circle with the prism surface. If a plane rotates about an axis through the centre parallel to the direction of the object space axis, the width of the beam which can be transmitted is determined by the intersection of the plane with the points on the prism surface at the greatest distance from the axis. Rotation of a plane about another axis determines the field of view, the axis of rotation in this case passing through the point where it is proposed that the eye shall be placed. Since the instrument is assumed to be a telescope this point must be on a side of the prism parallel to that on which the incident light is represented, and the angular field will depend upon the angle between the lines in which the plane through the centre and the eye point meets the plane for incident rays in its extreme positions; these positions are, of course, determined by the requirement that the plane must everywhere meet the prism surfaces within the limits set by the prism height. It is evident that in practice the axis for the aperture and that for the field of view will be approximately perpendicular. *Fig.* 23 shows in perspective the prismatic diagram with the extreme planes corresponding to *Fig.* 11. In this simple case the diagram shows at once that the separation of the lenses must be twice the focal length, that the axes for aperture and field of view are preferably at right angles, and that the front section of the tube may be equal to that of the middle section and twice as great as the third section.



Aperture Axis and Planes **Field Axis and Planes**

FIG. 23.

In the diagrams corresponding to other simple cases the essential relations between geometrical magnitudes may be derived at once from the properties of the polygon or prism. For example, when the sections are the sides of a regular hexagon the focal length of each lens is equal to the distance separating successive lenses, and when the polygon is an equilateral triangle each separation becomes equal to three times the focal length. It is, of course, unnecessary to assume that all the sections or the focal lengths of all the lenses are equal. The geometry of the polygon shows by itself what relations must subsist between the focal lengths and the separations for a system which is telescopic of power ± 1 to be secured. In any particular case, when a position for the eye has been selected, the extent to which the tube may project beyond the first lens without reducing the extent of the field is determined by producing the side of the polygon which corresponds to the object space until a point is reached as far from the field axis as any other point on the fundamental polygon. The variation in brightness as the field is changed is determined most readily by considering a movement of the eye point parallel to the axis of the prism, so that the field axis is inclined to a principal section, and finding the extent of the field for the displaced eye position. Considered in this way it is at once obvious that the greatest extent of field is visible only when the eye is on the axis of the tube.

Figs. 24 to 30 show the polygonal diagrams corresponding to the six-lens systems of *Figs.* 14 to 20. To render the exact character of the system more evident from the diagrams a small separation has been introduced between the faces, when these should strictly

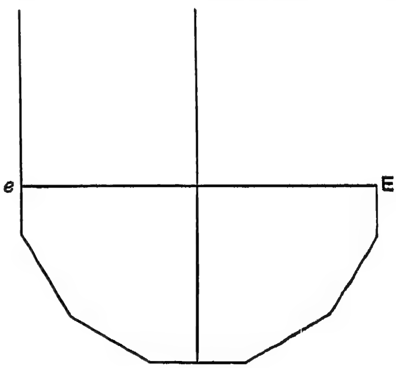


FIG. 24.

be represented by coincident lines. In all cases but *Figs.* 25 and 27, corresponding to systems 15 and 17, the axes for aperture and field of view are perpendicular to one another.

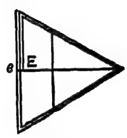

FIG. 30.

§ (6) TUBES OF VARIOUS DIAMETERS.—The preceding theories are chiefly of value in considering the best arrangement of lenses when it is desired to compare alternative systems in a tube of given diameter. The actual diameter of the tube is of great importance apart from the ratio of the diameter to the length, since in actual observation the pupil of the eye should be approximately filled with light, and thus the ratio of the pupil diameter to that of the tube enters into the problem.

The periscope that has been considered may be compared with a geometrically similar instrument in which the diameter of the tube is equal to the diameter of the eye pupil. Both have the same field of view, since this depends on the ratio the transverse dimensions bear to the longitudinal measurements. On the other hand, the periscope with the larger diameter transmits much more light from any given object point, the ratio depending on the areas of the cross sections of the tubes. Some of this will enable the larger tube to present to an eye on its axis a large field of sensibly uniform illumination, while in the smaller instrument the intensity will fall off directly the object point departs from the axis. Much useless light will, however, be transmitted in addition in the larger telescope, and the instrument can be readily modified in a way which enables this unwanted light to be exchanged for an increased field of view, or alternatively for a system containing a smaller number of lenses for a given length of tube. Thus, large diameters are of great assistance in yielding simple solutions of the optical problems involved in periscope design. On the other hand, in nearly all military periscopes great importance has been attached to a small head which renders the periscope inconspicuous. In submarine periscopes these two conflicting requirements are to some extent reconciled by the combination of a short narrow head with a long main tube of large diameter. It thus becomes of interest to inquire how the dimensions of the system vary when a change is made in the aperture which the lenses may have. As a result of the change of aperture the complete instrument when telescopic need not be of unit magnifying power, so that the expressions for B and C must be generalised by the introduction of a further arbitrary quantity. Bearing in mind that the identity

$$BC-AD=1$$

has to be satisfied, it is natural to consider systems in which the four Gaussian constants take the form

$$\left.\begin{aligned} A_1&=\frac{\sin\alpha}{l}\\ B_1&=\frac{p\cos(\alpha-\frac{1}{2}\alpha_1)}{\cos\frac{1}{2}\alpha_1}\\ C_1&=\frac{\cos(\alpha-\frac{1}{2}\alpha_m)}{p\cos\frac{1}{2}\alpha_m}\\ D_1&=-\frac{l\sin(\alpha-\frac{1}{2}\alpha_1-\frac{1}{2}\alpha_m)}{\cos\frac{1}{2}\alpha_1\cos\frac{1}{2}\alpha_m}\end{aligned}\right\}, \quad . \quad (6)$$

so that when the system is telescopic the magnifying power is p. Let these be the constants of a first system to which a second is to be added with values l' and p' in the places of l and p. The second system referred to the terminal point corresponding to the last lens of the first system will then have constants

$$A_2=\frac{\sin\alpha'}{l'},$$

$$B_2=\frac{p'\cos(\alpha'+\frac{1}{2}\alpha_m)}{\cos\frac{1}{2}\alpha_m},$$

$$C_2=\frac{\cos(\alpha'-\frac{1}{2}\alpha_n)}{p'\cos\frac{1}{2}\alpha_n},$$

$$D_2=-\frac{l'\sin(\alpha'+\frac{1}{2}\alpha_m-\frac{1}{2}\alpha_n)}{\cos\frac{1}{2}\alpha_m\cos\frac{1}{2}\alpha_n},$$

and by equations (1) the Gaussian constants of the combination of the two systems are given by

$$A_{1,2}=\frac{\sin(\alpha+\alpha')}{L},$$

$$B_{1,2}=\frac{P\cos(\alpha+\alpha'-\frac{1}{2}\alpha_1)}{\cos\frac{1}{2}\alpha_1},$$

$$C_{1,2}=\frac{\cos(\alpha+\alpha'-\frac{1}{2}\alpha_n)}{P\cos\frac{1}{2}\alpha_n},$$

$$D_{1,2}=-\frac{L\sin(\alpha+\alpha'-\frac{1}{2}\alpha_1-\frac{1}{2}\alpha_n)}{\cos\frac{1}{2}\alpha_1\cos\frac{1}{2}\alpha_n},$$

subject to the relations

$$\left.\begin{aligned}L=pl'=\frac{l}{p'}\\ P=pp'=\frac{l}{l'}\end{aligned}\right\}, \quad . \quad . \quad . \quad (7)$$

the latter of which might have been written down at once as obvious from the meaning of magnifying power. Consider now a system of lenses placed in a tube, of which the first portion is of uniform diameter d, a second portion in which the diameter increases from d to kd, and the third portion of uniform diameter kd. Let the systems which occupy these sections be identified by the numbers 1, 2, 3 respectively. Since the l's are proportional to the sizes of the images that the system forms of any given external objects, and these for the same angular field must vary as the diameter of the tube, the values which should be inserted in (7) are

$$l_{1,2}=l_{1,3}=kl_1, \quad . \quad . \quad . \quad (8)$$

in addition to the conditions that the systems in the outer sections are of the type used in a tube of uniform diameter, that is,

$$p_1=p_3=1. \quad . \quad . \quad . \quad (9)$$

Considering now the combination of systems 1 and 2, equations (7) give as a consequence of (8) and (9)

$$l_2=kl_1, \quad p_2=p_{1,2}=\frac{1}{k}. \quad . \quad . \quad (10)$$

If the second portion is telescopic this merely amounts to the statement that the magnifying power of this telescope is $1/k$. Applying (7) now to the complete instrument, which is divided into two parts (1, 2) and 3, the first equation gives

$$p_{1,2}l_3=l_{1,3},$$

or by (8) and (10)

$$l_3=k^2l_1. \quad . \quad . \quad . \quad (11)$$

This result is of the greatest importance, since it shows that if the diameter is increased k times, and consequently the focal length of the system enlarged in the same ratio, the focal lengths of the individual lenses in the enlarged portions and their separations will be increased k^2 times. Thus, if the diameter of the tube is halved the lenses must be packed four times as closely, and since this means both a greater amount of scattered light and increased astigmatism or curvature and a more dispersed secondary spectrum, the curtailment of the length of the narrow portion of the periscope tube to the minimum possible value is evidently of great importance. *Fig.* 31 illustrates the modification, as the diameter changes, in a system of the type shown in *Fig.* 15.

In actual periscopes the system which occupies the section where the enlargement in the diameter occurs is not usually a telescope, but this is not vital to the argument that has been employed, for portions of the systems which precede or follow may be arbitrarily regarded as parts of the intermediate system. It is, however, always possible to regard this section as a Galilean telescope, though, in fact, no negative lens is employed. The negative lens in this case is supposed to be combined with a lens of the system in the narrower portion of the tube, the two together being either equivalent to a positive lens or preferably to a single lens of zero power, so that no lens is required. In like manner the positive lens may be combined with a lens of the other system to produce a more powerful lens, but this course offers no special advantages. The powers and separations of the lenses on changing the diameter of the tube then are represented by the expressions given in Table II., where lens $m-1$ is the last of the

TABLE II

Powers.	Separations.
$\dfrac{\sin\alpha_{m-2}}{l}$	
	$l(\tan\frac{1}{2}\alpha_{m-2}+\tan\frac{1}{2}\alpha_{m-1})$
$\dfrac{\sin\alpha_{m-1}}{l}$	
	$l\left(\tan\frac{1}{2}\alpha_{m-1}+\dfrac{k-\cos\alpha_m}{\sin\alpha_m}\right)$
$\dfrac{\sin\alpha_m}{kl}$	
	$kl\left(\dfrac{1-k\cos\alpha_m}{\sin\alpha_m}+k\tan\frac{1}{2}\alpha_{m+1}\right)$
$\dfrac{\sin\alpha_{m+1}}{k^2l}$	
	$k^2l(\tan\frac{1}{2}\alpha_{m+1}+\tan\frac{1}{2}\alpha_{m+2})$
$\dfrac{\sin\alpha_{m+2}}{k^2l}$	

smaller diameter and lens m the first of the larger diameter. The four Gaussian constants when lenses $m-1$, m, $m+1$ have just been included are given in Table III. :

TABLE III

n.	$A_{1,n}$.	$B_{1,n}$.	$C_{1,n}$.	$D_{1,n}$.
$m-1$	$\frac{\sin \alpha_{1,m-1}}{l}$	$\frac{\cos(\alpha_{1,m-1}-\frac{1}{2}\alpha_1)}{\cos \frac{1}{2}\alpha_1}$	$\frac{\cos(\alpha_{1,m-1}-\frac{1}{2}\alpha_{m-1})}{\cos \frac{1}{2}\alpha_{m-1}}$	$-\frac{l \sin(\alpha_{1,m-1}-\frac{1}{2}\alpha_1-\frac{1}{2}\alpha_{m-1})}{\cos \frac{1}{2}\alpha_1 \cos \frac{1}{2}\alpha_{m-1}}$
m	$\frac{\sin \alpha_{1,m}}{kl}$	$\frac{\cos(\alpha_{1,m}-\frac{1}{2}\alpha_1)}{k \cos \frac{1}{2}\alpha_1}$	$\frac{\sin \alpha_{1,m}-k \sin \alpha_{1,m-1}}{\sin \alpha_m}$	$-\frac{l\{k \cos(\alpha_{1,m-1}-\frac{1}{2}\alpha_1)-\cos(\alpha_{1,m}-\frac{1}{2}\alpha_1)\}}{\cos \frac{1}{2}\alpha_1 \sin \alpha_m}$
$m+1$	$\frac{\sin \alpha_{1,m+1}}{kl}$	$\frac{\cos(\alpha_{1,m+1}-\frac{1}{2}\alpha_1)}{k \cos \frac{1}{2}\alpha_1}$	$\frac{k \cos(\alpha_{1,m+1}-\frac{1}{2}\alpha_{m+1})}{\cos \frac{1}{2}\alpha_{m+1}}$	$-\frac{kl \sin(\alpha_{1,m+1}-\frac{1}{2}\alpha_1-\frac{1}{2}\alpha_{m+1})}{\cos \frac{1}{2}\alpha_1 \cos \frac{1}{2}\alpha_{m+1}}$

All these values take the regular form when $k=1$.

If more alterations than one have taken place, or if a previous portion of the system does not belong entirely to a regular system, so that p is not unity before the diameter of the tube changes, it is only necessary to introduce the factors for all preceding changes into the expressions for the Gaussian constants and for the powers and separations of the lenses as they have been shown to occur in the present example.

§ (7) THE LIGHT PUPILS.—It might appear that a knowledge of the details of the leading lens system would be necessary to enable the properties suitable for later lenses to be determined, and hence necessary also in deciding what field of view can be included in a system of lenses to be inserted in a given tube when the number of lenses is fixed. This, however, is not the case, and a general view of what is physically attainable with an assigned number of lenses under these conditions may be gained without paying any regard to the lens system by which the result is to be achieved. To make this clear it is desirable to approach the problem from a different point of view from that hitherto adopted. For this purpose it is convenient to regard the problem as it will appear to a designer who is asked, without previous experience of periscope design, to devise a system to go into a given body and transmit light over a certain field of view, the magnifying power and the size of the central emergent pencil being assigned, while the illumination should be as uniform as possible, and in any case the marginal illumination must not be less than a known fraction of that at the centre.

These conditions are most simply represented by considering three circular apertures in the object space, one limiting the field which is to be visible, another the aperture of the objective situated at the instrument (the diameter being usually the diameter required for the emergent pencil multiplied by the magnifying power), and the last an aperture, usually situated between the other two, which cuts down the

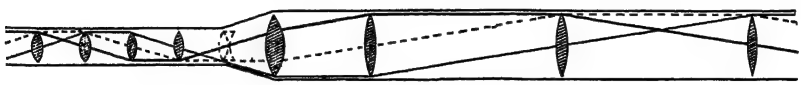

FIG. 31.

areas of marginal pencils without affecting those at the centre of the field. Alternatively corresponding conditions may be given for the image space. The three apertures determine a region of space containing all the useful light rays, and the instrument should have its optical elements of such sizes and in such positions that no ray which does not cross the boundary of this space is obstructed in its passage from the object through the instrument to the observer's eye. It is assumed that the apertures are circles lying in planes normal to the axis of symmetry of the instrument, and that their magnitudes and positions are known for either the object space or the image space. In the illustrations to be given it will be assumed that the various lenses between the objective and the eye lens may be permitted to have an aperture not exceeding a common value d. The modification necessary when the maximum aperture varies from lens to lens will be obvious.

Suppose, then, that the boundary to the channel containing the rays to be transmitted by the instrument is defined by means of three circular apertures which are met by a plane through the axis in P, P′; R, R′; S, S′ (*Fig.* 32). The section of the boundary by this plane is the convex hexagon RSP′R′S′P, the sides SP′ and S′P passing through infinity. The image of this hexagon formed by any part of the optical system of the instrument

will likewise be a convex hexagon, and this image will determine the channel for the refracted rays. After every refraction there is necessarily some part of the boundary which extends to infinity, and this may correspond to any assigned normal section of the original channel.

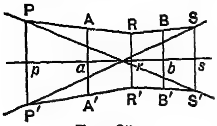

Fig. 32.

Only that part of the boundary which lies between successive lenses is of interest from the present point of view. These various segments pieced together and regarded as a whole constitute repeated outlines of the whole hexagon, which always presents its convex side to the axis, but the outline has an additional angle wherever a lens is encountered. At such places one section ends and another begins, and the angle at their junction is opposite in sign to the angles of the hexagon if the lens is positive. Lenses are introduced wherever necessary to bend back the boundary of the channel from encroaching over the prescribed bounds.

Fig. 33 illustrates the effects that may be produced by successive refractions, the cross

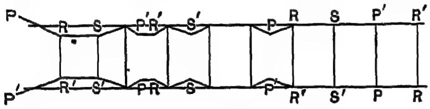

Fig. 33.

lines representing lenses. The various points of the original hexagon are identified by the same letters in their refracted images. The only limit to the amount of the initial hexagon that may be imaged between successive lenses arises from the fact that a pair of opposite sides of the hexagon always extend to infinity, and it is not possible in consequence to image one half of the outline on one side of the boundary within a single cell of the body.

The separation between the lenses limiting a given cell is readily found. Suppose that the lenses meet the boundary in planes corresponding to AA′ and BB′ of *Fig.* 32. If each of the transverse lines AA′ and BB′ has its image of diameter d, the transverse magnifications are d/AA' and d/BB'. By a well-known elementary theorem the longitudinal magnification will be the product

$$\frac{d}{\mathrm{AA}'}\cdot\frac{d}{\mathrm{BB}'},$$

and the separation of the lenses will thus be

$$\frac{d^2\,.\,ab}{\mathrm{AA}'\,.\,\mathrm{BB}'},$$

where a and b are the axial points of the planes AA′ and BB′. The total length between the extreme lenses after any number of refractions is found by adding together the lengths corresponding to the successive intervals. The law already derived from different considerations, that this length will be proportional to the square of the diameter of the tube and to the number of lenses, and inversely proportional to the diameters of the field of view and of the external aperture of the system, at once follows.

§ (8) Standard Cases. (i.) *General Spacing.*—Particular cases which require special attention occur when the lenses occupy positions corresponding to the limiting apertures PP′, RR′, SS′. If a lens is placed at every aperture image the greatest length is attained when the hexagon is developed into a straight line, so that the rays occupy the whole available space within the body of the instrument. The length reached is given by the sum

$$d^2\left\{\frac{sp}{\mathrm{SS}'\,.\,\mathrm{P'P}}+\frac{pr}{\mathrm{P'P}\,.\,\mathrm{R'R}}+\frac{rs}{\mathrm{R'R}\,.\,\mathrm{S'S}}+\frac{sp}{\mathrm{S'S}\,.\,\mathrm{PP}'}+\frac{pr}{\mathrm{PP}'\,.\,\mathrm{RR}'}+\ldots\right\},\qquad(12)$$

where it is assumed that SS′ corresponds to the position of the first lens. All the terms in this sum necessarily have the same sign, as changes of sign take place simultaneously in the numerator and the denominator. Several alternative arrangements suggest themselves. Suppose, for instance, that a lens is placed at the image of every alternate aperture only. The length is then

$$d^2\left\{\frac{sr}{\mathrm{SS}'\,.\,\mathrm{R'R}}+\frac{rp}{\mathrm{R'R}\,.\,\mathrm{PP}'}+\frac{ps}{\mathrm{PP}'\,.\,\mathrm{SS}'}+\ldots\right\},\qquad(13)$$

the terms having exactly the same values as before but differing in order. If in these cases the total number of lenses is a multiple of three the lengths of the two instruments will be exactly equal.

As another example, suppose there were no field lenses, so that no lens is placed at any image of the aperture PP′. The sum is now

$$d^2\left\{\frac{sr}{\mathrm{SS}'\,.\,\mathrm{R'R}}+\frac{rs}{\mathrm{R'R}\,.\,\mathrm{SS}'}+\frac{sr}{\mathrm{S'S}\,.\,\mathrm{RR}'}+\ldots\right\},\qquad(14)$$

every term being equal to one of the terms in (12). The other apertures may be treated in the same way, and it is evident that the first and second methods of construction will not give either the longest or the most compact instruments if the values of the individual terms differ. The estimation of the relative values of the terms is thus interesting, and this

can be done by a very simple construction. Let pS and Ps meet RR' in t and u respectively (*Fig.* 34).

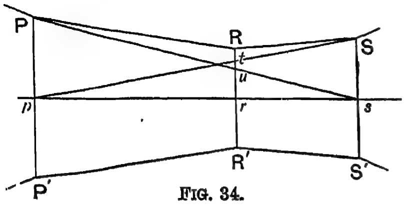

FIG. 34.

The relative values are in the ratios of the products

$$ps\,.\,RR' : pr\,.\,SS' : rs\,.\,PP',$$

that is, of the triangles

$$pRs : pSr : rPs,$$

which are equal to the triangles

$$pRs : pts : pus,$$

which are in the ratio of their heights

$$Rr : tr : ur.$$

The length (12) may therefore be written as

$$\frac{d^2\,.\,ps}{PP'\,.\,SS'}\left\{1+\frac{tr}{Rr}+\frac{ur}{Rr}+1+\frac{tr}{Rr}+\frac{ur}{Rr}+\ldots\right\}. \quad (15)$$

PP' and SS' may be taken to represent the actual object and the entrance pupil, so that the factor outside the bracket will be known. The greatest attainable length of any cell not bounded at an image of the aperture which cuts down the marginal light has then a definite value. The next term gives the length of a cell bounded by an image of the field and of the intermediate stop. As ps may be always considered large in comparison with rs, the utmost that can be done is to make this cell equal in length to the previous one, by making the diameter of the intermediate stop image of the same size as the entrance pupil. This involves an immediate fall in the light intensity as soon as the object departs from the axis. The length of the third cell, which is bounded by images of the intermediate stop and of the entrance pupil, depends upon the relative illumination at the edge and at the centre of the field of view. If the width of the marginal beam in the axial plane of symmetry is half that of the central beam, PRs will be a straight line and the lengths of the first and third cells will be equal. If the edge illumination is increased, the length of this cell is diminished, and if the illumination falls, the length may be increased. When the width of the marginal beam is greater than half the central width, it will evidently be possible to attain a greater length per lens when lenses at images of RR' and SS' do not immediately succeed one another.

(ii.) *Uniform Spacing.*—The case when all three cells are of equal length is a convenient one to take as a standard of reference, and systems of this type possess great flexibility. It is always possible to attain a given standard extent of field with a standard aperture and the distribution of illumination characteristic of the type with any given number of cells. The length per cell thus gives complete information about such systems. This may be illustrated by the following examples. The cells begin with the first objective, indicated by S, and end with the formation of a real upright image of the object, denoted by P. If the system ended with P′ the final image would be inverted.

TABLE IV

No. of Cells.	Lens Positions.	Remarks.
2	S, R′, P	Not divisible into separate telescopes.
3	S, P′, S′, P	Not divisible into separate telescopes.
3	S, P′, R′, P	Not divisible into separate telescopes.
3	S, R′, S′, P	No field lens.
4	S, P′, R′, S′, P	
5	S, R′, P, S, R′, P	Not divisible into separate telescopes.
6	15 solutions	A lens coincides with at least one image of each stop.
7	35 solutions	At least two lenses coincide with images of each stop.

In general with $2n$ inversions and p cells the number of solutions is

$$\frac{p!}{(6n-p-2)!\,(2p+2-6n)!},$$

where p may have any value from $3n-1$ to $6n-2$.

It does not follow that because several solutions enable the same length of body to be obtained with the same number of lenses that these are all equally desirable. Other things being equally satisfactory, the solution preferred will be that which involves the use of the least powerful lenses. It should be

immediately evident that the omission to place a lens where an image of a certain aperture is formed will involve increases in the powers of the lenses at the two neighbouring images, since the deviations at the margins of these lenses must be greater. The failure, therefore, to fill completely the space available for the rays will be associated with increased lens powers, and consequently with greater trouble due to secondary colour effects and increased curvature of field. To determine how serious these defects are likely to be, the powers of the lenses are required. There is no need to consider the refracted light to determine these powers, but attention may be directed as before to the object space hexagon. If, for example, successive lenses are to be located at images of PP′, RR′, SS′, the lens at the image of RR′ is required to deviate the image of RS into alignment with the preceding image of PR. Now the angular magnification at any plane is inversely proportional to the linear magnification, and the angular deviation is equal to the product of the lens power and the distance from the axis at which refraction takes place. It at once follows that the power of the lens required is $(\mathrm{RR}'/d)^2$ times the power of the lens which would produce the corresponding effect in the object space boundary. This is in reality the same result that has already been reached regarding the length of the instrument, since the focal lengths of the lenses evidently bear a fixed relation to the lengths of the cells, but it serves to show how great is the advantage from every point of view in making the diameter of the body as great as possible. Various expressions are easily found for the power of the lens necessary at RR′. Let this be denoted by $\kappa(d/\mathrm{RR}')^2$, so that κ is the power of the lens required in the instrument. The deviation at R is then $\frac{1}{2}(\kappa d^2/\mathrm{RR}')$, and the area of the triangle PRS by various expressions leads to the equations, when inclinations to the axis are assumed to be small,

$$\frac{\kappa d^2}{\mathrm{RR}'} \cdot pr \cdot rs = 2\rho\mathrm{R} \cdot ps \quad . \quad . \quad (16)$$

$$= \mathrm{PP}' \cdot rs + \mathrm{RR}' \cdot sp + \mathrm{SS}' \cdot pr, \quad . \quad (17)$$

where ρ is the point of intersection of $\mathrm{R}r$ and PS. Equation (17) itself shows the result reached above in a different way that κd^2 is unaltered by refraction. For it may be rewritten in the form

$$\kappa d^2 = \frac{\dfrac{rs}{\mathrm{RR}' \cdot \mathrm{SS}'} + \dfrac{sp}{\mathrm{SS}' \cdot \mathrm{PP}'} + \dfrac{pr}{\mathrm{PP}' \cdot \mathrm{RR}'}}{\dfrac{pr}{\mathrm{PP}' \cdot \mathrm{RR}'} \cdot \dfrac{rs}{\mathrm{RR}' \cdot \mathrm{SS}'}},$$

and each term on the right is invariant on refraction. The expressions of this type for the powers of the lenses at images of PP′, RR′, and SS′ when no images are without lenses are evidently

$$\left.\begin{aligned} d^2\kappa_{\mathrm{RSP}'} &= d^2\kappa_{\mathrm{R}'\mathrm{S}'\mathrm{P}} \\ &= \mathrm{SS}'\frac{\mathrm{RR}' \cdot sp + \mathrm{SS}' \cdot pr + \mathrm{P}'\mathrm{P} \cdot rs}{rs \cdot sp} \\ d^2\kappa_{\mathrm{S}'\mathrm{PR}} &= d^2\kappa_{\mathrm{SP}'\mathrm{R}'} \\ &= \mathrm{P}'\mathrm{P}\frac{\mathrm{SS}' \cdot pr + \mathrm{P}'\mathrm{P} \cdot rs + \mathrm{R}'\mathrm{R} \cdot sp}{sp \cdot pr} \\ d^2\kappa_{\mathrm{PRS}} &= d^2\kappa_{\mathrm{P}'\mathrm{R}'\mathrm{S}'} \\ &= \mathrm{RR}'\frac{\mathrm{PP}' \cdot rs + \mathrm{RR}' \cdot sp + \mathrm{SS}' \cdot pr}{pr \cdot rs} \end{aligned}\right\}, \quad (18)$$

where all the factors are considered with due regard to sign. In each numerator two terms have one sign and the third the opposite sign, in each case giving rise to a positive κ. In the standard case the terms are all equal, and the focal length of each lens is equal to the length of a cell. This is readily seen geometrically by considering the intercepts on the third aperture by the line forming the boundary between the other two.

The cases in which an image of an aperture is without a lens may be treated by analogy with (18),

$$\left.\begin{aligned} d^2\kappa_{\mathrm{RSR}'} &= d^2\kappa_{\mathrm{R}'\mathrm{S}'\mathrm{R}} = d^2\kappa_{\mathrm{S}'\mathrm{RS}} \\ &= d^2\kappa_{\mathrm{SR}'\mathrm{S}'} = \frac{2\mathrm{RR}' \cdot \mathrm{SS}'}{rs} \\ d^2\kappa_{\mathrm{SP}'\mathrm{S}'} &= d^2\kappa_{\mathrm{S}'\mathrm{PS}} = d^2\kappa_{\mathrm{PSP}'} \\ &= d^2\kappa_{\mathrm{P}'\mathrm{S}'\mathrm{P}} = \frac{2\mathrm{PP}' \cdot \mathrm{SS}'}{ps} \\ d^2\kappa_{\mathrm{PRP}'} &= d^2\kappa_{\mathrm{P}'\mathrm{R}'\mathrm{P}} = d^2\kappa_{\mathrm{R}'\mathrm{PR}} \\ &= d^2\kappa_{\mathrm{RP}'\mathrm{R}'} = \frac{2\mathrm{PP}' \cdot \mathrm{RR}'}{pr} \end{aligned}\right\}, \quad (19)$$

showing that in the standard case the omission of a lens requires the power of each neighbouring lens to be doubled. Again, if a lens is omitted on each side of a given lens expressions are obtained corresponding to (18), but with every term of the same sign, so that in the standard case the power of the lens is three times its previous value. The expressions are

$$\left.\begin{aligned} d^2\kappa_{\mathrm{PSR}'} &= d^2\kappa_{\mathrm{P}'\mathrm{S}'\mathrm{R}} \\ &= \mathrm{SS}'\frac{\mathrm{PP}' \cdot sr + \mathrm{SS}' \cdot rp + \mathrm{R}'\mathrm{R} \cdot ps}{rs \cdot sp} \\ d^2\kappa_{\mathrm{R}'\mathrm{PS}} &= d^2\kappa_{\mathrm{RP}'\mathrm{S}'} \\ &= \mathrm{PP}'\frac{\mathrm{R}'\mathrm{R} \cdot ps + \mathrm{PP}' \cdot sr + \mathrm{SS}' \cdot rp}{sp \cdot pr} \\ d^2\kappa_{\mathrm{SR}'\mathrm{P}} &= d^2\kappa_{\mathrm{S}'\mathrm{RP}'} \\ &= \mathrm{R}'\mathrm{R}\frac{\mathrm{SS}' \cdot rp + \mathrm{R}'\mathrm{R} \cdot ps + \mathrm{PP}' \cdot sr}{pr \cdot rs} \end{aligned}\right\}. \quad (20)$$

By considering the various cases that may arise it is seen that the effect of omitting to place a lens at an aperture image is to contribute for this vacant aperture twice the normal contribution to the sum of the powers of the lenses, assuming that the standard case is under consideration. If account is taken of a final field lens but not of an eye lens, with $2n$ inversions and p cells the sum of the powers will be proportional to $12n-p-3$. In this respect all arrangements which involve the same number of lenses and the same number of inversions are on an equality in the standard case.

In the general case the increase in power associated with the omission of a lens at an image of P is

$$-\frac{(SS'.pr+P'P.rs+R'R.sp)^2}{d^2.pr.rs.sp}, \qquad (21)$$

the term in the bracket being that in the numerator of the fraction in the second of equations (18). The corresponding expressions for other cases are easily written down. The sum of the additions incurred by each separate omission gives the total addition to be made to the sum of the powers.

A convenient expression for the increment in power in terms of the lengths of the cells is

$$\frac{\kappa^2 l_1 l_2}{l_3}, \quad . \quad . \quad . \quad . \quad (22)$$

where κ is the power of the lens which it is proposed to omit, l_1 and l_2 are the lengths of the cells on either side, and l_3 is the length of the combined cell when the omission is made. The three lengths l_1, l_2, l_3 are those considered earlier in this discussion when the length attainable by a periscope was investigated.

It is evident that when weight is attached both to the attainment of great length and to a minimum value of the power sum, the most favourable type of construction is that which has been generally adopted for submarine periscopes, with a lens at every image of the three apertures.

(iii.) *Advantage of Non-uniform Spacing.*—In investigating the attainment of great length attention was directed to each cell as a separate element. It has still to be considered whether, when the conditions permit of it, any advantage will be gained by deliberately introducing inequalities in the lengths of the three cells. Suppose the lengths of the cells exceed the mean value L by amounts λ_1, λ_2, λ_3, where $\lambda_1+\lambda_2+\lambda_3=0$. From (18)

$$\kappa_1=\frac{l_2+l_3-l_1}{l_2 l_3},$$

with symmetrical expressions for κ_2 and κ_3, so that

$$\kappa_1+\kappa_2+\kappa_3 =\frac{3L^2-2(\lambda_1^2+\lambda_2^2+\lambda_3^2)}{L^3-\frac{1}{2}L(\lambda_1^2+\lambda_2^2+\lambda_3^2)+\lambda_1\lambda_2\lambda_3}$$

$$=\frac{3}{L}-\frac{\lambda_1^2+\lambda_2^2+\lambda_3^2}{2L^3-L(\lambda_1^2+\lambda_2^2+\lambda_3^2)} \text{ approximately,}$$

showing that inequalities in length tend to reduce the aberrations which depend on the sum of the powers. In this respect the standard form is the least satisfactory solution of its class, but the advantage to be gained by uneven spacing is small, since it is a second order effect. For instance, if the lengths are in the ratios 2 : 3 : 4, the reduction in the power sum is slightly more than 4 per cent.

§ (9) Separation of Image and Field Lenses.—It has hitherto been assumed that the lenses will be placed in the planes at which aperture images are formed. In the case of field lenses exact coincidence with the image is generally undesirable, and the effect of placing the lenses in other planes requires consideration. Obviously the sizes of the lenses are determined by the sections of the channel to which their positions correspond. Suppose in *Fig.* 32 the planes AA′ and BB′ are proposed as lens planes. The relation between transverse and longitudinal magnitudes is

$$AA'.pr=PP'.ar+RR'.pa,$$

and thus if the apertures PP′, RR′, SS′ relate to a standard form,

$$AA'.SS'.pr=(ar.ps+pa.rs)\frac{d^2}{l}$$

$$=as.pr.\frac{d^2}{l},$$

showing that a cell bounded by AA′ and SS′ will be of standard length. Similarly

$$PP'.BB'=pb.\frac{d^2}{l},$$

and combining the two cases,

$$AA'.BB'.ps=pb.as.\frac{d^2}{l}.$$

Thus if l' is the length of the cell bounded by AA′ and BB′,

$$\frac{l'}{l}=\frac{ab.ps}{pb.as}$$

or

$$\frac{l-l'}{l}=\frac{pa.bs}{pb.as},$$

showing that if two successive lenses are not in planes corresponding to the angular points of the hexagon the length of the cell they bound is reduced.

§ (10) Completion of the Instrument.—The theory developed in the foregoing sections suffices to enable the special problem presented

by the submarine periscope to be solved without difficulty in any given case. When the instrument has only a single magnifying power the arrangement of lenses for the main part of the tube may first be investigated, the objective may be arranged to fit in with this system, and finally the eyepiece be added to secure a suitable power. The problems here involved do not differ essentially from those presented by any simple telescope.

§ (11) Bi-focal Instruments. — Though very great importance is attached in submarine periscopes to the attainment of a very wide field at a low power, it is also advantageous to be able at will to substitute a higher magnifying power with a correspondingly smaller field of view. In small telescopes (*q.v.*) this is usually secured by the use of a variable power eyepiece, but for a submarine periscope this method of changing the power is unsatisfactory. It has to be remembered that the brightness of the image is a factor of outstanding importance whether the power is high or low, and therefore at the high power it is necessary for the pupil to be filled with light. If the diameter of the eye pupil for which the instrument is designed is e and the apparent field of view is Ω, the minimum diameter of the beam of light which must be carried through the instrument is m_2e and the minimum angular field of view to be carried to the eyepiece is Ω/m_1, where m_1 is the magnifying power for the low power and m_2 for the high power. The duty to be performed by the main part of the instrument is thus represented approximately by

$$\frac{e\Omega m_2}{m_1}$$

when a variable power eyepiece is used. On the other hand, when the power is changed by varying the objective the corresponding expression is $e\Omega$ whatever m may be. As m_2 is usually about four times m_1, it follows that the results attainable with a variable power objective are approximately four times as good as can be obtained from a variable power eyepiece.

As with a telescope, it is essential that the change of power shall not necessitate any change in the adjustment for focussing the eyepiece on the image. Accordingly, when the power has been changed the image formed by the objective must remain in the same plane as it originally occupied; the consequent portions of the system will then transmit the light under conditions exactly similar for both powers. The discussion of variable power eyepieces [1] shows that a continuous variation of power without a change of image position is possible if two lenses move suitably relatively to the rest of the system. Arrangements of this kind are considered unsuitable in submarine periscopes, for they not only involve a considerable enlargement of the outer tube for the accommodation of the necessary mechanism where it is particularly desired to reduce its diameter as much as possible, but also the likelihood of their failure to act through distortion or slight damage to the periscope renders their introduction distinctly undesirable in so vital an instrument.

The exclusion of these systems which give a continuous variation of power implies that the objective is rapidly exchanged for another of different focal length, the object under examination being momentarily obscured while the change is being effected. This change has been secured in a variety of ways. In an instrument due to Messrs. Ross, separate fixed objectives are used for the high and the low powers, and one or the other is obscured by shutters. This arrangement involves a slight loss of light at the high power, since a reflecting prism has to be slightly cut away to allow the low power beam to pass. A design by Messrs. Zeiss makes use of the fact that with any lens the separation of the object and the image is the same whether the magnification is m or $1/m$. Thus, if the ratio of the two magnifying powers is 4 : 1, values for m of 2 and $\frac{1}{2}$ would be selected; if the moving lens is of focal length f and a preliminary lens presents to it as an object an image distant about $\frac{3}{2}f$, this second lens will form an image twice the size at a distance of approximately $3f$ (*Fig.* 35). If now the second lens is

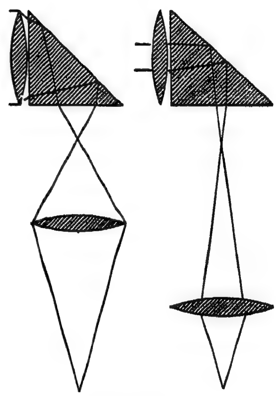

Fig. 35.

moved a distance $\frac{3}{2}f$ further away from the first lens, the resulting second image will be half the size of the first or one-quarter the size of the original second image, but its position in the instrument will be unchanged. The movement of a single lens along a tube in this way is not open to the same objections as in

[1] See "Eyepieces."

the more complicated movements of the variable power eyepiece type. The chief objection to this system is that unless the instrument can be corrected for aberration when this lens is of symmetrical construction the lens should, in addition to its translation, be reversed on moving between its two positions.

An entirely different system is one due to Sir Howard Grubb (*Fig.* 36). In this case two

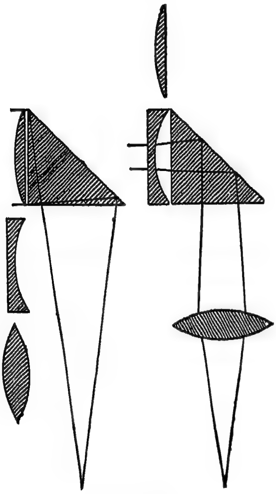

FIG. 36.

objectives are mounted in the same frame which slides in front of the entrance window, so that either lens may receive the light. One of these lenses acts as an objective alone for one power. For the other power the second lens occupies the position of the first, the frame being moved parallel to the tube axis through the distance separating the lens centres. It is evidently necessary that this lens shall differ in power from the first and that another lens shall be introduced into the system, in order that the power shall be different and the image in the same position. In the arrangement used this supplementary lens moves about a hinge near one side of the tube, and lies close to the tube when the single objective is used, but turns through a right angle into the optical system when the second power is employed. By a simple but ingenious mechanism a single movement effects both changes. If t_1 is the separation of the lenses when the double objective is used, and t_2 is the distance from the second of these lenses to the image, so that t_1+t_2 is with sufficient approximation the distance from the single objective to the image plane, the powers of the lenses must be for the single objective

$$\kappa=\frac{1}{t_1+t_2},$$

and for the double objective

$$\kappa_1=\frac{m}{t_1+t_2}-\frac{m-1}{t_1},$$

$$\kappa_2=\frac{m-1}{m}\left(\frac{1}{t_1}+\frac{1}{t_2}\right),$$

giving a power for the combination of

$$\kappa_{1,2}=\frac{m}{t_1+t_2}.$$

A particularly attractive means of changing the power is that introduced by Messrs. Goerz (*Fig.* 37), in which use is made of the fact that an objective composed of a positive and a negative lens well separated from one another have their principal planes very unsymmetrically situated. Under suitable conditions the mid-point of the actual lens system may approximately coincide with the point midway between the object and image planes when the magnification differs appreciably from unity. The system is thus a special case of the one utilised by Messrs. Zeiss, but the translation is converted into a rotation. The arrangement actually adopted is to use two pairs of positive and negative lenses mounted as a whole with two right-angled deflecting prisms. This complete block is rotated

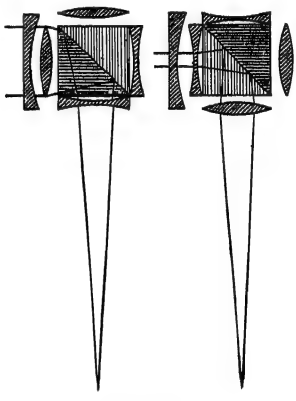

FIG. 37.

through two right angles about an axis normal both to the vertical tube axis and to the horizontal axis of the incident light. The use of two separate objective systems may be due to difficulties in connection with the removal of aberrations. This system must be preceded by a fixed negative lens to yield a virtual image at the same distance from the axis of revolution as the first image formed in the periscope tube. If t is the separation between the lenses and d is the distance of both object and image from

the nearest lens, the system is determined from

$$\kappa_1=\frac{1}{d}+\frac{1+m}{mt},$$

$$\kappa_2=\frac{1}{d}+\frac{1+m}{t},$$

$$\kappa_{1,2}=-\frac{t}{d^2}-\left(m+\frac{1}{m}\right)\frac{1}{d},$$

where m of course is negative.

The most usual powers of bi-focal periscopes are $1\frac{1}{2}$ and 6, the former rather than power 1 giving an impression equivalent to a naked-eye view when the apparent field of view is limited. The value adopted for e is usually about 6 mm. and the apparent field may exceed 60°. In a 25-ft. periscope the narrow portion may be 4 ft. in length, and the external diameters will be approximately 6 in. and $2\frac{1}{2}$ in. for the main and top tubes respectively.

§ (12) Sky-searching Periscope.—The earlier periscopes provided only for a view towards the horizon, and all light entered through a fixed window in the side of the tube. It became necessary at a later date to provide in addition means for searching the sky from the horizon to beyond the zenith. The angle here involved is too great to make it practicable to include the whole in a system with a fixed axis. Apart from this, since the definition is only at its best near the axis, it is necessary to be able to secure at will a horizontal direction for the axis. A movable reflector accordingly became necessary at the head of the instrument, and the most satisfactory arrangement consists of two isosceles prisms silvered on their bases, which are cemented together into a frame with their bases parallel (*Fig.* 38).

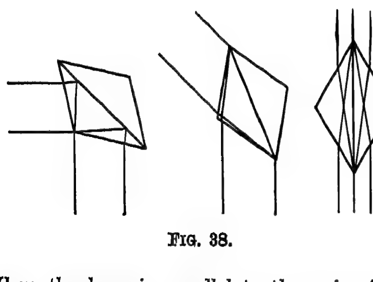

Fig. 38.

When the base is parallel to the axis of the instrument an axial beam of light continues in the same direction after reflection, and, as the inclination of the base to the tube axis is altered by rotation about an axis perpendicular to the length of the tube, the deviation of the light is altered by twice this amount. The use of two prisms mounted in this way gives more equal illumination for prisms which can rotate within a given space than is possible when only a single prism is used. The window through which light first enters the instrument, and which is chiefly provided to prevent the entrance of water into the periscope, is in this case inclined to the axis of the instrument at about 45° instead of being parallel thereto as in earlier instruments. Supplementary systems of prisms may be used to secure more advantageous use of incoming light.

§ (13) Miscellaneous.—The foregoing description is confined to the optical systems which have been actually employed in periscopes. A great variety of interesting instruments have been designed, offering, for instance, panoramic views of the whole horizon arranged in a circular view with an enlarged direct view in the middle, but it is impossible in a single article to attempt to describe them. Actual periscopes also must be provided with much auxiliary equipment in order to remain serviceable under the conditions of use. In some cases, they are from time to time filled with dry compressed air to render the ingress of water more difficult and to prevent the deposition of moisture on any internal surface when the temperature of the sea is low. The discussion of all these necessary but non-optical auxiliary features has not been attempted in this article.

§ (14) Illustrations of Modern Periscopes.—It will be of interest to add some illustrations of recent periscopes showing the actual appearance of the two ends of the instruments. Exhaustive illustration of the many variations is impossible, but those that are given here will serve not only to give an idea of the appearance of the instruments in actual use, but will also indicate in a few directions the developments of which the periscope is susceptible. These illustrations are from photographs of periscopes made by Messrs. Barr & Stroud, by whose courtesy it has been possible to include the illustrations and descriptions of this and the following sections. Incidentally the principle of the arrangement for securing two magnifying powers which this firm has adopted, and which differs from those illustrated in § (11), is shown diagrammatically in *Fig.* 42.

It is not practicable within the limits of space imposed by the pages of this dictionary to show either a general outline of ordinary periscopes or illustrations of the internal mechanism. It may, however, be said that the length of submarine periscopes varies from very short instruments for night use which do not greatly exceed 3 metres in length to instruments reaching 15 metres or more in length. In many of the recent instruments the reduction in the diameter of the top section, which in early instruments was a very pronounced

feature, has been much more slight or even entirely absent. The reason for this is that the instruments are used in a different way. In approaching the object of attack the small-topped periscopes were kept for some considerable time above the surface of the sea. Though the periscope itself might escape observation, it was found that the presence of the submarine was detectable through the track it made in the water when used in this way. The more general method now is to elevate the periscope above the surface at intervals for a few seconds only at a time. Under these conditions, even with a thick top, the periscope usually runs little risk of being seen, and the surface disturbance created when this method of operation is adopted resembles very closely the normal surface irregularities, and so is of no assistance in detecting the approach of an enemy. The possibility of using the thicker head with lenses of larger diameter is of very special importance for very long periscopes, since it is in these instruments that the loss of light due to the large number of lenses becomes most serious, and the narrowness of the smallest section is the chief factor, as has been shown earlier, in increasing the number of lenses that are necessary. The raising and lowering of the periscope is usually performed by hydraulic or electrical power.

The material of which the main tubes are made is of much importance. A periscope made of ordinary steel would inevitably be strongly magnetic, and would affect the reliability of the indications of a magnetic compass in a quite intolerable way. The alternatives are to use a bronze or a non-magnetic steel. In the early periscopes a bronze tube was employed, but later this was replaced by a special nickel steel. At the best, however, tubes of the latter material are somewhat magnetic, and in addition they are slightly corroded by the action of sea-water. This corrosion is of more importance than might at first sight appear since it may cause the tube to work stiffly in the long gland where it pierces the hull of the boat, and so cause difficulty in manipulation. In both of these respects a better material is available, and Messrs. Barr & Stroud prefer to utilise Immadium bronze. This is completely non-magnetic and possesses remarkable powers of resisting corrosion in sea-water, its surface retaining its original polish after prolonged immersion. Needless to say, it possesses the mechanical qualities necessary in a material which must withstand very severe stresses without any considerable deflection.

Fig. 39 shows a photograph of the upper end of a periscope of the sky-searching type. The glass which comes in contact with the water is a window with flat surfaces. Inside may be seen the prism by the rotation of which about a horizontal axis the direction of sight may be varied from the zenith to below the horizon, according to the principle illustrated in *Fig.* 38.

The lower end of the periscope is illustrated in *Fig.* 40. The handles are used to rotate the instrument about its axis, and so enable the line of sight to be directed to any part of the horizon as required. The bearing of any object to which the periscope is directed may be read on the scale seen in the upper part of this figure. When the instrument is not in use the handles may be folded into a vertical position out of the way. The eyepiece, surrounded by a rubber eye-guard, is seen between and slightly above the handles. The kind of view obtained

FIG. 39.

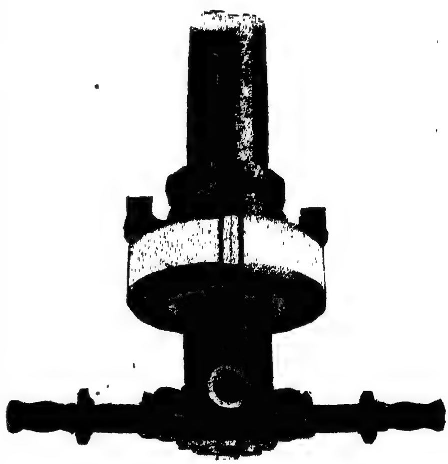

FIG. 40.

on looking into the eyepiece is shown in *Fig.* 41. In focus together with the image of distant external objects, the graduations of vertical and horizontal scales are seen. These correspond to suitable angular intervals by means of which the apparent sizes of objects may be more accurately estimated. The need for such measurements will be fully realised when the more precise measuring devices described below are considered.

Inset in the top of the field of view, so as to be visible without taking the eye from the eyepiece, is a view of a portion of the bearings scale. This is obtained by the introduction of a small auxiliary prismatic telescope.

In addition to reading the bearing, it is obviously of importance that any desired object should be readily brought to the centre

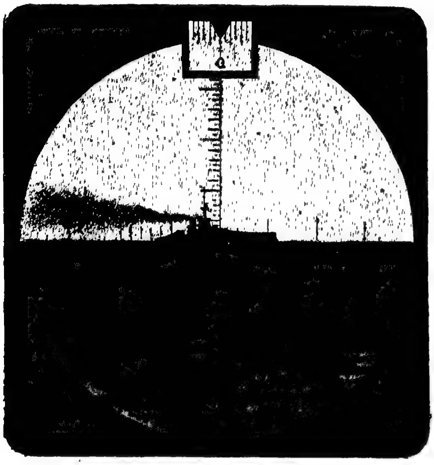

FIG. 41.

of the field under the conditions in which it can be best seen, without the observer being under the necessity of removing his eye from the eyepiece. This evidently involves suitable control over the angle of elevation of the line of sight in addition to its bearing, and ability to adjust the focus, and in special cases to interpose or remove rapidly suitably coloured screens. In this particular periscope the top prism may be adjusted for elevation as required by rotating one of the bearing handles about its axis, and the focussing adjustment and the light filters are controlled by means of the two milled heads seen projecting from the bottom of the periscope in *Fig.* 40. It will be recognised that all these controls are placed very conveniently for the observer. The coloured glasses are placed within the tube and lie close to the eye lens. The focussing is effected by changing the position in the tube of a movable lens. The principles on which the optical system is constructed are shown in *Fig.* 42, which is necessarily diagrammatic and not to scale. The eyepiece consists of lenses M and N, of which the former is cemented to the lower prism L to reduce the number of glass to air surfaces, and thus to obviate an avoidable loss in the amount of light transmitted by the instrument. Focussing is accomplished by movement along the axis of the collector lens K. This lens, together with the eyepiece and the objective H, forms an astronomical telescope. To transmit a sufficient quantity of light down the length of the periscope and secure a suitable field of view, this lower telescope is preceded by another astronomical telescope composed of three lenses E, F, G. Of these E corresponds to the eyepiece, F is a field lens, and G may be regarded as the objective. Considered in this way this telescope produces an angular magnification measured by the ratio of the focal lengths of lenses G and E. If E is regarded as the objective and G as the eye lens, the way this telescope is actually used, it appears to diminish objects viewed through it. The combination of the two telescopes of course is itself a telescope, and as EFG produces an inverted image, and this is subsequently reinverted when viewed through the second telescope HKMN, the combination yields an upright image. To make the system suitable for use as a periscope it is only necessary to insert an upper prism B, and before this to place a plane surfaced window A to prevent the ingress of water into the instrument. This, in fact, constitutes a high-power telescope, the magnifying power being usually 6 with a field of view of 10°. A lower power is obtained by the very simple device of introducing a reversed Galilean telescope in front of the high-power system. The negative lens of this

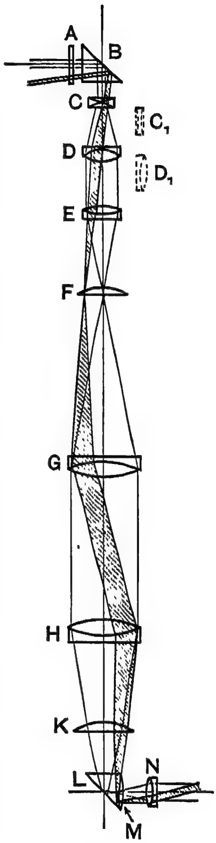

FIG. 42.

telescope is marked C and the positive D. When the high power is wanted these are swung to one side of the tube as at C_1 and D_1. The Galilean telescope is ordinarily constructed to be of magnifying power 4 when used alone as a telescope, with C as the eye lens and D as the object glass. As used in the periscope the magnifying power is thus $\frac{1}{4}$, making the power for the complete low-power system $1\frac{1}{2}$. The field of view is increased in the reciprocal ratio, and is thus approximately 40°. The diagram illustrates the passage of a central and of an oblique beam of rays through the low-power system, and the reduction of the area of the oblique beam in comparison with the central beam is clearly seen. This reduction may not

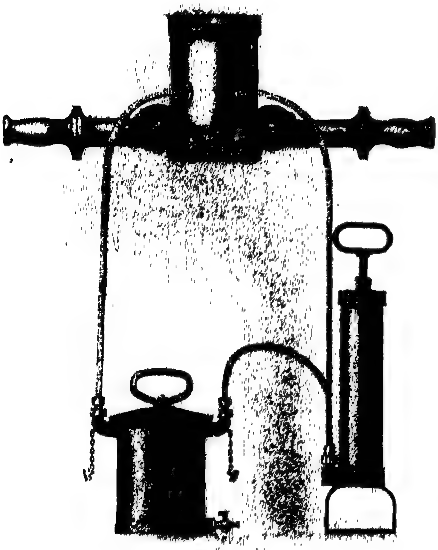

FIG. 43.

be carried beyond the point at which the difference in intensities at the centre and margin becomes apparent to the eye when the change takes place continuously from centre to margin.

When the high-power system is substituted the paths of the rays between D and N are not affected, but in the upper portion of the instrument the paths are modified and may be found by tracing back the paths between D and E. The variation in the illumination from centre to margin is substantially the same for both powers, for this depends chiefly on the separation of the two objectives G and H. The change of power is effected by rotating one of the training handles shown in *Fig.* 40; the other, as has been mentioned, is used to change the elevation of the line of sight. In general the low-power telescope is employed, and a change is only made to the high power when it is desired to observe an object, that has been sighted, more minutely than is possible with the low power. By using the low power, which embraces an angular area sixteen times as great as the high power, large regions can be observed much more rapidly than with the high power with its smaller field of view.

As has been mentioned, it is necessary from time to time to dry the air within the periscope. For this purpose a desiccating chamber is provided in which the damp air from the bottom of the periscope is dried by passing over calcium chloride prior to being forced by a pump to the top of the instrument. The connections to the desiccator are made at the back of the lower end of the periscope as shown in *Fig.* 43. When the desiccator is not in use the inlet and outlet are protected by water-tight plugs.

§ (15) RANGE, COURSE, AND SPEED MEASUREMENTS.—The periscope as described above fulfils functions equivalent to the look-out, with or without the aid of a telescope, on a surface craft. The surface vessel in addition makes use of a number of other optical instruments, such as gun-sights and range-finders. Any corresponding instruments for the submarine must assume a periscopic character, and as the power of making accurate measurements is as important for the under-water as for the above-water ship, it is natural to find that attempts have been made to obtain such measurements, in spite of the special difficulties inseparable from the peculiar conditions of observation from a submerged boat.

For finding the distance of a visible object, one of the simplest methods is to measure the angle it subtends when the dimensions of the object are known. The graticule seen in *Fig.* 41, the divisions of which have known values, enables an approximate value of the range to be found. The method can be increased in accuracy by using a variable wedge to produce a double image by placing it in front of a portion of the beam. A convenient arrangement is one in which the wedges are annular in form, as shown in *Fig.* 44. When the thickest portion of one wedge is superposed on the thinnest portion of the other and *vice versa*, the two are equivalent to a plane sheet of glass if of equal angle, and the images formed by light which has traversed the wedges are not displaced to one side of those formed by the central portion of the pencil. If one prism is rotated in one direction and the other turned through an equal angle in the other direction, the outer rays will be displaced in the plane perpendicular to that originally containing the lines of greatest slope, and this displacement receives its maximum value when each prism has been turned through one right angle, the

position illustrated in *Fig.* 44. Up to this value the separation of the images may be of any desired amount. If the lines of greatest slope now correspond to the vertical plane the two images will be above one another, as shown in

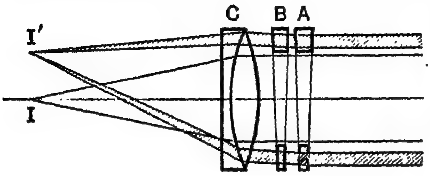

FIG. 44.

Fig. 45, and if the height of the smoke-stack above the water-line of the vessel sighted is known, a setting can be made and the range read with considerable accuracy from the scale attached to the prisms. If now the two prisms are rotated together through a right angle horizontal measurements may be made, as in

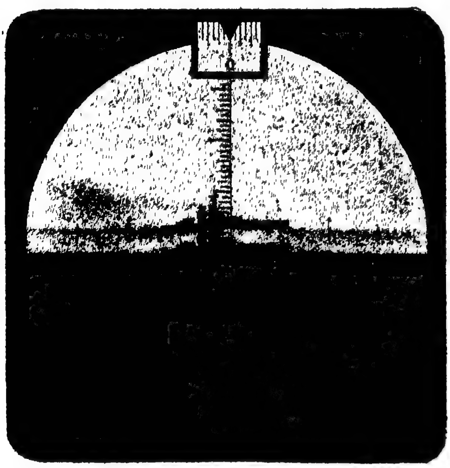

FIG. 45.

Fig. 46. As the apparent length of a vessel depends upon her course relative to the direction from her to the submarine, it is evident that when both the height and the length of the vessel are known the former is a suitable basis for the determination of her range, and the latter for finding her course when the range is known.

In addition to these particulars it is evidently of importance to find the speed of the vessel under observation. The time taken by the vessel to cross any fixed line in space is the time she takes to travel her own length, and thus if her length is known and the time taken to cross any fixed line is observed her speed can be determined. It is not satisfactory to take the projection of a line fixed relatively to the periscope as the line fixed in space for this purpose, as the errors caused by movements of the submarine and of the periscope itself may be considerable. Messrs. Barr & Stroud

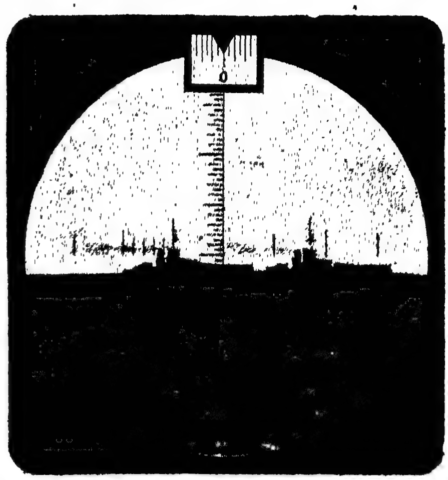

FIG. 46.

have overcome this difficulty by projecting into the field of view the image of a line which is controlled in direction by a small spring-driven gyrostat attached to the lower end of the periscope. *Fig.* 47 illustrates an instru-

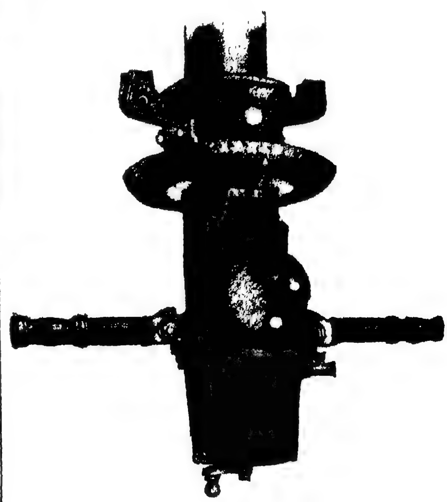

FIG. 47.

ment fitted with this device, the handle seen at the bottom serving to start the gyro. The system employed is shown diagrammatically in *Fig.* 48. A is the gyro pivoted on the bracket N, and B is the mark controlled by it,

the image of which serves for the line fixed in space. It is illuminated by the lamp C, and the light is introduced into the field of view by means of the prism D and the transparent reflector F. By means of the lens E, which must be arranged to give the proper magnifica-

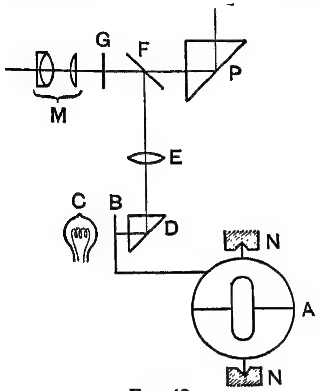

FIG. 48.

tion to the movement of the image of B as seen in the periscope, the mark appears focussed at G in coincidence with the images of external objects. The bracket carrying the gyro and the whole optical system are, of course, rigidly attached to the periscope.

When more precise range measurements than are possible on the principles utilised in the instruments just described are desired it be-

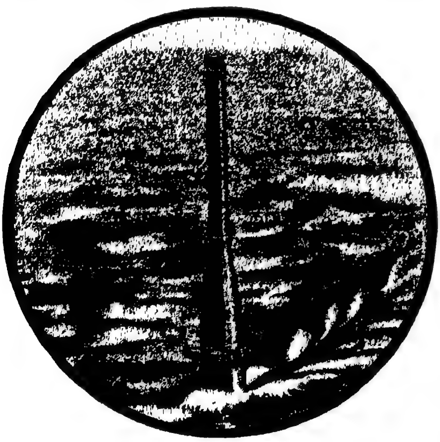

FIG. 49.

comes necessary to derive distances by observing the difference in direction from two stations on the submarine at a known distance from one another. Either the coincidence or the stereoscopic principle may be used to make settings as in ordinary range-finders (*q.v.*), and in the former case the base may be either horizontal, as with instruments used on land, or vertical, the arrangement which the shape of an ordinary periscope suggests as the more convenient. All these alternatives have been embodied in periscope range-finders. *Fig.* 49 shows the upper part of a vertical base range-finder, in which the two entrance windows, the separation between which is the base from which the measurements are made, may easily be recognised. The lower end is shown in *Fig.* 50, the handle on the right serving to effect coincidence, and the range scale being shown to the right of the eyepiece. The appearance of the field of view before

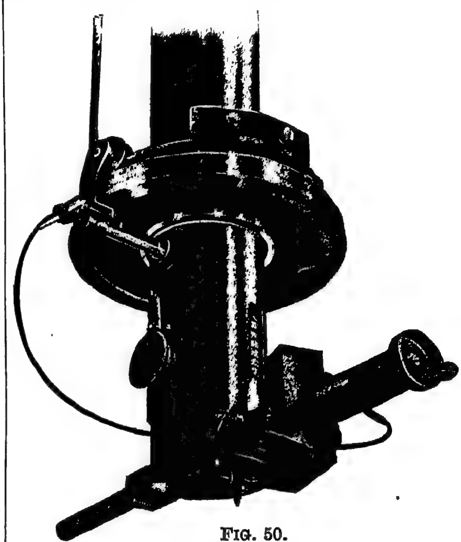

FIG. 50.

coincidence has been effected is shown in *Fig.* 51. The view seen through the lower window is brought to the central rectangular strip, and is surrounded by that from the upper window. An important advantage of the vertical base is that coincidence can be effected in spite of movements of the image due to the roll of the submarine, provided this is not so great as to cause the image to disappear entirely from the field of view.

The vertical base is not free from a number of objections, and to avoid these a horizontal base must be used. The difficulties caused by the rolling of the ship are overcome by special features in this range-finder which enable the image to be kept in the centre of the field of view. *Fig.* 52 shows the lower end of such a range-finder having a base of length 2·7 metres and a vertical length of 6 metres. This instrument is intended to be operated by two observers, and is fitted with a number of special devices for increasing the rapidity by which ranges can be transmitted. The magnification

is 20, and the accuracy under good conditions of seeing is 24 metres at 5000 metres, and 1

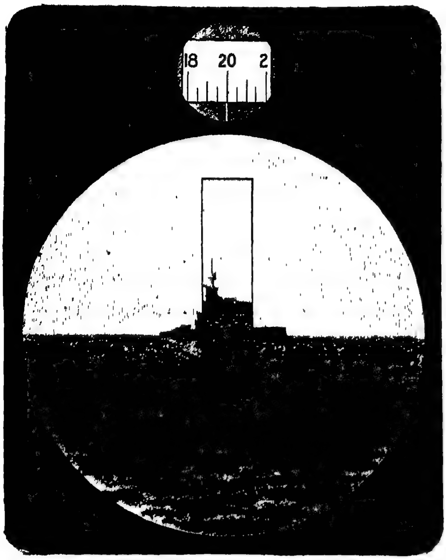

FIG. 51.

metre at 1000 metres. Of the two eyepieces seen, the right is that of the range-finder, that

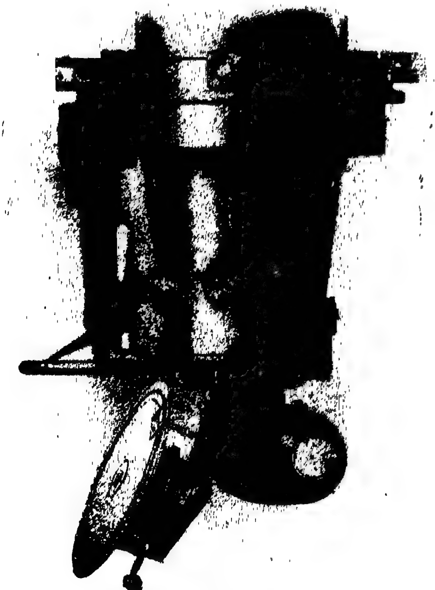

FIG. 52.

on the left being available when required for taking direct readings on the range scale. In addition there is on the other side a periscope eyepiece for a separate trainer. The main periscope tube thus contains two separate periscopic systems, one for the range-finder and one for the trainer periscope.

Fig. 53 illustrates another horizontal base instrument, and gives a general idea of the

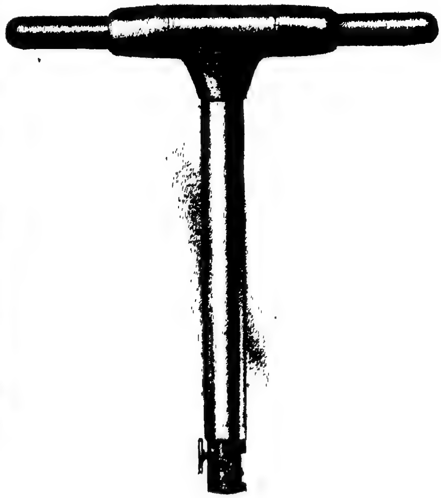

FIG. 53.

appearance of a complete instrument of the type. In this case the stereoscopic principle is employed, and the two eyepieces are clearly seen in the illustration.

PHONOGRAPH AND GRAMOPHONE, THE

§ (1) HISTORICAL.—The first mechanical reproduction of sound was effected by Edison in 1877. He wrapped a sheet of tinfoil round a cylinder and obtained a trace upon it of the movement of a diaphragm by a point which produced a scratch of varying depth as the cylinder was rotated. On allowing the point to travel a second time over the same groove the sound was reproduced, though, of course, very imperfectly. A horn was used in reproducing in order to intensify the

sound. In order that the tinfoil might be more easily indented by the recording point the cylinder had a groove under the foil where the trace was to be made. It was also mounted on a long screw so that the record was formed on a helix. Edison further suggested that the record might be made upon a flat disc and that both sides might be used.

In a later machine the recording style was short and was carried at the end of a spring, which was connected to the thin metallic membrane by two rubber buttons, which transmitted the vibrations of the membrane and at the same time damped the natural vibrations of the spring.

Edison himself dropped the phonograph as the result was so poor. It was Graham Bell, together with Chichester Bell and C. Tainter, who as the Volta Company went on with the idea. It was they who substituted solid wax for the tinfoil or waxed paper, and who cut away the wax with a sharp sapphire point instead of indenting it, and later used a chisel-end to produce a flat bottom to the groove. They, however, dissolved in 1885, and then Edison, going on from where they left off, made a successful machine and created the boom. The pitch of the screw was made much finer to increase the number of revolutions that could be made before reaching the end of the cylinder. Later the wax cylinders were made thin strengthened with ribs, the mandril on which they fitted was made taper, and they were driven by clockwork. Also the cylinders had no traversing movement, but the diaphragm was moved along by a screw as the cylinder rotated. The diaphragms were made of glass and had the stylus attached to them directly. Among other interesting devices, Edison, instead of black-leading the master wax cylinder, covered it with a film of gold by passing an electric current through a gold wire *in vacuo*, using this film to make the wax conducting.

The chief drawbacks of these instruments were the rapid deterioration of the records due to their soft material, and the amount of space required for their storage; moreover, the groove could only move the diaphragm in one direction—upwards—the reverse motion had to be produced by the spring of the diaphragm itself. Thus it had to press somewhat heavily upon the wax to enable it to follow the rapid vibrations of speech.

§ (2) THE PHONOGRAPH RECORDER.—These defects were largely overcome by making the record a transverse one, that is to say, one in which the groove, instead of varying in depth, is sinuous with approximately uniform width and depth; thus if a needle-point is placed in the groove, it will be moved to and fro sideways, the whole movement being imparted by the groove itself. The needle lies in a plane parallel to that of the diaphragm producing the sound—not perpendicular to it as in the phonograph; it is pivoted about its middle point, and while one end lies in the

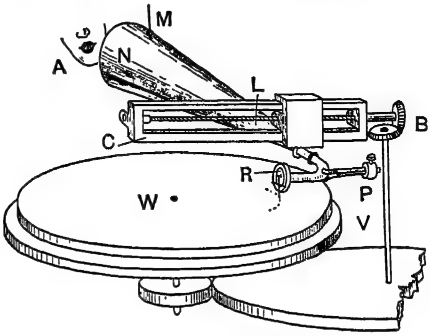

FIG. 1.—The Recorder.

groove the other is connected to the centre of the diaphragm (see *Fig.* 3).

When obtaining a record the singer (or instrument) faces the mouth of a large horn LN, *Fig.* 1, which is suspended by a string M at the mouth and is connected at the small end by a swivelling tube to the recording box R. This box is nearly counterpoised by a weight P. The box R with its connections is carried by an arm which can be traversed along a slide C by a screw S. The disc of wax upon which the record is to be taken is mounted on a turn-table V and rotated uniformly by a clockwork usually driven by a weight and connected through the bevel wheels B with the screw S. In this way the stylus cuts a spiral groove on the wax.

The stylus CD, *Fig.* 2, is brazed to the rod AB and strengthened by a rod EF. This little framework is pivoted at A and B, so as to rock about AB (which is parallel to the plane of the diaphragm) as axis. C is connected by a short wire to the centre of the diaphragm, which is of glass or mica, and to which it is cemented with wax; the end D is hardened and sharpened and cuts the trace on the wax disc. This disc is made of a mixture of waxes—ozokerite 2 parts and paraffin wax 1 part—or of a soap composed of stearic acid, caustic soda, and aluminium-hydrate mixed with ceresine or Japan wax; it must cut cleanly and not be too soft nor too brittle; it is warmed either as a whole in an oven or locally (by an electric current) while it is being cut. The wax disc is next black-leaded and an electrotype made from it. This electrotype (or a copy of it) is

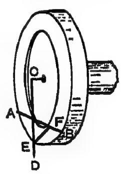

FIG. 2.

used to form the records. The records themselves are made of a composition of an inert powder and cotton fluff, with shellac or some similar material as a binder. The exact formulae used for the wax discs and the records are naturally kept secret by the manufacturers. After the composition for the records has been well mixed in the powdered form, it is rolled between hot rollers into sheets, cut into suitable-sized pieces, and pressed between the heated electros above described. The records so made are in the form of circular discs, usually either 10 or 12 inches in diameter, with a spiral trace having about four turns to the mm., commencing about 1 cm. from the edge and ending about 5 to 7 cm. from the centre.

§ (3) The Reproducer.—The reproducer or "speaker" is very similar in principle to the recorder. Instead of a sharp stylus, a rounded needlepoint slides in the groove on the record, with which it makes an angle of about 60°. This is hinged on a pair of V's against which it is held by two springs, so that it rotates through a very small angle about an axis, parallel to the plane of the diaphragm (*Fig.* 3); the other end is connected to the centre of the diaphragm by a small screw and a touch of wax. This diaphragm is usually of mica, it has a diameter of 4·5 to 6 cm., and is mounted between rubber rings called "gaskets" to prevent it from rattling, to damp its vibrations, and yet to allow it to move freely. Some diaphragms are made of glass, and it has been claimed that zirconium is a valuable ingredient in this glass. Others are of silk or other flexible material with a cork or card disc in the centre. The diaphragm forms the front of a short cylindrical box of magnalium or similar metal; the box has a metal tube in the face opposite to the diaphragm. This tube is inserted in the end of a pivoted conical tube called the "tone-arm," which terminates at its larger end in the beginning of the horn. The horn used to be a bell-shaped metal one, but it is now usually made of thin wood of rectangular section. It is found to give the best results if the passage from the sound-box to the horn has smooth bends everywhere. There is no mechanism required to cause the sound-box to follow the groove as in the phonograph, for if the tone-arm is freely suspended the groove itself is a sufficient guide. In order, however, that the needle may follow the groove easily it is obvious that it should always lie in a plane tangential to the groove. But as this latter is a spiral of varying diameter this can only be approximately achieved. Let P, Q, R be points on this spiral of which Q is on the middle ring, draw a tangent at Q, and with a point O on it as centre strike an arc of a circle, cutting the inner and outer rings of the spiral at P and R; it is obvious that OP and OR cannot be tangents at P and R. A better result is obtained by taking O on a line making about 14° with the tangent as at Q′ in *Fig.* 4. This circle will cut the spiral at points P′ and R′, at which tangents will make angles which are approximately the same with the lines OP′ and OR′; thus by setting the plane of the diaphragm at 14° with the line joining the centre of rotation of the tone-arm to the point of the needle, the latter will remain more nearly tangential to the groove throughout the reproduction.

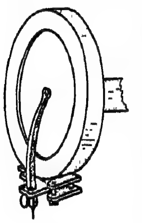

Fig. 3.

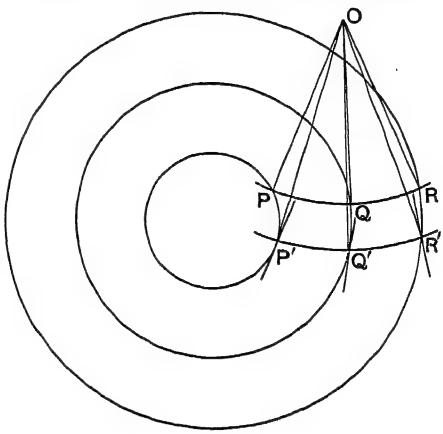

Fig. 4.

It is very important that the angular velocity of the cylinder, both in making the record and in reproducing it, shall be kept perfectly uniform, or the pitch will be affected. The linear velocity varies of course according to the diameter of the spiral, but as this variation of speed is the same in the reproduction as it was in the original recording, the resultant pitch is unaffected provided the angular velocity is constant. The linear velocity varies from about 120 cm. a second at the circumference to 40 cm. a second at the middle. By a recent invention the linear velocity is reduced to a uniform one of about 40 cm. a second—both in recording and reproducing the record—and thus the length of the record that can be made on a disc is greatly increased; the scratching noise is also said to be reduced by the diminution of the velocity.

Although the records are sufficiently good to afford a fair rendering of a musical composition or song, and so to give pleasure, they are far from perfect. The defects most commonly met with and the most difficult

to eliminate are (i.) a scratching noise, which is especially noticeable in the more delicate pieces; (ii.) an unpleasant and very obvious nasal tone, due no doubt to the horn; (iii.) a loss of many of the consonants in speech; (iv.) an inequality of rendering of the soloist and the accompaniment, due, of course, to the soloist being stationed immediately in front of the horn while the accompaniment is to one side.

In 1904 Parsons exhibited to the Royal Society a reproducer in which the needle, instead of being connected to a diaphragm, actuated a grid which covered a series of slots in a box, and thus opened and closed these slots. Compressed air was supplied to the box and issued from the slots into a horn when the slots were opened. Thus the record controlled the escape of air and produced in it variations which gave a powerful and yet good rendering of the record, comparatively free from scratch. From this has developed the Auxetophone and the Stentorphone.

The movement of the diaphragm of the recorder has also been used, generally with the aid of a mirror, to deflect a beam of light which was passing through an aperture on to a photographic film, and so to vary its intensity (Rankine increased the sensitiveness by projecting the image of one grid upon another grid); this photographic trace was afterwards used to control the light falling upon a selenium cell; the resultant varying current was passed through a telephone. A great number of attempts have been made to use some form of this method for the simultaneous recording of speech upon a cinematograph film, but so far without much success.

PHOTOGRAPHIC APPARATUS

§ (1) INTRODUCTORY.—The ordinary process for the production of a monochrome picture of any object by means of photography consists of two operations—firstly, the making of a "negative," and secondly, that of the corresponding "positive."

The negative is a record of the form of the object expressed, as all monochrome pictures are expressed, in terms of gradations of light and shade, consequent on the exposure of a sensitive surface, composed of particles of a silver halide, to an image of the object in the camera, the changes induced in the sensitive substance being afterwards completed by the chemical process termed development. The positive or print in its simplest form is made by exposing to the action of light a similar sensitive surface under the negative, when there results, after development, a picture, the light and shade of which corresponds—within the limitations of the process—to that of the original object.

The sensitive substance now most generally employed for the purpose of making photographic records in the camera is silver bromide or bromo-iodide emulsified in gelatine. This emulsion is coated upon glass or celluloid and dried, and the coated plates or films come into commerce as "photographic dry plates" or "films" as the case may be. It is proposed in this section to consider the instruments, other than lenses,[1] by means of which photographs are made, and, in the main, those which are used for the production of negatives.

A photographic camera in its simplest form is a light tight, rectangular box terminating in two flat ends which are parallel. In the centre of one end there is pierced a very small aperture, the pinhole, which is then covered by a simple shield that is readily removable. If there now be placed inside the box (under suitable "safe" illumination), at the end opposite the aperture, a sensitive plate, all that is necessary for the production of a photograph has been provided. If the box be placed upon a rigid support in front of a well-illuminated object, on uncovering the aperture an image will be formed upon the plate. If exposure to this image be made for a sufficient length of time—if the conditions are suitable

[1] See "Photographic Lenses."

the period will not be unduly long—the plate will yield upon development a negative image of the object.

It is assumed often that satisfactory photographs cannot be made by the use of a "pinhole" in place of a lens, but this is not correct, and well-constructed pinholes are sometimes used on modern cameras for subjects where brief exposures are not necessary. Provided that the aperture be properly made and its diameter in relation to the plate distance fulfils the requirements of the optical theory governing the formation of pinhole images, little objection can be taken, so far as "definition" of the image is concerned, to photographs of still life, architecture, and landscapes, when meant for pictorial purposes, more especially if the photographs are fairly large in size. The interest of the "pinhole" is, however, mainly theoretical, and in practical everyday photography of different kinds, lenses are used for the formation of images in the camera.

It would be foreign to the purpose of this section to discuss the apparatus specially designed for the purpose of employing light sensitive materials as recorders in investigations in different branches of science and technology, for the apparatus varies greatly according to the nature of the inquiry which is to be made, and is generally peculiar to the particular research. Much laboratory apparatus is of standard type and is applicable to wide fields of endeavour, as for example the camera in conjunction with the telescope, the spectroscope, and the microscope, and in these respects other sections[1] should be consulted.

In many instances photographic apparatus is employed to record the behaviour of photographic material itself, as when the spectrum camera is used to ascertain the distribution of spectral sensitiveness in a dry plate or other sensitive surface, or the camera shows the appearance under the microscope of the silver bromide grains in a gelatino-bromide emulsion, and thus provides a permanent picture of certain aspects of its physical state.

As well as being an aid to a large and increasing degree in a number of branches of scientific and technical research, it should not be overlooked that photography of itself is an important industry—either alone or in conjunction with other crafts—utilising some of the finest products of optical, chemical, and mechanical skill. With its growth there has come specialisation, and each branch has evolved forms of construction to meet its own needs. No one camera will meet conveniently all the requirements in the many activities of modern photography. In view of the specialisation ordained by these requirements, it seems desirable that the essentials for an ordinary camera in its simple form should be stated. Cameras are essentially chambers for the purpose of exposing sensitive plates to the action of luminous images formed by optical means. Disregarding for the moment the precise mechanical form of the construction, a camera of simple type as used in ordinary photography consists of a support for the lens (the "front"), used to form the image of the object; another support (the "back") for the movable receptacle (the dark slide), usually employed for holding the sensitive plate, and a device (the "bellows") for preventing any light reaching the plate other than that which forms the image, the distance between the "front" and the "back" being adjustable, while parallelism is maintained. To enable the image to be examined and adjustment made, a screen of ground glass ("focussing screen") is arranged in a movable frame in the back. To permit these adjustments to be made, certain devices for movements in the "back" (reversing frame and swing-backs) and in the "front" ("rising and falling" and sometimes sliding and cross-fronts) are provided. During exposure the sensitive plate in its receptacle occupies the position previously held by the screen and therefore receives a similar image. The camera is supported upon a stand, by means of which its position relative to the object is adjusted and maintained.

The most important items of photographic apparatus, excluding lenses[2] and correction and colour filters,[3] are

Cameras,
Finders, plate-holders, and changers,
Exposing shutters,
Stands,
Enlargers,

and in every division there are differences in type and a great variety of patterns following the types.

§ (2) Cameras.—Discarding arbitrary distinctions as far as possible, and for the purpose of description, cameras may be classified as follows:

Stand Cameras.
- Field or portable.
- Studio.
- Copying (including cameras specially designed for photo-mechanical photography).
- Kinematograph.

Hand Cameras.
- Plate or "cut film."
- Rollable film.

Aerial Cameras.

[1] See "Telescope," "Microscope, Optics of the."

[2] See "Photographic Lenses."
[3] See "Light Filters."

This differentiation should not be taken to mean that in no case can a camera designed specially for one purpose be used for another. In some cases there are limitations, but not necessarily exclusions. A field camera, for example, could be used in the portrait studio, but it would not be so suitable for many reasons as the studio type. Even though the design of the field camera were good it lacks "stiffness" (due mainly to reduced material) and, in consequence, would be strained by the constant stress of the lens suitable for portraiture in the studio, which, being of considerable focal length and large aperture, is relatively heavy to the lenses used normally on a camera of the field type. The swing-backs on the field camera would not be so convenient for rapid manipulation as those on a good studio camera, and the field camera lacks certain desirable accessories as, for example, the repeating back. The studio camera of high grade is a heavy rigid instrument of considerable bulk, necessitating a strong stand of a different pattern to the portable camera—and it cannot be folded for transport. It would in consequence be extremely inconvenient "in the field."

(i.) *Field or Portable Cameras.*—Two cameras of the original patterns of this class are shown in *Figs.* 1-4. *Figs.* 1-2 represent the "square bellows, heavy-form," and *Figs.* 3-4 the

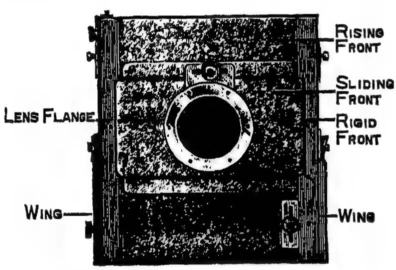

Fig. 1.

"conical bellows, light-form," instrument. The "heavy-form" camera of the best makers is still practically the same as when introduced,

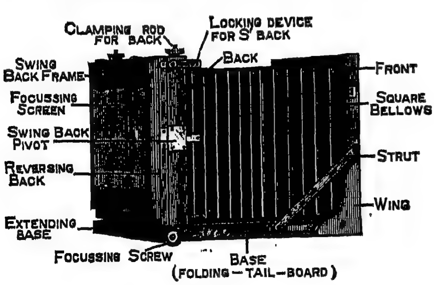

Fig. 2.

but the "light form" has undergone several modifications with the object of reducing weight and bulk. The cameras following these forms differ mainly with respect to their focussing arrangement, which is the governing factor. In the "heavy form" the back is movable and the front is fixed, the side of the

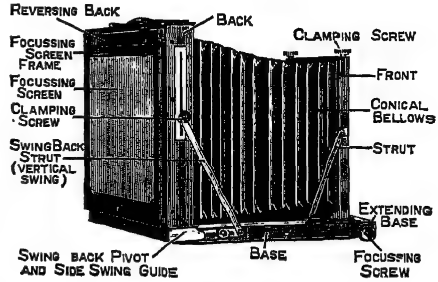

Fig. 3.

bellows being parallel, whilst in the "light form" the front is movable and the back stationary, the bellows taking the form of a

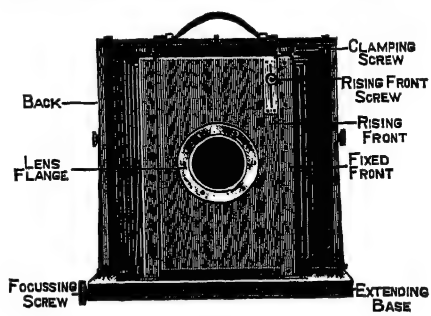

Fig. 4.

rectangular cone, and this construction permits greater compactness when the camera is folded.

The front and back of the camera should move to and fro parallel to each other, and this is provided for in the construction, the movement being generally effected by means of a rack and pinion. The "extension" should preferably be not less than twice the length of the diagonal of the largest size of plate that the camera is made to take. In many cameras greater extensions are possible, but the cameras used in that state under field conditions are never so rigid as when more closed, and in some "light-form" instruments are unreliable even before the limit of the extension is reached. The normal position for the lens is opposite to the centre of the plate; the prolongation of its axis should meet the plate centre and be perpendicular to its surface. In practice variations are necessary. To give the required movement in a vertical direction a panel (rising and falling front) fits into a groove in the fixed front, and to this the lens is attached, and by this device

movement up and down is readily effected. The rise should be greater than the fall. In the camera shown in *Fig.* 1, $8\frac{1}{2} \times 6\frac{1}{2}$, the rise is 2 in. and the fall 1 in., and in *Fig.* 4, 12×10, 3 in. and $1\frac{1}{2}$ in. respectively. To secure a lateral movement (sliding or cross-front) another panel is fitted to the vertical front, and to this the lens is attached. The rising and falling front is a necessary adjunct, but the sliding front is much less important and may be eliminated without serious inconvenience. Movements of the lens made by means of the cross-fronts are equivalent in effect to lateral movements of the plate in the opposite directions. To effect movements of the plate would mean an impracticable complication. The front in a "light-form" camera is usually brass strutted to secure rigidity, a quite necessary provision in the larger sizes. Where more than one lens is used the front should be pierced to take the flange of the larger, and the smaller is fitted when required by means of a brass adapting ring.

When the front of the camera is set back to permit the use of lenses of short focal distance the conical bellows tends to crowd to the back and so cut off image from the margins of the plate. This drawback is prevented by providing "tapes" on the sides of the bellows, by means of which external connection is made to the front, and the bellows are thus drawn forward. Photographic dry-plates are rectangular and are made to standard sizes, and with one exception (lantern slide plates, British $3\frac{1}{4} \times 3\frac{1}{4}$ in.) have dimensions longer on one of their sides than on the other. To meet this condition cameras are made with the backs square and are fitted with a removable frame carrying an inner (generally hinged) frame bearing a focussing screen equal in size to the largest size plate that the camera is made to take. The outer frame or reversing back being square and removable, it may be placed in the back with either dimension vertical or horizontal at will.

The receptacle (dark slide) for the sensitive plate replaces the focussing screen frame, which is turned out of the way and generally folds over the slide when in position.

Another movement of importance is the swing-back system, by means of which the plate can be tilted in a horizontal or a vertical direction. The swings in the camera shown in *Fig.* 3 take place from the hinges which attach the back to the base. In *Fig.* 2 the back is in two parts. The rear portion—to which the bellows is attached—draws out and swings from the centre on attachments to the fixed part. The vertical swing-back is used to correct distortion of perpendiculars due to camera tilt. Both swings are used, where necessary, as an aid in focussing.

Several changes have taken place in the early "light-form" camera. The solid baseboard has been reduced as much as practicable, the central portion being cut away, and in its place there is now fitted a light combined tripod head and turn-table. This eliminates the loose head which usually accompanies the tripod. The front is smaller and lighter and is arranged so that it can be swung. The rising panel remains, but the whole front (which carries the bellows) can be raised. This means that a greater rise can be obtained without interference by the bellows. A distinct improvement resulted from the addition of back-extension focussing. When the image is small in proportion to the object it is immaterial for all ordinary purposes whether the front or the back moves for focussing, but where the image is large, as when objects near to the lens are to be photographed, more particularly when the image is to be made to a predetermined size, front focussing is impracticable, and such cameras can only be used by a device which practically makes them back-focussing instruments. The duplex system is therefore a great advantage, and it moreover permits the use of lenses of short focal length to obtain pictures embracing wide angles.

The result of these changes has been to reduce considerably the weight and bulk of the camera, but it is proper to observe that such instruments are only reliable when their design is united with the best possible workmanship.

Cameras of the "heavy" type in modern use are exemplified by the "Premier" (Watson) and the "Square Bellows" (Ross), and of the "light" type by the "Acme"

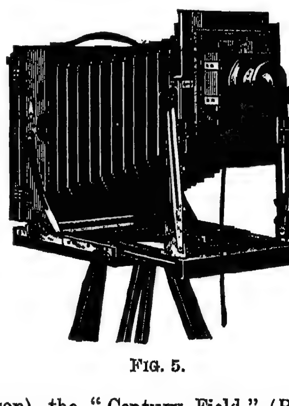

FIG. 5.

(Watson), the "Century Field" (Ross), and the "Sanderson," *Fig.* 5 (Houghton).

No departure of moment beyond those indicated has been made in portable-stand cameras during recent years, and it is probable that the patterns will persist. The high pitch of development reached

by the best forms of modern hand camera has caused these instruments to satisfy the requirements of some of the most exacting workers. The tendency since the introduction of the high-class anastigmat lens has been to make negatives of small size, and to enlarge the pictures when required, a tendency only accentuated as improvements in that instrument and in other directions take place. Consequently, it is not likely, in view of its convenience and excellence, that the small hand camera will be laid aside in favour of the instrument generally used in earlier days. In the more restricted fields of industrial photography, with its generally less adventurous task, as well as in many fields of technical work, the ordinary portable camera will continue to be used.

(ii.) *Studio Cameras.*—The cameras of standard form are heavily built, back focussing and non-folding. The instrument has long extension, fixed or movable front, which is provided with lens panel for slight rise and fall. In some of the better forms the front is movable by rack and pinion, so that front adjustment without moving the camera can be made, which is an advantage when copying. The lens is usually fitted to an inner "lens board," readily removable, behind which may be placed the exposing shutter, and this shutter being invisible enables exposing to be done without the knowledge of the sitter for a portrait. The arrangement of the back is different to that in a field camera. The size of camera selected for the portrait studio generally permits a fair range of sizes, say from 15/12, 12/10, or 10/8 down to ½-plate. In a particular studio a certain size will be more used than others, and will be generally smaller than the full size that the camera is intended to take. As it is the common practice in good portrait studios to take several pictures, and rapid manipulation is desirable, provision is made for this by means of an auxiliary holder ("repeating-back" type). The focussing screen for the full-size plate—usually a loose frame—is removed, and in its place is introduced a larger frame bearing a second focussing screen of the smaller size which slides between two parallel bars. The plate-holder ("dark slide"), containing space for two plates side by side, also fits these bars. The focussing screen is masked from the front by a wooden frame flush with the face of the repeating back (and changeable at will), so that the operator sees on the screen only an area corresponding to the plate that will be used. This plan is much more satisfactory than the ruled lines on the screen showing limits (which are sometimes used), and prevents confusion. When the image is focussed the screen is moved laterally (though it is sometimes hinged and is swung out of position) and the plate-holder takes its place, being "set" so that the first plate is in position. After exposure the plate-holder is moved along until the second plate is brought into position, and exposure is then made. The shutter or the plate-holder is fully drawn all the time, but no extraneous light reaches the plate, the repeating back acting as a shield. When the camera is one made to take large plates the repeater form of back may be employed, but this means considerable bulk. The repeating-back principle is frequently applied to cameras not intended for portraiture and is capable of considerable application. The plate-holders are made square (save small holders for repeaters) and plates are placed with the major dimension horizontal or vertical at will.

The back of the camera swings in both a horizontal and a vertical plane. These movements are important, being often required when focussing images of objects in relief near to the camera when lenses with large apertures are used, though their use in this respect is often abused. The support (stand) is frequently combined with the camera, which makes for convenience and rigidity. Provision is made for raising and lowering, by rack and pinion, and for tilting the camera out of the horizontal. Castors are provided to the feet of the stand for ease of movement. Otherwise, independent stands of similar construction are used. The combined apparatus is well shown in the "Improved Studio" (Ross), "Soho" (Marion), and "Combination Studio," *Fig.* 6 (Watson).

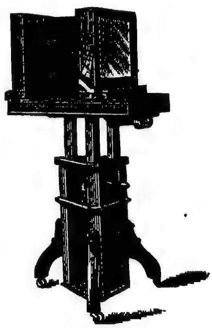

FIG. 6.

For special work, as in the portraiture of children, the reflex principle has been applied, as in the "Studio Minex" (Adams), and twin-lens cameras have also been used. These cameras have the advantage that the image can be viewed on a full-size screen, focussing effected, and exposure made at the precise moment when the appearance is judged to be satisfactory.

§ (3) COPYING CAMERAS.—The term "copying" is applied to that branch of work which deals with the photography of flat surfaces. For much copying the ordinary studio camera is quite satisfactory.

In pure photography the most important branch of copying is that of making transcripts of pictures of different kinds. For picture copying in galleries, museums, and private collections, the "heavy-form" portable camera, provided that the instrument is an efficient one of its kind and a suitable rigid

stand is employed, meets the requirements. Cameras of heavier construction and greater refinement, if combined with special stands, would confer certain technical advantages, but the inconvenience and cost of transport would mean serious objections. In some continental photographic houses where picture copying is a feature, apparatus of a special character is sometimes employed where the camera is the dark room. This camera-dark room (in which the operator works) and the picture-supporting easel are built on a platform mounted upon a "railway" turn-table, which permits the whole system to be rotated to allow for changes in the sun's position.

The greater part of copying work comes in the domain of photo-mechanical photography,[1] which is the branch of the craft producing reproductions or transcripts in various forms of different kinds of picture—using the term in a broad sense—by distinct methods differing from those of pure photography, which are finally associated with some form of the printing press (photogravure, photo-lithography, collotype, line and half-tone process block making in monochrome and colour and combinations thereof), and for this certain forms of copying camera have been devised. Great accuracy is required in the copying of maps and plans and of pictures for colour block making and photo-lithography, and for this work the modern camera has become to some extent an engineer's construction.

(i.) *Details of the Camera.*—A camera system for the purpose of "copying" should fulfil the essentials of parallelism between the "front" supporting the lens and the surface of the copy board bearing the subject to be copied (the "original"), and between the lens "front" and the focussing screen. If by proper construction these conditions are satisfied, the principal axis of the lens will be perpendicular to the surface of the plate and to the surface of the "original." If, however, negatives laterally reversed are to be made (which is necessary in many processes), the focussing screen must be at right angles to the copy board, and a right-angle reflecting prism, silvered on its hypotenuse, must be mounted in front of the lens, the reflecting surface being at an angle of 45° to the lens axis. In place of the prism, a plane mirror, silvered on its surface, is frequently used.

The camera and the copy board must be supported so that the centres of the focussing screen and the copy board, respectively, are in line with the lens axis. When this is done the image of an "original" which is placed on the centre of the copy board will fall in the centre of the focussing screen. If the camera be then rotated horizontally 90° (the prism being mounted in front of the lens) and the board be shifted laterally in a plane at right angles to the focussing screen to a sufficient extent, the image of the "original" will again be centred on the screen, but it will now be laterally reversed. Further, the camera and copy board must be so arranged in relation that, at desire, either of these conditions can be maintained, whatever be the distance between the lens and the "original," *i.e.* as the camera is moved to and fro by the operator for various sizes of image. By arrangements conforming to the conditions stated, "copying" can be done with accuracy and with the rapidity necessary to meet the economic and other conditions which obtain. A suitable method for large copying systems, say, for plates 36 × 24 in. and below, is to mount the camera and the copy board upon rigid stands, the feet of these being fitted with grooved wheels which engage on parallel metal rails laid on the floor of the studio, or a pair of rails may be laid at right angles to one of the walls of the studio to take the camera stand whilst the copy board is fixed upon the wall, provision being made for its movement laterally for centring when the camera is turned into the position (previously described) for making reversed negatives. In some studios where very large drawings have regularly to be copied a large area of the wall is prepared as a copy board, and there is then sufficient room to accommodate drawings when the camera is arranged for either "direct" or reversed negative making. Great care is necessary in the construction of boards to ensure flat surfaces which do not warp—a problem of difficulty, more especially when they are exposed to the heat of powerful arc lamps as in artificial light studios. The floor of the studio should be laid firmly upon a suitable foundation to avoid vibration. The camera stands and copy-board stands are made of wood (preferably teak) and metal, but the most recent practice is to use only metal. Cameras constructed for map and plan copying (which are suitable also for general copying) of large size are shown in *Fig.* 7, "Calcutta" pattern (Penrose), and the "Precision" pattern (Penrose). The stand in *Fig.* 7 is of wood and metal; in another pattern a metal stand is employed. Both were constructed for the Survey of India office and are in use in many similar establishments. In some studios when large negatives are made the "dark room" is the camera. The lens is mounted on a suitable panel fixed in the wall of the room. The "original" to be photographed is supported on a copy board fixed upon an easel which travels on rails on the floor outside the room, whilst the focussing screen (and eventually the sensitive plate)

[1] See "Photography and the Printing Press," *J. Roy. Scottish Soc. Arts*, "Keith" Lectures, Nos. 10, 11, xvii.; *Dict. App. Chem.*, Thorpe.

rests in a holder mounted upon a stand having a similar traverse on the floor of the dark room. The holder can be moved upon the

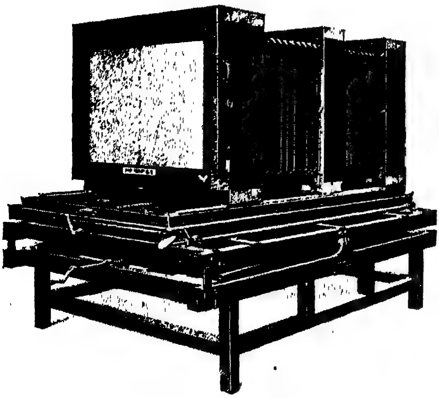

FIG. 7.

stand by means of a screw, and is itself fitted with adjusting screws for producing parallelism with the copy board. Setting for size of image is effected by moving the stand, the final focussing being made by the screw upon the stand which moves the plate holder.

A brief allusion has already been made (*q.v.*) to photo-mechanical printing processes and the difference between these and processes in pure or ordinary photography. For a more detailed explanation the reference given should be consulted. Maps, plans, and drawings in line (broken tone) of different kinds, drawings in colour, and oil paintings, nature photographs, where the light and shade is continuous (continuous tone), may all be copied in the same apparatus (the ordinary camera copying system as described), provided that the positive or print method for which the negative is to be used is confined to processes of pure photography [1] and to certain others in photo-mechanical photography, but not to all. Briefly, the visual effect of the continuous shading or continuous tone in a wash drawing or a nature photograph, for example, can only be produced by certain important methods by translating these shadings into "broken" tone. This translation may be, and generally is, effected by optical means by the application of the half-tone principle of Ives. The most important process where this principle is used is in the ordinary type-high half-tone process block which supplies the great majority of illustrations accompanying printed matter of various kinds. The translation of tone is produced in the copy negative, and is brought about by placing in front of the sensitive plate during exposure the so-called "ruled screen." The ordinary ruled screen consists of two rectangular plates of transparent colourless glass—cemented together in optical contact—bearing upon their inner surface alternate clear and opaque lines usually of equal width. The lines form angles of 45° with the sides of the plates, but in each one of the pair the orientation of the lines is the opposite of that in the other. In consequence, when the plates are in facial contact there is formed a series of uniformly distributed transparent spaces, rectangular, and of equal size.

The effect of the screen is to break up the continuous tones of the original into dots of various sizes, and in the completed printed picture the illusion of shading is produced by optical mixture.

The surface of the screen when in use must be parallel to the surface of the sensitive plate, the interval between the two being of small order. This interval is, however, not a constant amount whenever a "copy" negative is made, but is varied as required in harmony with other conditions, the screen distance being only one factor out of the total number to be considered. The screen plate must be held rigidly in a smooth-working traversing frame fixed on a support inside the camera, which frame can be caused to move to and fro at right angles to the lens axis and accurately set within the limits required. The traversing frame holding the screen is moved on its support for adjustment as to screen "distance" by lever and micrometer screw, the screw providing an adjustable limit to the position of the lever. This limit is the correct screen distance or "setting" as determined by examination of the image on the focussing screen, or by the particular system of working adopted by the operator, and this distance can be read off from the indicator scale provided. If the screen distance has once been set the lever can be moved to throw the screen back out of position, but on reversing the direction of the lever the screen can be brought back with exactitude to the original "setting," because the position of the micrometer screw provides the limit to its movement. A movement of this kind is necessary, because when the screen has been set by examination it is necessary to throw it back for the insertion of the plate holder (dark slide), and when the shutter of this slide is withdrawn to prepare for exposure of the plate the screen must be brought forward to the predetermined position in front of the sensitive plate, and thrown out of position when the slide is to be removed from the camera. If, on the other hand, the screen is "set" to a distance by any other system than visual examination of the image, it suffices to fix the micrometer screw to the required dis-

[1] See "Photography, Photo-Mechanical Processes," *Dict. App. Chem.*, Thorpe, 2nd ed. iv. 230.

tance by the indicator, and the screen is brought up to the required position when the shutter of the plate holder *in situ* in the camera has been withdrawn. When not in use the screen holder is thrown back "out of action," and if the camera is to be used for ordinary copying without the screen the latter is removed from its holder.

Cameras with this provision are termed "process" cameras. So far as the camera *qua* camera is concerned the presence of the screen gear is not a detriment to its use for other copying purposes, which gain indeed from the accuracy and rigidity and convenience in movements given to the instrument to fit it for its special purpose. During recent years very great advances have taken place in this branch of camera instruction, largely because it was recognised from the first that the problems to be solved were essentially those for the engineer. As far as practicable, wood as an element in the construction of cameras and plate holders has been replaced by metal. To obtain the necessary accuracy in cameras of this type and to maintain it, strength combined with good design and workmanship is required. In many studios, particularly those situated in hot and moist climates, the conditions are extremely trying to apparatus and personnel, and these factors are recognised. Modern constructions are made as far as practicable to meet the most difficult conditions, and the adoption of a standardised pattern designed to meet not the normal but the abnormal is economically sound from every point of view, when, as in this instance, it means, principally, good design and an intelligent choice of material.

In modern process cameras of the best class the back and front are separately mounted on iron base plates which travel upon steel runners, the distance apart of the two being adjusted by means of screws, and a screw and bevel gear is employed for adjusting the lens panel. These screws are all worked from the back of the camera by means of one removable handle. The focussing screen and lens board are detachable. The plate holder or dark slide is directly interchangeable with the focussing-screen frame. The plate holders contain adjusting bars for holding different sizes of sensitive plate. When, however, a large camera is not employed for the full or the larger sizes of plate for which it is constructed, an adapting frame ("Studio Cameras," *q.v.*) is fitted in place of the full-sized focussing screen. The adapter takes a smaller focussing screen and a corresponding plate holder. This practice considerably reduces the fatigue in manipulating large and heavy dark slides.

The camera stand and easel for the copy board are generally in one construction. The precise form varies, but essentially the arrangement consists of a pair of parallel rails framed up in a cradle, which is suspended by springs from a second and rigid construction resting upon the floor. The easel is fixed at one end of the sprung cradle and the camera is supported upon a travelling carriage, which is provided with a turn-table to enable the camera to be rotated into the correct position for reversed negative making. The camera in its carriage will travel to and fro easily (maintaining correct relation with the copy board), and the arrangement may be clamped firmly in any position. The copy board is of wood, articulated, to avoid as far as practicable the effect of warping, any shrinking occurring being taken up by means of the screws in its framing. It runs on the guides which form part of the easel, and the board is fitted with devices for securing parallelism with the focussing screen, and, since arc lamps are usually used in reproduction studios for illuminating originals to be photographed, it has been found convenient to attach adjustable supports for these lamps to the camera stand.

The best modern stands are wholly of metal, the only wood employed being in the copy board. The "springing" of the cradle bearing camera and copy board is for the purpose of avoiding transfer of vibration from floor to camera system, but even the best arrangements do not wholly avoid this trouble under certain circumstances, and great care is required, especially when the exposures are prolonged.

The "Empire" process camera, *Fig.* 8, and

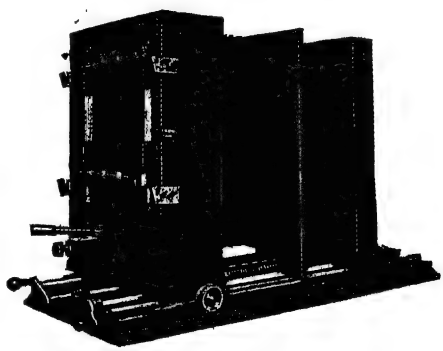

FIG. 8.

"Empire All Metal Stand" (Penrose) (not shown), and the "Arc Gear" process camera (Hunter), *Fig.* 9, are good modern examples of these constructions.

(ii.) *Automatic Focussing.*—For rapidity of work it is desirable that some form of automatic setting for the respective focal conjugates be employed in copying systems, and attention has been given during recent years

to the best means of using the principle. Given the focal length of the lens accurately, and the position of its nodes being known,

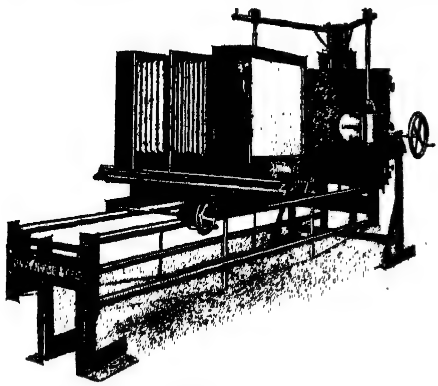

Fig. 9.

scales can be prepared and adjusted, so that by setting the respective index pointers, adjusting for size and sharp image, it would appear, could readily be done. In practice, however, the employment of this plan is not so simple. It is, however, practicable to use scale setting as a close approximation and finally focussing in the ordinary way. The scales for any apparatus are conveniently prepared by trial. Such a system can be made to effect a great saving of time. More satisfactory is a linkage system by means of which, on focussing, the image varies in size, but is always "sharp." This plan is adopted in certain forms of camera, but it entails considerable cost.

(iii.) *Reversing Devices.*—Reference has been made to the production of laterally reversed negatives which are necessary in certain photographic processes. In the wet collodion and collodion emulsion processes the negative may be made direct and reversed by stripping the film from the support, turning it over, and causing it to adhere to the glass, or by suitable procedure it may be converted into an unsupported flexible film, and the same plan has been largely adopted with the so-called stripping dry plates. Reversal, in practice, may be also effected by the use of certain celluloid films on which negatives are produced thin enough to be printed from either side. Another method especially convenient with dry plates when used in portable cameras employed away from the studio is to reverse the plate in the dark slide so that the glass side instead of film side is towards the lens, allowance being made when focussing. But the general practice is to use the optical devices referred to previously, viz. the right angle prism or the plane reflecting surface.

There have been at all times difficulties in obtaining as a regular supply, blocks of glass sufficiently free from internal strain and striae to make prisms of more than 3 in. face which could be used without detriment in conjunction with high-grade lenses, the production of blocks for larger sizes being often a matter of uncertainty and considerable time. Prisms have, however, been made of 5½, 6½, and even 8 in. faces. The mounting of the prism of moderate size is not difficult, with large sizes by no means easy. Prisms are mounted in triangular metal boxes with an external ring bearing a screw thread which engages into the lens mount, the face of prism and front combination being as close as practicable. The weight of the prism is borne by the lens mount, a system to which objection might be taken. To adjust accurately the face of the prism parallel to the copy board, probably the best way is to attach the lens to the front by means of a flange supplied with a rotating collar provided with a clamp (Zeiss). The same result can be brought about and the strain of the prism weight can be taken off the lens by means of an adjustable bracket, on which the prism mount rests, fixed to the lens board. In this way horizontal tilt of the prism can be entirely prevented, and there is no tendency to "sag."

Mirrors are plain glass or metal. The glass is surface silvered. The surface of the silver tarnishes and requires re-polishing, and being delicate is easily damaged. Metal mirrors are more durable if care be taken, but they suffer in acid atmospheres, and especially when the air is humid, but are costly, and those produced to the time of writing (1922) have not been perfectly satisfactory. Efforts are being made to employ chromium steel, and the results are promising. Platinised glass mirrors are at present the subject of experiment, but the difficulties connected with the vitrification have not been overcome. Mirrors are mounted in right-angled boxes of wood, of wood and metal, and of metal alone. Boxes of wood, which are largely used, are open to considerable objection. The best form of box is of metal with cast frame, and provided with adjusting screws to set the mirror with respect to the lens. The mirror is mounted behind the lens. This, although not absolutely essential, is necessary in practice. The mirror is in this way protected from extraneous light—a very important condition—and from the possibility of mechanical damage.

A serious objection to the prism arises from the absorption of photographically active light, which increases rapidly as the mass of the glass increases. This applies more especially when the process is "wet collodion" and the source of illumination is enclosed arc lamps, owing to the particular spectral sensitive-

ness of the silver salt. This cannot be avoided, but it may be minimised by a careful selection of the glass. Loss also occurs with metallic mirrors, especially when tarnished. With glass mirrors silvered on the surface the loss is appreciable even when the tarnish is very slight.

(iv.) *Colour Screens.* — Provision must be made for the support of colour screens, either the correction filter—" yellow " screen—employed in conjunction with orthochromatic or panchromatic dry plates, or for the selection filters [1] employed in the three-colour process, or any method where the colour luminosities of the subject are to be controlled.

In ordinary photography with portable cameras simple screen holders provided with caps may be attached to the lens, or the filter may be mounted behind the lens board by any convenient device, the necessities being freedom from stress on the filter and that it be supported with filter face at right angles to the lens axis. In the case of reproduction cameras where filters are made with optically worked glass " flats," great care is necessary, and it is now usual to employ a filter holder as part of the lens front, the carrier for the filter flat sliding behind the lens.

(v.) *Ruled Screen Carriers for Special Purposes.*—It frequently happens that a picture made by a half-tone (ruled screen) process is to be copied in the camera for the making of another printing surface by the same principle. Thus, for example, the only available picture of which a " half-tone " block is desired may be itself an impression from a " half-tone " block. A translation made in this way will always produce a " pattern," [2] which " pattern " may in certain conditions amount to a pronounced moiré. This phenomenon varies in appearance as the angle between the existing screen lines in the print, and those in the screen used when making the second negative, alters. The " pattern " can never be in practice eliminated, but the objectionable effect may be minimised to an extent that it becomes inoffensive by adjustment of the screen when making the copy negative.

Similarly, when the screen block process is employed for producing transcripts of pictures in colour, as in the three-colour block or other screen process methods, impressions from different surfaces in their respective colours are superimposed. Consequently, to avoid the moiré effect and produce a visually negligible pattern, the angles of crossing of the screen lines of the components must be adjusted. The most convenient plan is to employ a circular screen fitted in a rotating carrier mounted in the screen gear frame, when the suitable angular differences for the separate negatives can be made.

§ (4) Self-contained Camera Copying Systems.—Photography is widely employed to-day for the purpose of rapidly multiplying copies of letters, reports and documents of all kinds, printed matter, drawings, and matter of a like nature. Hand copying in many instances would be slow and expensive, and would entail always careful checking, whereas the photographic copy is in essentials free from error. To reduce operations to a minimum, and to enable the work to be done rapidly and without photographic skill, the apparatus—of which the " Photostat " (Alfred Herbert, Ltd.) is the most important example —is made complete in itself, and the operations of arranging the original, lighting, focussing to scale, exposure, development, and finishing are practically automatic. The copies are rapidly made upon sensitive coated paper which is in continuous roll form in the apparatus, negative pictures resulting. In the greater number of cases a negative copy answers the purpose, but if positives be necessary the negative is copied, when a positive of the original subject results.

§ (5) Plate Holders and Changers. (i.) *Holders.*—The plate holder or dark slide usually employed with portable field cameras is that known as the " double book form." This holds two plates back to back, separated by a diaphragm, and opens like a book. Movable shutters draw out to expose the plate when in the camera, which shutters fold back over the slide.

Solid (non-opening) slides for two plates are now largely in use, particularly for small sizes, and when well made are satisfactory, possessing many advantages—lessened weight and bulk, and greater protection of the plate from light and from the possibility of accidental exposure due to careless handling. The slides are filled from the front by withdrawing the exposing shutters, and, in this respect, with many forms especially, are not so convenient as the book-form slide. The shutters are made of hard rubber, ebonite, metal, or " compressed fibre," and draw right out of the slide for exposure, and in good makes care is taken to provide efficient light valves so that no harm occurs to the plates when this is done. The solid single and double slide is also made with flexible " roller blind " or " venetian blind " shutters (narrow strips of wood in close contact mounted on fabric). A prejudice has been shown towards these by some photographers, for which there is little or no justification, for they met the exacting conditions of aerial photography during the war when slides were used. For plates larger

[1] See " Light Filters."

[2] See Lees, S., " On the Superposing of two Cross-line Screens at Small Angles and the Patterns obtained thereby," *Mem. Manchester Lit. and Phil. Soc.*, 1918-19, lxiii.

than $8\frac{1}{2} \times 6\frac{1}{2}$ in., and for standing the wear and tear of everyday photography, the well-made double dark slides in sound mahogany would probably be preferred, because they are stronger and more reliable for "register." Good double slides for small plates are now made in metal, and small "single" metal slides are available, and both of these are particularly useful for hand camera work where it is desired to reduce bulk and weight in carrying cases. A refinement and a useful one in many slides is a safety catch or indicator to obviate double exposure on plates. For cameras used indoor, single slides of strong construction are usually employed, their greatest use being in copying and studio cameras. For copying cameras "roller blind" shutters are almost entirely used, and the same applies with modern studio apparatus save for small sizes. When a slide is to be employed for smaller plates than the maximum, inner frames or carriers are used, but "nested" carriers should be eschewed as they are liable to errors in register. In large slides, which are often built on a metal framework, carrier bars adjustable for different sizes are often employed. The essential requirements in a plate holder are absolute light tightness under the conditions in which it is used and accurate "register," which means that when the slide is in the camera the sensitive surface must be in the same plane as that previously occupied by the focussing screen when the image was focussed. The slide should be easily attached to the camera back, and the junction between the two must be sufficiently close to prevent the entry of extraneous light.

Cut sensitive coated celluloid films may be held in steel sheaths or carriers, which take the place of the plate, and adjustment for register must be made.

(ii.) *Changing Boxes.*—For holding a number of plates magazines termed "changing boxes" are often used with small hand cameras, but their use is not always so confined, for changers of different forms are largely used in aerial cameras, and some forms have proved satisfactory. One of the most reliable for use with the ordinary hand camera is the simple bag changer. In this the plates are held in a box in sheaths (preferably steel) and arranged one behind the other, the front plate being kept up to the "register" position. After exposure the plate is lifted up by a simple device and enters the bag at the top of the box, and is then grasped—through the bag—at the edges and placed at the back of the pile. The whole operation is quite simple, and where the boxes are well made the system is reliable.

In semi-automatic changing boxes the flexible bag is replaced by a drawer fitted with spring detents, and the action of transferring an exposed plate from front to back of the magazine is effected mechanically by simply pulling out the drawer (when the plate is projected into the lower part of the box by springs or falls by gravity) and then replacing it, when a fresh plate is ready for exposure. The device is fitted with a curtain shutter of wood or flexible shutter of metal, which protects the face of the front plate when the drawer is withdrawn, and a pull-out shutter or curtain which performs the same function as the shutter of an ordinary dark slide. An index is provided which shows a progressive number each time the drawer is pulled out, indicating the number of plates changed. It is necessary to note the number of exposures made in one form of box, as the changing action does not stop at the last plate of the series, but repeats; but in another form the last sheath of the series differs from those preceding and the drawer will not operate, thus indicating the completion of the series.

The ease and reliability of the changing boxes of this type, and indeed all changers, depend on good design and workmanship in the sheaths, and the boxes will not function when they are deformed, especially in mechanical changers. A well-known changing box as described is the "Ernemann" (Ica Co.), which operates by springs. This box may be used for small or medium-sized plates. Up to 5/4 the type works with twelve plates; above this size it is desirable to reduce the number, as the weight of the greater number is a bar to easy changing.

Changing boxes of the gravity type are well shown in the "Richard" (Jules Richard) and in the "Jacquet" (Tiranty). In this case the plates are small, the boxes are made with precision in metal, and the system is seen at its best. The experience of years shows that with reasonable care they are reliable.

All changing boxes require care in usage, and some operators are temperamentally unable to observe the necessary caution, hence the principal difficulties which arise in their use. As to whether or not they are desirable must be decided on considerations of general convenience.

§ (6) Panoram Cameras.—It frequently happens that photographs are required embracing a large angular "stretch" of country. Several negatives may be made by rotating the ordinary portable camera on the head of the stand, and prints from these negatives may be mounted edge to edge. Such pictures, however, will not join accurately. If, however, the camera be so mounted that the axis of rotation is vertically under the node of emission, this fault disappears, and cameras so mounted—which is quite simple—have been frequently used. Panoramic pictures may be made on film curved to the arc of a circle, the image being formed by means of a lens mounted at one end of a tube which has a narrow slit opening at the other end and coming close to the film. The tube swings through the arc of the circle about the

node of emission of the lens. The image is therefore stationary and in focus at all positions, and, provided the movement is sufficiently rapid, the camera can be held in the hand. This principle is utilised in the "Panoram Kodak" (Kodak), two models of which are available, giving angular pictures embracing 112 and 142 degrees respectively. A further development is the "Cirkut" camera (Century Camera Division, Kodak). In this type a mechanism unrolls flexible film past a slit opening, and by the same means the camera is caused to rotate on the head of the tripod stand. Negatives may in this way be made from 5 to 16 in. high, and for various lengths up to 16 ft., according to the camera and the length and width of the film used.

§ (7) Finders.—These are devices used for the purpose of indicating the amount of subject which would be included on the focussing screen of a given camera placed in the same position. In consequence, they may be employed in lieu of the focussing screen when the ordinary method of image adjustment by use of the screen is not practicable, and further they are required in the photography of moving objects. They are essential with all types of hand camera (save the Reflex, the focussing screen of which renders external agency unnecessary), with kinematograph and aerial cameras.

Finders are employed attached to the camera (or may form part of it), but finders may be used separately for preliminary observation, and are then, strictly speaking, to be regarded only as "view meters." The simplest device to use as a finder is the d.v. view meter, which is a small metal frame fitted with cross wires and a centralised rear sight, the sides of the frame having the same proportions as the camera plate, or is sometimes the actual size. The sight is placed at such a distance that view angle (plate) equals the field angle (subject), which distance may be determined by calculation or trial. The eye placed at the sight sees the subject through the metal frame, when correct pointing of the camera can be effected. In practice the eye is usually placed a little further away; this narrows the angle and gives a margin of safety, useful when moving objects are being photographed. In lieu of the wire frame there is sometimes employed a double or plano-convex lens with a mask showing the plate proportions, which requires a fixed sight correctly placed. In practice it is difficult to keep the eye fixed, and these finders are not reliable.

The instrument most frequently employed is the "brilliant finder," which consists generally of a little box with a small lens in the front, a mirror fixed at an angle to its axis, and a horizontally placed lens which acts as a magnifier to the image produced. The view is limited by a mask having the proportions of the plate, which mask is sometimes rotating. Other forms of "brilliant finders" have been introduced, but the one indicated, if well made and accurately adjusted, answers the purpose.

When the front of the camera is raised or lowered the ordinary finder as described is no longer reliable. To meet the new conditions the front supporting the image lens is made to raise and lower, and is in linkage with the rising and falling front of the camera, so that variation in the camera front automatically shows in the finder ("Identoscope"), whilst in other systems engraved scales are provided on finder and camera front, so that after arranging the view on the finder, which may mean raising or lowering its lens, the scale reading indicates the setting of the rising front to correspond ("Una") and ("N. & G.").

§ (8) Exposing Shutters. — These are mechanical contrivances for exposing the sensitive plate in the camera, generally, for brief durations. Several types are in use, of which the chief are (*a*) roller-blind, (*b*) focal plane, (*c*) between lens, and (*d*) flap. Both *a* and *b* are roller-blind shutters, but *a* works at the lens, whilst *b* is used in front of the plate. The roller-blind shutter is a flexible opaque blind, in which there is a rectangular opening travelling vertically across the front or the back of the lens, the movement being caused by a spring-actuated roller, the tension of the spring determining the speed of rotation, and in consequence the duration of the exposure. The efficiency is increased by increasing the length of the opening—which should never be less than twice the lens aperture—but this requires an increase in spring tension as compared with a shorter length to secure equal exposure duration, and high spring tensions are conducive to vibration. The blind opening must be wide enough to completely uncover the lens during exposure, and the framework of the shutter must not act as an obstruction, otherwise the margins of the plate will receive less illumination than the centre. When the lens is hooded the hood should be removed and fitted on the mount as close as possible to the front combination, otherwise an unduly large shutter is required. This shutter is shown in *Fig.* 10. The focal plane shutter consists of a moving blind in which is a rectangular adjustable opening—a "slit"—that is slightly greater in length than the longer dimension of the plate. The blind is actuated by spring roller, and when released travels across the plate. The duration of the exposure at any part of the sensitive surface depends upon the width of the slit opening and the rate at which the blind moves. The shutter is built into the

back of the camera, which must be enlarged for the purpose. The construction should permit the blind being as close as possible to

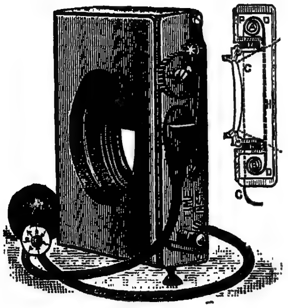

Fig. 10.

the plate, otherwise the efficiency is reduced. Two types are in use. In one the adjustment for exposure, so far as concerns one determinant, viz. the " slit," is effected by removing the blind from its channel and altering the width of opening by varying the length of the side cords or chains holding the parallel edges apart. The tension of the spring roller is then adjusted. With this form of the shutter (*Fig.* 11) care must be taken not to open the shutter of the dark slide before the blind is wound, otherwise if the lens be uncapped the plate will be accidentally exposed. To obviate this difficulty and to simplify setting, "self-capping" shutters are employed. In this form the slit in the blind is closed until the shutter is wound up so that the plate is protected from accidental exposure. The slit width is determined by an external setting device, the effect of which comes into operation when the blind is at the end of the wind. After exposure the slit automatically closes, and is ready for rewinding for a fresh exposure.

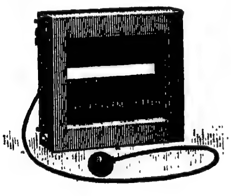

Fig. 11.

Focal plane shutters are necessary for very brief exposures. They suffer, however, from many defects — partly inherent, partly constructional. A serious defect is that the images are frequently distorted, due to the fact that the whole plate is not exposed at once but in sections, and although these defects are not always obtrusive they nevertheless exist.

The " between lens " shutter is generally a spring-worked sector diaphragm which opens from and closes to the centre, not interfering with the ordinary diaphragm for reducing aperture. The shutter mount replaces the ordinary mount of the lens. Such shutters are very convenient in use, but their efficiency is sometimes low, and their marked speeds are frequently not reliable.

Flap shutters are described by their name. They are used as a convenient substitute for the cap for exposures of appreciable duration. A flap—generally a light frame covered with velvet—is fitted in a mount which is fixed, generally, behind the lens. By means of a lever actuated pneumatically or by " antinous" release the flap is raised, uncovering the lens, and is lowered after the exposure by releasing the pressure. They are sometimes made with the flap in two parts to open in the centre, which is the better plan. Such shutters are generally only used in the studio. As well as " flap " shutters, a form of sector shutter actuated by pneumatic device is employed for this purpose and is to be preferred.

For the methods of testing shutters, and the considerations of their efficiency, see "Shutters, Testing of Photographic," Vol. IV.

§ (9) Stands.—The support for the camera is an essential part of the equipment, and its selection is generally an index of the user's judgment. Field or portable cameras are usually supported upon stands of the folding tripod type, although when employed as indoor instruments they are often mounted upon the rigid stand—the commonly termed " studio " stand—which will, as a rule, be found more convenient. The portable tripod is made of wood or metal, and ranges in form from the massive constructions with mechanically tilting and rotating heads used for cinematograph cameras to the simple rule joint folding tripod, which folds compactly and serves a less exacting purpose. Whilst wood is the more satisfactory material for the portable tripod for ordinary cameras, metal may be used, but really good stands would be more costly. Excellent tripods are made in steel tubing for cinematograph cameras. The most suitable wood is good well-seasoned ash, but other woods are employed—oak, cherry, maple. Rigidity is the essential point, and to this other requirements must reasonably conform. Tripod legs should be long enough to permit of their extension to form a wide base without reducing camera height below average eye level. For convenience the " legs " themselves are made folding and twofold with one adjustable element—usually termed " threefold "—are satisfactory if well made, the strength of the members of the stand being proportioned to the *size* and weight of the camera to be carried. The " head " should be for reliability approximate in width to the base of the camera, and the terminals of the legs

should be fixed to this as far apart as practicable. Heads are frequently provided with a tilting top, which is useful for architectural photography, and with universal heads to enable the camera to be levelled when the stand is in any position. Small ball-and-socket supports are, however, unreliable, except for tiny cameras. Whatever form is adopted, camera and stand should feel as if one, and the system should particularly resist torsional stress. For cameras used in the studio or indoors, permanent stands of the rigid tripod or two-pillar form, with tilting table and full range of rise and fall, are employed, the portable tripod being inconvenient and sometimes impracticable. For indoor work of a technical character a simple rigid tripod with rising pillar support, fixable by friction clamp, answers quite well, but for portrait work in the studio the requirements are greater.

§ (10) Enlargers.—Enlarging is a general term applied to the process of amplifying photographic images. Any camera system when the camera extension is sufficient to provide for the greater focal conjugate, will suffice in principle and is frequently used in practice. Actually, the enlarging equipment of many photographers is provided by using the ordinary camera in a darkened room, the instrument with the negative in place of the focussing screen (for a simple demonstration) being supported with its back before an aperture in an opaque screen fitted to the window frame. Outside the window is fixed a white diffusive reflector at an angle of 45°, which serves to illuminate the negative uniformly. Opposite to the lens is arranged a board covered with white paper upon a simple easel. By adjusting the respective distances of lens to negative and board to lens a sharp image enlarged to a particular amount will be formed, and eventually this image may be caused to fall upon a sheet of sensitive paper.

In *Fig.* 12 an arrangement on this principle is shown. A carrier for the negative is fitted

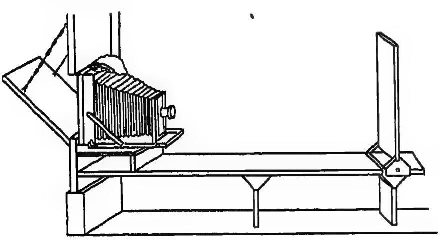

Fig. 12.

in the window frame, and the camera (with reversing frame removed) is arranged with its back close to the negative, extraneous light being excluded. The easel centred to the lens runs on a board as shown, and is so fitted as to be parallel with the negative at any distance. The apparatus is simple, inexpensive, and efficient.

Special apparatus is, however, designed for the production of enlargements, and its use involves fewer restrictions. Practical considerations generally require that the work be done by artificial light, at least in those countries where atmospheric conditions are inimical to uniformity, and, moreover, the necessity for providing for extended periods of work and at all times of the day and season require the use of sources of illumination additional to daylight.

The principle of the construction of the optical lantern underlies that of the artificial light enlarging apparatus, the elements being luminant, condenser, negative carrier, projecting lens, and screen, but in many instances an "extended source" of light is employed, in which cases the principle is simplified by the omission of the condenser.

A typical enlarging lantern comprises the "lamp-house" (containing the luminant), which is connected by bellows with the condenser body, beyond which is the negative carrier frame, and this, on the other side, is attached by a bellows to the front holding the projecting lens. The condenser is fixed, but the "lamp house" and lens front can be moved to and fro. The condenser and projector are mounted in line axially, and the luminant can be centred with these. Means are provided for raising and lowering the carrier, for its lateral movement, for swinging horizontally about a central axis, and for rotating it in a vertical plane.

The lantern as a whole may be conveniently mounted upon rails, upon which moves the screen easel, so that the two can be moved to and fro for adjustment of size of image, parallelism being maintained.

With respect to the luminant.

It is desirable that this, for optical reasons, be small in size, and to secure reasonably short "exposures" of the sensitive surface, intense. The small "enclosed" arc lamps, with right-angle carbon pencils, are convenient and efficient, but a "half watt" electric glow, with a suitable "concentrated" filament, or the tungsten arc ("Pointolite"), have many advantages and are more uniform in radiation. Acetylene, incandescent mantle (coal gas or spirit heated) are used with success. Vertical incandescent mantles often occasion difficulty owing to the large size of the illuminated area, and its frequent unevenness is a source of trouble. The inverted form is generally freer from these objections. It is often found that an image of the mantle appears on the screen. This may be avoided by placing between the condenser and source a piece of ground glass.

This then becomes the source, and rightly used should be provided with an adjustment to control the distance between itself and the light. From a purely optical point of view its use is to be deprecated. On the other hand, optical arrangements are frequently considered without taking account of purely photographic necessities. The image deposit in a negative is, as a rule, appreciably "grainy," and this causes "scattering" of the light, with the result that the gradations of tone in the enlargement are falsified as compared with those in the negative. Not only so, but flaws of a mechanical nature in the negative are often unduly apparent in the enlarged image, and the same applies to the marks of a spotting brush or retouching pencil. When the luminant is small these are, if not exaggerated, often unpleasantly visible; on the other hand, when the light is diffused, as when ground glass is employed, this objectionable appearance in the enlargement is not so manifest, so there is often a gain in departing from purely optical dictates. The ground glass is, however, something which upsets the action of the condenser when employed in the usual way, more particularly if placed on the side next to the negative (which is sometimes done), and this should be remembered.

When condenser systems are employed, it is necessary for even illumination of the negative that the diameter of the condenser be slightly greater than the diagonal of the negative, so that the whole area of the latter shall be included in the base of the cone of light. In practice this means placing the negative as close to the condenser as practicable. The focal length of the condenser should be suitable for the projector employed, or it may be found impossible even by adjusting the distance of the luminant to provide even screen illumination for every amplification desired.

If the negative is to be enlarged as a whole, and it be placed centrally, the raising, lowering, and lateral movements would not be required. But in practice it is frequently necessary to enlarge a portion only of a negative, and this not in the centre. It is desirable to place this area central to condenser and projector, and the movements named are wanted.

Tilting devices are for the purpose of correcting convergent distortion, which sometimes is produced in photographic negatives. For correct restitution similar arrangements must be provided to the screen receiving the enlarged image. Complete restitution of convergent distortion is a difficult and complicated matter, and the arrangements necessary are reasonably omitted from the ordinary enlarger, being required seldom and greatly increasing the cost.

The rising panel generally fitted to the front of the enlarger, by means of which the lens can be moved in a vertical plane, is not required, its use being wrong in principle, for the axis of the condenser and the axis of the lens should be one continuous line; moreover, it is quite unnecessary. The focussing adjustment for the front should be "fine," and it is a great advantage to have the means of focussing when the user is near to the screen. This is sometimes effected with enlargers having a central focussing screw (instead of rack and pinion at the side) by means of an extension rod fitted with Hooke's joint ("Ensign Premier," Houghton).

The projecting lens used is frequently that provided with the enlarger by the makers; equally it may be the one employed in making the negative, provided that the aperture be sufficient and the focal length suitable to the negative and the condenser—with daylight enlargers only the negative need be considered. The lens should be well corrected, and it is desirable that its principal focal length be not less than 1¼ times the diagonal of the negative to be enlarged. The aperture of the projecting lens permissible is largely governed by the size of the light source—with large sources, as an incandescent vertical mantle, a small angular aperture would mean inability to obtain an evenly illuminated screen. In practice it is desirable not to select a lens with an aperture less than F/6. There is no objection to the use of a lens having a greater focal length in relation to a particular negative than that specified, save on the ground of convenience. The increased distance required for large magnification may cause practical difficulties, and the ordinary condensers of commerce are not made for use with such objectives. In many respects increase of focal length would be advantageous.

With respect to screen or supporting sensitive paper, a plain board mounted upon an easel provided with the means for clamping on the rails so as to remain where placed is generally sufficient.

The board should be well framed to prevent warping, and may be covered with cork linoleum glued down, upon which a sheet of white paper has been pasted, or, better than the white paper, the linoleum can be painted with white "water" paint, renewed when dirty. There are, however, several special forms of easel which are convenient, and take various standard sizes of paper.

When a plain board easel is used a lens cap should be employed, glazed with a "safe" red glass or celluloid, and the paper is adjusted to the image as seen on the easel.

For making enlarged negatives a special easel, with carriers to take the plates, is very convenient, focussing being effected upon a

piece of ground glass used in the carrier. The enlarging lantern is frequently used for the purpose of making "reductions," *i.e.* pictures smaller than the original negative, as in lantern slide production. For this purpose it is well to have a special easel with a small focussing screen $3\frac{1}{4} \times 3\frac{1}{4}$ in., which swings out of plane when the image is focussed, when

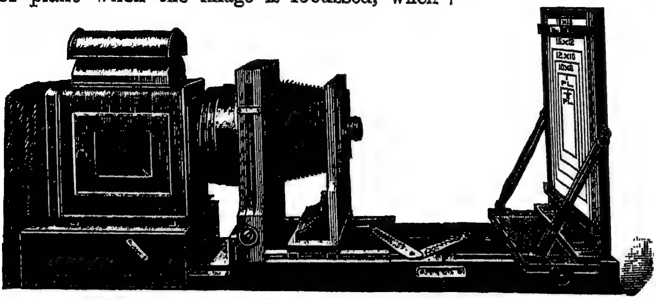

FIG. 13.

the sensitive plate contained in a similar holder takes its place.

Many efforts during recent years have been made to make camera systems, employed for copying and enlarging, "self-adjusting" or "self-focussing" or "automatic," either by setting to scales or, for the adjustment of the two focal conjugates, by means of cams and other devices. The apparatus is illustrated in *Fig.* 13 (Houghton Butcher). In this, focussing is effected by a device which in one movement adjusts lens to negative and screen to lens. To the lens panel is fixed a curved arm attached to one end of a right-angle cam, the other end of the cam terminating in a wheel that traverses a curved rail graduated to suit the focal length of the particular projector. The curved rail is fitted to an extension of the base of the easel, which is provided with a rack and pinion. As the easel is moved to and fro the wheel on the cam moves in the curved rail and adjusts the distance of the lens front. Focussing is, therefore, automatic, following the adjustment of the easel for the size of the image desired.

A further advance in this direction has been made by the introduction of the "Projection Printer" (Eastman), shown in *Fig.* 14. The apparatus consists of a camera supported above a screen upon which the image is projected. The camera unit consists of a "lamp-house" holding a 250 watt gas-filled metallic filament lamp, supported above the negative carrier, the sight area of the negative being regulated by means of adjustable masks. Below this there is arranged the projection lens, which is connected with the negative carrier by means of a bellows. The mechanism for "focussing" (using the term in its general sense) "consists of a cam and gear, the gear controlling the movement of the lens in relation to the negative, and the cam controlling the movement of the gear as the printer is raised or lowered to alter the size of the negative."

The swinging arms carry the camera unit, the balance being arranged that this portion of the apparatus moves up and down without difficulty, and as this is done the image varies in size, always remaining sharp. The paper is adjusted upon the screen below, and the margins are controlled by two right-angle masks. The light is controlled by foot-switch. To eliminate the defect in enlargements previously referred to, that of blemishes or marks in the negative being eliminated or reduced in the print, there is provided a series of optically worked glass diffusion discs which, placed over the lens, control the definition of the focussed image. This beautiful device is particularly valuable with portrait negatives which have been retouched, for with such

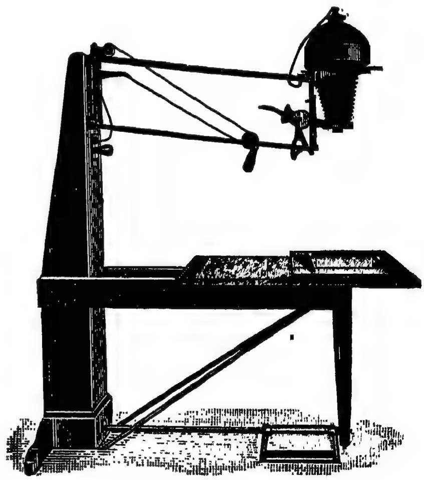

FIG. 14.

negatives there is always unpleasant prominence given in the enlarged print to the marks of the pencil in ordinary artificial light condenser enlarging systems. The apparatus takes negatives up to 7×5 in., and the range of amplitude from this size is from 10×8 to 56×40 in. There is a smaller size taking 5×4 negatives.

If the light source be much enlarged, so that it is greater than the negative, the condenser may be eliminated. This is the "extended source" system, and is now employed in many establishments very satisfactorily for the making of enlarged prints, particularly from big negatives. Enlarging apparatus constructed on this system use a brilliantly and uniformly illuminated area behind the negative, the light being either "transmitted" or "reflected." The initial source is generally a series of fairly closely placed straight mercury vapour tubes, or, for compactness, a specially constructed M-shaped tube. The light from this relatively large source is further diffused by sheets of suitably disposed ground glass. The system is shown in principle in the simple daylight enlarger shown in *Fig.* 12, the illuminated vertically arranged ground-glass screen taking the place of the opaque white diffusive reflector shown. In practice an indoor enlarging room is constructed with suitable movements for adjusting the lens to the negative and easel to lens. If an opaque screen be employed instead of the translucent arrangement it is generally illuminated from the front by carbon arc lamps or, for small equipments, by a series of gas-filled half-watt lamps, the negative being shielded from the direct light of the source employed.

There are many advantages, technical and economic, with an apparatus of this character. The light source requires no alteration for different degrees of enlargement—a matter of moment in industrial production—whilst with a condenser system adjustment must be made whenever there be a change of amplification. Enlargements made on this principle are far better as regards *photographic* quality, because the system of illumination by an extended diffused source is more suitable to the physical condition of the image in the negative, and, moreover, the enlargers are able to deal with large negatives which would be impracticable by means of condenser systems.

Extended source illumination enlargers—non-condenser systems—are becoming largely used in the form of vertical enlargers. Here the apparatus is fixed to the wall and occupies small space.[1]

Enlargements of small amplification, small box "fixed-focus" enlargers, are employed generally for daylight, and by these an enlarged print may be obtained by the simple operation of placing a negative at one end and a piece of sensitive paper—generally held in a dark slide—at the other, and exposing by turning the negative end towards the sky, or towards a white screen illuminated by daylight or on occasion by artificial light. More convenient enlarging boxes are made to work in conjunction with particular patterns of hand cameras for which they are designed.

§ (11) Hand Cameras.—The hand-held camera implies "exposures" of brief duration, and these have been rendered possible by the speed of the modern sensitive surfaces, and the production of satisfactory images by means of lenses of large angular aperture, with the subsequent elimination of the tripod and all that its use implies. Convenience dictates the employment of apparatus compact and easy to carry, simple in operation and quickly made ready for use. The employment of small plates from which enlargements could subsequently be made has reduced the necessity for large direct work, and the use of rollable film has caused photography to appeal to an ever-widening circle.

It is difficult, unfortunately, to find any form of classification for hand cameras which shall be really helpful and have, at the same time, the advantage of a logical justification, for hand cameras are the most individualistic things amongst photographic apparatus. The term "hand" camera is not in itself a distinction, and certainly not an exclusion, for any hand camera can be used as a stand camera if the operator so desires. The most distinctive introductions, so far as concerns type, have probably been the "Eclipse," which was the parent of one important class of folding camera in use to-day, the "Reflex," and in respect to far-reaching effect, the folding "Kodak," which embodied the idea of rollable film-holder and camera in one.

Modern hand cameras are, essentially, small picture cameras, the sizes ranging from $2\frac{5}{16} \times 1\frac{3}{4}$ to 5×4 in., and occasionally $6\frac{1}{2} \times 4\frac{3}{4}$ in. or "half-plate." They are used for plates or cut films, or both, but when the film is rollable the camera is generally made for this purpose.

A consideration or general application is the method of focussing. Disregarding the reflex (and the now seldom used "twin-lens" type) camera the actual image to which the plate will be exposed is not seen prior to exposure. The amount of subject included and the position of any portion therein, say the principal object, is observed by means of an external instrument—a "finder" (*q.v.*). The focussing may be done by judging the distance of the object and then setting the lens for that distance by means of a scale provided. The minimum distance of lens to plate will be when the lens is set for an object at "infinity," but in practice this position on the scale is of little value save as a datum line, for the best definition is seldom required for objects at a considerable distance. If the camera be of the

[1] For special apparatus see "The Printol" (Brown), *British Journal of Photography*, April 23, 1920, p. 257. For simple form of this convenient type see d'Arcy Power, H., *British Journal of Photography*, 1909, p. 475, and 1916, p. 328; and *British Journal of Photography Almanac*, 1910, p. 583.

"fixed focus" type the setting of the lens should be for an object at the hyperfocal distance of that lens when used at its maximum aperture. This plan secures sharp definition, for the greatest depth of field and objects exceeding a certain minimum distance are as well defined as possible *with that particular lens.* When the lens is set this way the depth of field may be taken, practically, from about half the hyperfocal distance onward to "infinity." The minimum distance becomes less if the aperture be reduced and therefore the depth of the field increases.

The "fixed-focus" cameras are advisedly only used for small plates when lenses of relatively short focal length may be employed. If, as is generally the case, the angular apertures are small the hyperfocal distance is near to the camera. When, therefore, the lens is set for an object at the hyperfocal distance, the "near point" being half this distance and the "far point" being "infinity," the depth of field is well extended. In consequence, by conforming to certain conditions such apparatus has considerable usefulness. By the employment of supplementary lenses readily attached to the camera lens, objects quite near may be brought into sharp focus. It should be remembered that hyperfocal distances are "extra focal."

In the majority of instances, when the camera has a focussing arrangement it involves the movement of the lens, either the front as a whole moves or the lens may be moved by a "focussing flange," the front remaining fixed. For accurate and easy working efficient scaling is necessary, more particularly as the negatives are frequently used for enlarging. It is desirable that a scale in *yards* be provided for the particular lens, so that when the index on the moving portion be set to any distance-mark on the scale the operator may know that an object at that distance will be "sharp" upon the plate. Focussing thus becomes a matter of judgment. But the production of the maximum sharpness for an object in one plane is only a particular case, although one frequently important in practice. More generally the operator desires to know the setting which will yield the best general definition for a series of objects situated within a certain range of distance from the camera, and for this "depth of field" scales are necessary. This form of scale can serve to some extent for both purposes, but since the numbers are not in simple sequence it is better to have in addition a separate scale in yards suitably graduated for what may be defined as "object focussing," for such work often entails rapid decisions, and any complication militates against quick conclusions. The two scales are now provided with some of the best types of camera, and can always be added to any focussing camera when desired.

In a reflex camera focussing is performed in the usual way. The image formed by the lens undergoes a directional change by means of a mirror, and is received upon a focussing screen at right angles to the plate. When the camera is held in the ordinary way the focussing screen is horizontal, and being suitably shrouded from extraneous light the operator looking down on the screen sees the image formed by the lens. The camera is therefore its own finder, and by actuating the focussing screen the image may be focussed as desired. The shutter release as a first action lifts the mirror out of place, and when the plate or lens is uncovered the image observed on the screen falls on the plate.

Practical considerations dictate compactness in bulk, and folding cameras are the most generally used. When the cameras are small the term "pocket" is used, but the size is the only criterion for this distinction.

A most useful form is when the camera opens concertina fashion, and the front and back are held apart by means of metal struts, or by side wings as in the parent form the "Eclipse." The front, when the camera is extended, is at such a distance that the plate is practically at the "infinity focus" or principal focal distance of the lens; any further extension required for focussing near objects is obtained by altering the distance of lens to plate by means of the "focussing flange" in which the lens is mounted. The exposing shutters are either focal plane or "between lens." This form is probably the best for rapid manipulation.

A type of hand camera follows the general style of the "light-form" portable field camera (*q.v.*), where the base board falls, and the front—to which the bellows are attached—draws out on the base, and focussing is effected by moving the front to and fro. Consider the focussing screen (where present) protected, and that the whole of the movements are enclosed when the camera is folded, and there results one of the most important forms of hand camera. Such instruments are provided with focussing adjustments, rising, falling and swing fronts, reversing back, focussing scales and finder. The exposure device is either a focal plane or "between-lens" shutter. These cameras are employed for plates, held in dark slides, or for cut films. Examples are shown in the "Una" (Sinclair), "Vesta" (Adams), "Sibyl" (Newman Guardia), and "Sanderson" (Houghton Butcher).

The typical camera for roll film is the folding kodak (Kodak, Ltd.). This apparatus, when closed, is self-contained, the sensitive material being held in a spool in the camera. The "base" on release falls and locks in a

horizontal position, and the front draws out, sliding upon parallel guides in the base, focussing being effected by means of rack and pinion. The essential movements are provided as in any other camera, but additions and refinements are provided in the many forms available. A distinctive feature of the kodak type is the employment of the "daylight-loading" spool of film, by means of which the camera can be replenished even under open-air conditions, a convenience which has had a most important bearing upon the diffusion of the practice of photography. The sensitive film is changed after each exposure by a winding key, and an indicator is provided showing when the change has been completed. The exposure is made by means of a "between-lens" shutter. In the "Kodak" camera known as "Autographic" there is provided the means to inscribe the title of each exposure upon the film before changing, and the developed pictures bear their own record.

The distinctive principle of the "Reflex" camera has already been described. This camera is advisedly the best for the more studied work of those advanced photographers with whom careful pictorial composition is the rule. Although good composition is determined by a visual study of the subject itself, it is undoubtedly an advantage to be able to see the image upon a screen, the same size as the plate, before exposure. Inasmuch as the essential requirements of a good camera remain constant, there is only the special addition to be considered. The ordinary reflex employs a focal plane shutter, it being necessary to protect the plate "held in waiting" from exposure until the mirror is lifted out of the way, the perfect closing of the top of the camera so as to prevent extraneous light from entering through the finder screen being essential. The drawback in many respects to the focal plane shutter is that it is not entirely satisfactory for the relatively slow exposures required in much reflex camera work, especially that of the pictorial kind. This drawback has been overcome in the "N.S. Reflex," where the focal plane blind has been eliminated and a "between-lens" shutter substituted. A supplementary flap protecting the plate follows the mirror when the release is pressed; this flap, however, only comes into action when the lens shutter, open for the focussing, has returned to the closed condition. By this device the plate—uncovered ready for exposure—is protected until the lens is covered, and the mirror having risen excludes any light which otherwise would enter the camera through the ground-glass finder screen. At this stage the exposure takes place. A most important necessity in the reflex camera is the perfect functioning of the release system which controls the sequence between the raising of the mirror and the exposure.

As an example of the reflex camera the "Soho" (Marion) may be cited.

The reflex camera is of necessity somewhat bulky and relatively heavy, but with the tendency to employ small sizes this drawback to the use of a beautiful instrument is mitigated. To overcome the bulk difficulty folding reflex cameras have been made, but it may be observed that the folding principle does not receive its best exemplification in the reflex camera.

As well as monocular cameras the stereoscopic principle is applied to hand cameras, and in these to-day it finds its principal use.

§ (12) Aerial Cameras.—The aerial camera, leaving aside the forms employed in survey during the last 60-70 years, owes its development to recent military necessities. As originally designed for the purpose of reconnaissance, the aerial camera was, essentially, a simple fixed focus box camera of wood or metal provided with a lens of large angular aperture, a focal plane shutter, and a simple finder, the plate being placed at the principal focal distance of the lens. The plate receptacle used was either a changing box or some form of single or double plate holder. The camera was hand held. The principal focal distance of the lenses employed was 8·25-10 in.

To avoid the many difficulties inherent in hand-held cameras, the apparatus was afterwards fixed externally to the side of the fuselage of the machine, or internally. Eventually the camera was fitted with a simple changing device. The plates held in steel sheaths were contained in a magazine, and were received after exposure in a receptacle of the same kind. The apparatus was operated by hand, the plate being changed and the exposing shutter set by one operation, exposure following at will by actuating the shutter release, and the cycle was repeated for the next plate. Subsequent developments led to a much improved changer system and to the building of the camera wholly of metal. The camera was also separable into two portions, the upper part or body forming the changer system with the shutter, and the lower—the cone—holding the lens. By the use of cones of different lengths it was possible to utilise lenses ranging from 4½ in. to 20 in. focal distance. The shutter was made detachable and of the self-capping type, with external adjustments for slit width. In this apparatus changing the plate and setting the shutter is performed by mechanism operated by hand or by motive power derived from a small independent propeller on the exterior of the aeroplane, driven by the current of air as the machine travels through space. The camera

can be used intermittently for single photographs or continuously for a series, determinable at will, so long as plates remain in the magazine. The camera mechanism can be put in or out of action when at a distance from the observer by means of a Bowden wire. To avoid the effects of vibration the apparatus is fitted on a special cushioning device. The negatives made in small cameras (5/4 in., 9×12 cm. and 13×18 cm.) may be enlarged, but, in lieu, negatives of greater size may be made in cameras of similar form to those indicated, using dark slides or magazine changers hand operated, or in automatically worked apparatus, all of which methods having yielded good results even under the relatively trying conditions of aerial flight. To avoid the use of plates, roll film cameras of different types, automatically driven, have been used. Attention has been paid in every country interested in aerial photography to the design of these cameras, and it is probable that in these the main line of development will be made in the future. One of the principal difficulties with film cameras is the want of planarity of the film. In one form of apparatus it has been sought to overcome this trouble by pressing the film against a plate of glass, and in other instances suction devices have been employed to maintain the film flat in the focal plane, and this plan offers probably the fewest drawbacks.

PHOTOGRAPHIC LENSES

§ (1) INTRODUCTORY.—The lens in photography is employed to concentrate a large amount of light of certain wave-lengths in the form of an image of external objects on a thin layer of sensitive matter which is otherwise shielded from all light. Convenience requires the sensitive layer to be in the form of a plane, and the exceptions to this rule may for the purposes of the present article be neglected. According to elementary theory a lens produces, for light of any given wave-length, collinear images of all points, and consequently the image of a plane is itself a plane. According to this theory any lens, if achromatic, will tend to give a plane image of say a picture, and this image will be an exact copy of the original picture if the axis of the lens meets the plane of the picture at right angles. By choosing a position for the lens at a suitable distance from the picture the image may be made as large or as small as is desired, and thus any lens which transmits a cone of rays wide enough to include all parts of the picture will be suitable for the reproduction of the picture to any size required. This conclusion has to be modified when aberrations are taken into account, but, except with lenses of very large aperture, it is sufficiently correct for most photographic work provided the lens is of good design.

The case of the plane object, which is almost invariably the only one considered in textbooks, is not the most frequent one in actual photographic work. The typical problem is the reproduction of a scene out of doors where objects at very varied distances from the lens are included within the angle of view. Some of these it is desired to have recorded in sharp focus on the sensitive layer though they may be at different distances from the lens, and again it may be desired that other objects shall, as far as possible, not be evident in the reproduction on the sensitive surface. Moreover, some of the objects may be in motion, and the time during which the surface may be exposed to light has therefore to be made small. Hence the aperture of the lens is required to be large in order to transmit sufficient light in small intervals of time. In many cases the image is required to cover a large solid angle also. All these considerations introduce special difficulties, some tending in their influence on the design of the lens in one direction, others in an exactly opposite direction. It will readily be appreciated that under the circumstances considerable diversity is called for in the design of lenses, and that even so each one represents a compromise between conflicting requirements, the aim of the maker being to balance the desirable qualities in such proportions that each lens he manufactures will be found sufficiently satisfactory by a large class of users.

§ (2) CENTRAL ILLUMINATION. (i.) *The Stop.*—However small they may appear to be, all the objects suitable for terrestrial photography must be regarded as of finite size, and it follows that in considering the illumination at any part of the image the finiteness of the size of the image must be taken into account. Suppose that the centre of the field of view is occupied by a small plane object of

area S placed normal to the lens axis. If the distance between the object and the lens is d and the area of the stop is A, the total amount of light from the source which passes through the lens will be represented with sufficient accuracy for our purposes by

$$\frac{\mathrm{ISA}}{d^2},$$

where I is proportional to the light given out by unit area of the object. If the lens is properly designed, all this light, with the exception of a proportion which is unavoidably reflected or scattered when the light is refracted at the surfaces of the lens, will reach the sensitised surface. If the area of this image is S′, the illumination on unit area of this surface will be

$$\frac{\mathrm{ISA}}{\mathrm{S}'d^2}. \quad . \quad . \quad . \quad . \quad (1)$$

If the stop is so placed that its images are in the unit planes, that is to say, if the stop image appears of the same size when examined from the front of the lens as when seen from the back, and d' be the distance between the second unit plane and the image of the object, then, since the magnification m is measured by the ratio of the distance of the image to the distance of the object, we have

$$\frac{d'^2}{d^2}=m^2=\frac{\mathrm{S}'}{\mathrm{S}}.$$

It follows that the brightness of the image is proportional to

$$\frac{\mathrm{IA}}{d'^2},$$

or

$$\frac{\pi\mathrm{I}}{4}\left(\frac{a}{d'}\right)^2, \quad . \quad . \quad . \quad (2)$$

where a is the diameter of the stop when this is circular. When the object is fairly distant d' differs by a negligible quantity from f the focal length of the lens, and the exposure required to produce a satisfactory impression on the sensitive surface is therefore proportional to $(f/a)^2$. The sizes of stops are most generally denoted by numbers which indicate the values of f/a, and it is customary to designate the rapidity of lenses by quoting the smallest value of this fraction for which the lens can be used. Thus a lens may be described as having the rapidity $f/4$, meaning that the diameter of the largest stop it is possible to use is equal to one-quarter of the focal length. Such a lens would only require an exposure of one-quarter the time necessary with one in which the largest stop is $f/8$, or one-eighth of that wanted when a stop as small as $f/11$ is required.

(ii.) *The Effect of Distance.*—When the object considered is not very far away the image is removed to a greater distance from the lens, so that d' increases; the image falls off in brightness though the object remains equally bright. This is partly the reason why in a photograph of a scene in which both near and distant objects are included the former appear unnaturally dark. In copying a plane picture on any given scale the increase in the time of exposure required is independent of the focal length, since under these conditions the ratio S : S′ is given and d and d' are proportional to the focal length. In the case of natural objects the result, however, is dependent on the focal length, and our standard of comparison is provided by the effects we see with our eyes, instruments having a very short focal length. By a very well known optical formula the linear magnification for an object distant d from a lens of focal length f is

$$\frac{f}{(f-d)},$$

and therefore (1) becomes

$$\frac{\pi\mathrm{I}}{4}\left(\frac{a}{f}\right)^2\left(1-\frac{f}{d}\right)^2, \quad . \quad . \quad . \quad (3)$$

and the illumination falls off the more rapidly the greater the value of f. Taking 15 mm. (0·6 in.) as the focal length of the eye, the variations in light intensity due to proximity will be at least 5 times as great with a lens of 75 mm. (3 in.) focal length as with the eye, and at least 20 times as great with a lens of 20 cm. (12 in.) focal length. This characteristic indicates that under certain circumstances there may be a considerable gain in employing a lens of short focal length and enlarging the resulting picture rather than in taking a view directly of the size ultimately required.

(iii.) *Scattered Light.*—It has been mentioned already that a certain amount of light is inevitably scattered at each refraction. The amount so lost is far more detrimental to the production of brilliant images than the subtraction of the corresponding amount of light from the incident beam would indicate, for some of the scattered light from intensely illuminated objects will fall upon parts of the image corresponding to dark objects, with the result that a flattening in the tones of the image takes place. It is important to avoid this as much as possible, and it follows that lenses which have a small number of glass to air surfaces tend to produce brighter pictures, as the amount of light scattered is almost entirely due to refraction to or from air, that dispersed at surfaces where two glasses are cemented together being in comparison negligible.

It should not, however, be supposed that the presence of a number of such glass to air surfaces is the chief cause of flat photographs. Far more serious sources of trouble in many cases are due to carelessness in allowing bright

light from a source outside the proper field of view to fall upon the interior of the lens mount on the one hand, and to an attempt to secure undue compactness in the apparatus on the other, which leads to the omission of a lens hood, and still more serious, to the use of too small a bellows to the camera, causing a great deal of light to be reflected from the bellows on to the plate. A proper bellows should be large enough to allow two or three flexible stops to be inserted which will intercept light that might otherwise cause general fogging.

§ (3) Illumination in the Outer Parts of the Field.—Suppose now there is in the outer parts of the field of view another area similar to that at the centre, of the same brightness and in the same plane. Let the angle made with the axis by the line joining the centre of this area to the centre of the stop be ϕ. Suppose the object behaves as a self-luminous body. Then the amount of light emitted per unit area in a direction making an angle ϕ with the normal to the surface is proportional to $\cos\phi$, so that I must be replaced by $I\cos\phi$. The stop seen from the object appears foreshortened, its area being apparently $A\cos\phi$ instead of A. This substitution must therefore also be made. Further, corresponding to the distance d we have the increased distance $d\sec\phi$. S and S′ are of course unchanged. Taking all these factors into consideration, it appears that the illumination in the image of an evenly illuminated object falls off in proportion to $\cos^4\phi$. The accompanying diagram (*Fig.* 1) exhibits this graphic-

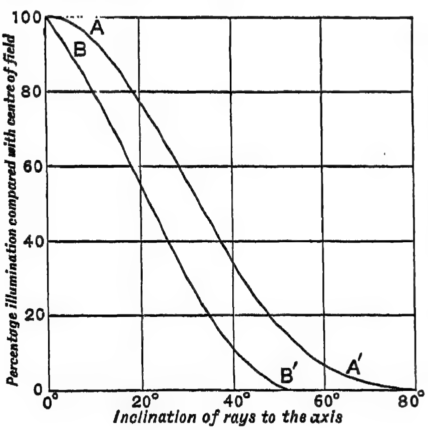

Fig. 1.

ally in the curve AA′. It will be seen that when

$\phi=20°$	the	illumination	is reduced	by	22	per cent.
$\phi=25°$	,,	,,	,,		33	,,
$\phi=30°$	,,	,,	,,		44	,,
$\phi=35°$	,,	,,	,,		55	,,

Serious as these figures are, they by no means represent the worst, for it almost invariably happens that for object points only a small distance from the axis a second limiting aperture begins to cut down the light still further below the figures given in this table. The way in which this comes about is illustrated in *Fig.* 2. A central beam is shown

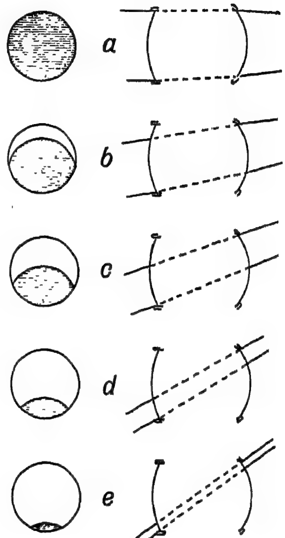

Fig. 2.

passing through the lens in section at *a*, a beam at 10° at *b*, at 20° at *c*, 30° at *d*, and at 35° at *e*. The reduction in cross-section is evidently due to the axial separation between the extreme lenses, and its influence on the illumination is indicated in the curve BB′ of *Fig.* 1. It is quite common to find that the illumination at 30° is of the order of 15 per cent of that at the centre. In spite of the 7 to 1 ratio in light intensity which this represents it is not usually noticed in photographs, because the eye is not very sensitive to *gradual* changes of intensity. If, however, the angle is made unusually large, such as by a very liberal use of the rising front of the camera, or if a composite photograph is made with "straight" prints, the variations are noticed immediately.

When it is necessary to cover a very large angle the most ready method of securing the greatest uniformity in exposure is to prevent the secondary reduction of aperture by stopping the lens down until the whole circle of the aperture can be seen from the corners of the image it is required to record. In some lenses the stop is so placed that this reduction is of no effect, and in a few cases stopping

down actually reduces the size of the total field of view and increases the disparity in illumination. Quite frequently it is necessary to reduce the size of the stop for this purpose to a far greater extent than is consistent with very sharp definition in the image. When this expedient is insufficient, recourse must be had to special stops contrived to reduce the amount of light at the centre to a greater extent than that at the edges. The principle employed consists essentially in the combination of a circular opening in a plane with an opaque circular stop in another plane, or alternatively with a conical stop (*Fig.* 3).

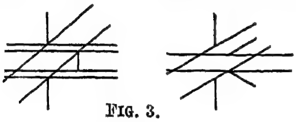

FIG. 3.

These arrangements date from a very early stage in photographic history, and were developed by Bow and Sutton. At the present time the best known application of this principle is in the case of the Goerz "Hypergon," in which a rotating star-shaped central stop is used. With this lens ϕ may be as great as 70°.

§ (4) DEPTH OF FOCUS.—When the view contains objects at different distances from the lens, it is not possible for the images of all of them to be formed in the sensitive layer, and the impression produced is that of a more or less badly focussed image. The simplest way of ascertaining the effect which will be produced is to neglect the depth of the sensitive layer, so that only one object plane is supposed to be sharply focussed. If P is an object point outside this plane, as at P_1 or P_2 (*Fig.* 4),

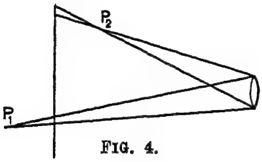

FIG. 4.

a geometrical theory leads to the conclusion that P, instead of being represented in the image by a point, will appear as a patch corresponding to the image of the circle in which the cone, whose vertex is at P and whose base is the lens aperture, intersects this plane. If d is the distance of the plane from the lens, and d_1 is the distance of the plane through P parallel to the plane rendered sharply, the diameter of the equivalent object circle will be ϵ, where

$$\frac{\epsilon}{a}=\frac{d_1 \sim d}{d_1}.$$

It follows that if the nearest and farthest objects to be rendered in acceptably sharp focus are distant d_1 and d_2, the proper distance to focus on is d, where

$$\frac{2}{d}=\frac{1}{d_1}+\frac{1}{d_2},$$

and the diameter of the circle in the image plane which serves as an image of a point in either of the two extreme planes is

$$\frac{a(1/d_1 \sim 1/d_2)}{2/f-1/d_1-1/d_2},$$

where f is the focal length of the lens and a the diameter of the stop in use.

In applying this formula it is usually assumed that a blurred image of a fixed diameter may be accepted as a standard, and the most usual tables adopt ·01 in. as this diameter. Probably the assumption of a fixed diameter is not unreasonable for lenses of focal lengths 8 in. or more, but this criterion appears unsuitable for photographs taken with lenses of very short focal lengths such as are now common, where it is reasonable to assume that every picture must be enlarged to be properly appreciated. In these cases the diameter of the blur should probably be reduced in proportion to the focal length, attaining the value for larger lenses when the focal length reaches approximately 8 in. For securing a sharp impression there is no doubt that in the case of the longer focal lengths ·01 in. is too large a value to assume, at any rate for objects of importance in the central parts of the view, and to attain the standard reached by the normal eye this requires to be reduced to about one-quarter. On the other hand, to make sure that certain objects will not be distinguishable in the print, it is desirable that a value exceeding ·01 in. should be adopted.

One of the most important applications of the above theory concerns the focus for "infinity" in small hand cameras. Here, if anywhere, the ·01 in. limit is tolerable, as the principal objects in views taken with such cameras are rarely really distant, and it is only important to ensure that the blurring of very distant objects does not present an unnatural appearance to the eye. For this case the formula becomes

$$\frac{\text{Distance to object sharply focussed for infinity}}{\text{Focal length}}$$
$$=1+\frac{\text{Diameter of stop}}{\text{Diameter of blur circle}}.$$

Thus with a lens of 5 in. focal length and full diameter 1 in. the object sharply focussed when the camera is set for infinity will be slightly over forty feet away, and the sensitive surface will be about ·05 in. from the plane conjugate to infinity.

§ (5) Depth of Focus and Phase Errors.—It is interesting to consider in connection with these traditional rules the results which would follow from the application of criteria for good definition suitable for the telescope, finding the depth of focus for instance in terms of the phase errors consequent on departure from the theoretical focus. Considering a point on the axis from which a ray to the rim of the lens aperture makes an angle ψ with the axis, the difference in path introduced by changing the distance of the point from the lens from d to d_1 for this extreme ray is

$$(1-\cos\psi)\,(d_1 \sim d),$$

and since $\sin\psi = a/2d$, this path difference may be written as

$$\frac{a^2}{8}\left(\frac{d_1 \sim d}{d^2}\right),$$

or

$$\frac{a^2}{8}\left(\frac{1}{d} \sim \frac{1}{d_1}\right).$$

If, then, $\pm c$ represents the greatest path difference consistent with acceptable definition, the connections between a, c, the near and far distances d_1 and d_2, and the distance d on which the lens should focus are

$$\frac{2}{d} = \frac{1}{d_1} + \frac{1}{d_2}$$

as before, and

$$\frac{1}{d_1} \sim \frac{1}{d_2} = \frac{16c}{a^2},$$

a formula differing markedly from that obtained by considering the area in which the ray bundles meet the image surface. According to this theory the depth of focus is inversely proportional to the area of the aperture, instead of varying inversely as the aperture diameter and the camera extension. The connection between the quantities involved in the two theories may be written

Path difference

$$= \tfrac{1}{4}\text{ diameter of image circle} \times \sin\psi_0,$$

where ψ_0 is the angle made with the axis by the extreme ray in the image space which passes through the axial point of the image plane. Taking an object fairly distant from the lens on which to focus, and assuming an aperture of $f/4{\cdot}5$ and a phase tolerance of 1 wave-length of yellow light, the diameter of the permissible image circle is found to be approximately ·0007 in. $=1/1400$ in. On account of the finite thickness of the sensitive layer and the appreciable size of the grains which become developable as a whole when affected by light, it is doubtful whether so small a tolerance is necessary under ordinary conditions. The wave-length theory is, however, undoubtedly applicable in considering to what extent accuracy in focussing has any meaning. Taking, as before, the case of a lens focussed on a distant object, it would be expected that under the best conditions imperfection in focussing would begin to be visible when the image plane was out of focus by about ·001 in., and for other stops the distance would increase as the square of the f number, and so be proportional to the correct exposure. Thus, with an aperture of $f/8$ the focussing depth in the present sense would be three times that for $f/4{\cdot}5$.

§ (6) Tilted and Decentered Use of Lens.—It is evident from the foregoing discussion that when it is desired to record in good focus two objects in different parts of a view which are at very unequal distances from the lens, the latter must either be used with a small aperture, or alternatively the lens must be used with its axis inclined to the normal to the surface on which the record is to be made, so that both objects lie approximately in the plane conjugate to this surface. Under these circumstances the plane containing the sensitive layer and that in which the objects are situated will be inclined to one another, and it is of importance to be able to make the necessary adjustment with facility. This is almost invariably carried out by swinging the back of the camera, with which the sensitive surface moves, relatively to the lens axis, which is pointed as usual to the centre of the view it is intended to include. The proper adjustment is indicated by a collinear theory of imagery. Since the object plane is not normal to the lens axis it will meet the first unit plane of the lens in a certain line, and hence the image plane must meet the second unit plane in a corresponding line. With almost all lenses the unit planes are very slightly separated from one another, and lie between the extreme components of the system. It is sufficiently accurate for the purpose of adjusting the camera back to assume that there is a common unit surface which bisects the lens mount. By considering where this plane is met by the plane it is intended to have in sharp focus, and directing the image plane through this line the correct approximate adjustment is easily made, and if necessary a final correction can be made after the image has been examined. The principle followed is illustrated in the accompanying figure (*Fig.* 5), where VQAP is the object plane meeting the common unit surface VC in V, and Vpaq is the image plane.

Obviously from this figure the view will not appear correct in the final picture unless it is seen from one side, or, if the object and image planes were inclined to the vertical, from above or below. In certain cases this effect is very objectionable, and in particular it must be avoided in architectural subjects where the use of a lens with its axis inclined

to the horizontal causes vertical lines in the object to appear to converge in the image. The simplest method of dealing with such

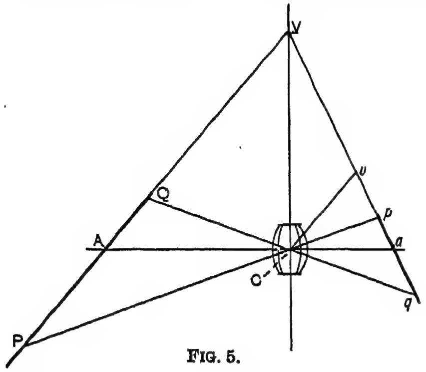

FIG. 5.

subjects when, as frequently happens, the desired view cannot be obtained with the axis of the lens intersecting the centre of the sensitive surface is to decenter the lens with respect to this surface, so that, for instance, in taking a view of a tall building from the ground the lens axis may be several inches above its normal position. The parallelism of vertical lines is thus preserved in the picture and the whole face of the building is kept in satisfactory focus if the image plane is kept vertical. This method, in extreme cases, is, however, unsatisfactory on account of the poor quality of definition in the image in parts remote from the lens axis, and also on account of the extreme difference thus introduced in the effective exposures for different parts of the image. In these extreme cases it becomes necessary to use the lens in an inclined position, and to rectify the convergence of vertical lines by re-photographing the original record.

Referring again to the figure, which shows a section in the plane containing the axis and the projection of the axis on the object plane, let Cv be a line, parallel to the object plane PQV, through C, the axial point of the common unit planes CV, meeting the image plane Vpq in v. Then v is the vanishing point in the record for the converging lines corresponding to the parallel vertical lines of the object. In copying this record so to correct this convergence it is evidently only necessary to ensure the parallelism of the line of greatest slope of the new image plane to Cv when pq is treated as the object. In order, however, to obtain a correct relation between horizontal and vertical distances in the final picture, the axis of the lens in this second operation must intersect the first record now serving as an object in the same point a as did the axis of the lens when the record was made. If the final record is to be increased in scale to m times that of the first record, the unit plane in the principal section must be made to meet the record in V where $\mathrm{V}v = m \cdot va$. If now a circle is described on Va as diameter the axial point of the unit plane C must lie on the circumference, thus making VCa a right angle. It is evident from this construction that the only limitation which must be imposed on the lens used for the second operation is that its focal length shall not exceed $\frac{1}{2}\mathrm{V}a$ or $\frac{1}{2}(1+m)va$ where m is considered positive. The original lens is, in such a case as has been considered, suitable for the purpose, but one of shorter focal length is frequently more convenient in order to reduce the axial separation between the object and image planes.

§ (7) THE POSSIBLE DEFECTS OF PHOTOGRAPHIC LENSES.—The matters that have been discussed hitherto relate to the correct use of a lens, and apply to all lenses alike, whether they are well or less well corrected for aberrations. The defects now to be considered depend upon the design of the lens, and are not under the control of the user.

(i.) *Filming.*—A defect which is not likely to be present in a new lens, but may develop in the course of time, is the filming of one or more of the glass surfaces. This is particularly likely to occur with extreme barium crown lenses of the types used in anastigmat lenses. When this filming is slight it is innocuous, but in some cases it causes the lens to appear of a decidedly brown tinge when examined by transmitted light, while iridescent colours may be seen by reflected light. In these more extreme examples the rapidity of the lens is seriously affected, and it is necessary to have the lens surfaces re-polished. It is needless to say that this should only be done by the maker of the lens.

Somewhat similar colours may be seen by reflected light when two surfaces which are supposed to be cemented together have become partially or entirely uncemented. The most probable cause of this defect is a fall or violent shaking. In these cases also the lens ought to be returned to the maker for correction.

(ii.) *Mounting Defects.*—A lens that has been performing satisfactorily may be found unsatisfactory after cleaning or re-mounting. This is frequently experienced after a lens formerly carried in the maker's mount has been fitted into a between-lens shutter. The cause may be a scratch on the lens surface, which scatters light in all directions within the camera; strain due to screwing up a lens too tightly in its cell; changes in the separations of components either through a lens being loose in its cell or to incorrect adjustment of the new mount; the insertion of a particular component the wrong way round, or to interchange of front and back com-

ponents; or to inexact adjustment of the axes of the various components into coincidence. The accuracy necessary in some of these adjustments is very often not realised, and particular care to see that all is in order is essential after any disturbance of the lenses from their original position. Even when all the parts are in relatively correct positions the optical axis may be found appreciably inclined to the mechanical axis of the screw by which the mount is attached to the camera front. The figures already given on the accuracy desirable in focussing indicate the great nicety to which these two axes ought to be brought into parallelism if satisfactory records are to be obtained.

(iii.) *Faults of the Glass.*—Defects of a different class are faults in the glass of which the lenses are made. Bubbles are practically unavoidable in some of the new types of glass which are always used in anastigmatic constructions, but they should not be too numerous or too large. On these conditions they are practically harmless, their chief effect being the stoppage of a small amount of light. More serious are veins and striae. These can only be seen under special conditions of illumination if they are slight. The simplest arrangement is to point the lens at a small source of light, and place the pupil of the eye at the image of the source formed by the lens. The defects will then become apparent as lines where the illumination is not uniform. Lenses showing such defects cannot be made satisfactory, and should not be accepted as good instruments. In the physical laboratory lenses or prisms showing these defects can usually be discovered, and are interesting subjects for experiments with the aid of an interferometer and in other directions.

(iv.) *Defects of Design.* — The remaining defects of importance depend upon the design of a lens. It has already been mentioned that light is reflected and scattered whenever a refraction from glass to air or *vice versa* takes place. For this reason, other things being equal, the design with the smallest number of such refractions is to be preferred. Another defect which may be coupled with this is the liability of a lens to show flare images. These images are images of the lens aperture formed by light that has been reflected twice at glass to air surfaces. As a rule these images will not be situated near the image of the object to be recorded, but in certain designs one or more of these images may occupy a position where it is clearly seen in the record. A lens having this defect is quite unsuited for photography under certain conditions of lighting. It is well known that one of the best known makers of photographic lenses was compelled to withdraw an otherwise eminently satisfactory lens from the market shortly after its introduction, owing to its marked failure in this respect.

§ (8) Aberrations.[1]—The remaining regular defects to which lenses are subject are of the character known to the optician as aberrations, and it is to the removal of these defects by the use of suitable materials and by the selection of suitable forms for the component lenses that the designer principally directs his attention.

(i.) *Chromatic Aberrations.*—The simplest of these defects are those known as chromatic aberrations; the images of the object formed by light of different wave-lengths differ in size and also occupy different planes. For any object position there are thus two primary defects to remedy, and if images at different distances from the lens are to be corrected three conditions must be satisfied. The crudest lenses fitted to some of the very small cameras are not corrected for these defects, advantage being taken of the very small size of the lens aperture which renders the fault less obtrusive in the picture. In all cases where a non-achromatic lens is used a visual examination of the image shows it to be out of focus, an improved appearance resulting from an increased separation between the lens and the image plane. This difference is due to the fact that the sensitive materials used to secure a photographic record are most sensible to light of a shorter wave-length than that to which the eye attaches chief weight, and the actinic or photographically active image is thus nearer to the lens than the visible image. The difference is of the order of 2 per cent of the focal length of the lens.

In more pretentious lenses this difference in the position of the image planes is always removed by using combinations of positive and negative lenses in which the negative lenses are constructed from glass having a greater dispersive power than that used for the positive lenses. The three chromatic conditions reduce to one when two thin lenses, one positive and one negative, are used in contact with one another. When the system consists of well-separated lenses, or of lenses of considerable thickness, attention has to be paid to the three conditions independently of one another, but as a rule it will not be found that the theoretical conditions are exactly satisfied, the designer finding it more convenient to reduce the defects to a point at which they cease to become evident than to eliminate them completely. In one important case the three conditions reduce to two through two of them assuming an identical form. This is when the complete system consists of two similar components whether

[1] For a fuller account of the aberrations of an optical system see "Optical Calculations," § (7), etc. See also "Microscope, Optics of the," § (5), etc.

of equal or unequal focal length. This is a simple case where the principle of symmetry applies, a principle of which great use is made in connection with other aberrations. It will be considered in more detail later.

It should be evident that little importance attaches to equality in the sizes of images of different colours when they occupy different planes. Accordingly, the chief attention should be given to the positions in which the images of various wave-lengths are formed, and if some latitude is necessary it may be given in a slight variation of magnification with the wave-length. Owing to the properties of the transparent materials available for the construction of lenses it will, as a rule, only be possible to secure exact agreement of focussing plane for two wave-lengths. The two regions it has been found most satisfactory to bring into agreement are the neighbourhood of the D lines of sodium and the G′ line of hydrogen, the former being not far from the dominant wave-length for visual observation, and the latter near the wave-length to which the photographic emulsions are most sensitive. This method of correcting enables a view to be correctly focussed for photographic recording by visual examination of the image.

(ii.) *Spherical Aberrations.*[1]—The remaining defects are of the type known to the optician as the spherical errors. The amount of these will also depend on the wave-length. They should usually be corrected for a wave-length in the neighbourhood of G′ rather than for D. If this is done the photographic record will present a better appearance than the visible image, and it may be a matter of importance to concentrate attention almost entirely on the portion of the image in the neighbourhood of the lens axis when judging the best position of focus visually. If the correction were made in the alternative way the visible image would appear very pleasing and the photographic record distinctly disappointing. In lenses for special purposes this consideration may not apply.

(*a*) *Distortion.*—In consequence of the spherical errors the image of a point in the object formed by light of a given wave-length will not on a ray theory be a point, or in one case its position, if a point, will be displaced from that which it should occupy were the image an exact projection of the object. This particular defect is known as distortion, and the displacement is necessarily directly towards or away from the point in which the image plane is met by the lens axis. The displacement may be represented mathematically by a series of odd powers of the distance the point would be from the axis were the defect absent. Thus, if y, z be the co-ordinates of a point in the image plane and we take the axis of y parallel to the direction in question, so that y represents that distance,

$$\delta y = a_1 y^3 + a_2 y^5 + a_3 y^7 + \ldots, \quad \delta z = 0.$$

The coefficients a_1, a_2, a_3 . . . may be used as measures of the extent to which the defect is present, and are named the coefficients of distortion of the first, second, third . . . orders. If the defect is serious it becomes obvious that lines in the image which correspond to straight lines in the object are appreciably curved. This want of straightness, as the above equation shows, gradually makes its appearance as the shortest distance between the line and the point of the image plane on the lens axis increases.

(*b*) *Spherical Aberration.*—Another aberration of a very simple kind is central spherical aberration, the "central" referring to the distinctive property that, though equally present in other parts of the field of view, it is only aberrations of this group which appear in images on the axis itself. This aberration consists essentially in the rays from narrow zones of the aperture, bounded by nearly equal circles centered on the axis, coming to foci on the axis which vary gradually from one zone to another. The rays which in an ideal lens should pass through a single point of the axis, in a lens suffering from this defect, will touch a caustic surface which has two branches, one being a surface of revolution about the axis and the other a length of the axis itself. If η, ζ are the co-ordinates of the point in which the ray meets the stop, the intersection of the ray with the image plane will be displaced from its ideal position given by y, z, by a distance whose rectangular co-ordinates δy, δz satisfy

$$\frac{\delta y}{\eta} = \frac{\delta z}{\zeta} = b_1 r^2 + b_2 r^4 + b_3 r^6 + \ldots$$

where $r^2 = \eta^2 + \zeta^2$. As before, b_1, b_2, b_3 . . . are aberration coefficients of the first, second, third . . . orders. In telescope objectives, the removal of this aberration is of outstanding importance, but it is common to find appreciable amounts of central spherical aberration present in good photographic lenses, the reason being that up to a certain point this defect is less harmful than some other aberrations which cannot in the particular design be removed simultaneously with this central aberration.

(*c*) *Curvature and Comatic Aberrations.*—Between the two simple aberrations considered in (*a*) and (*b*), there lie a series of others whose number and character depends upon the order of the aberration. Several of these have received names suggested by the shape of their trace in the image plane or by some other

[1] For a discussion of the expressions given below for the various aberrations see "Lens Systems, Aberrations of."

outstanding character. A very rough classification, based only on the aberrations of the first order, has been found sufficiently inclusive to group these under for testing purposes, and will serve for the present discussion. The loose character of the classification must, however, be borne in mind, as confusion may otherwise be caused when a more exact division is called for.

Under this grouping the remaining defects are classed as curvature errors or as comatic errors, the former class containing those members which tend to produce a symmetrical deviation from the ideal image point, the latter to those in which the departure tends to be unsymmetrical. Comparing this division with the two spherical aberrations already considered, central spherical aberration is evidently symmetrical in character, for corresponding to any displacement δy, δz in a ray from a given object point we obtain the complementary displacement $-\delta y$, $-\delta z$ by selecting the ray which meets the stop in $-\eta$, $-\zeta$ instead of η, ζ. On the other hand, distortion is an unsymmetrical aberration, since δy has a definite sign for all rays from a given object point. The characteristic feature of these aberrations in mathematical language is that the symmetrical aberrations may be represented by terms which contain odd functions of η and ζ, and even functions of y and z, while with the unsymmetrical aberrations the reverse is the case. Taking the first order aberrations, from which the classification is derived, it may be shown that the defect known as coma involves displacements of the ray intersections given by

$$\frac{\delta y}{cy}=2(\eta^2+\zeta^2)+(\eta^2-\zeta^2)$$

$$=r^2(2+\cos 2\theta),$$

$$\frac{\delta z}{cy}=2\eta\zeta=r^2\sin 2\theta,$$

where $\quad \eta=r\cos\theta,\quad \zeta=r\sin\theta,$

and c is a constant, showing that the rays which pass through a narrow circular zone of the aperture intersect the image in a circle, the radius of which is proportional to the square of the radius of the zone. The circle has the property that light from any one half of the annulus in the stop plane is distributed over the whole circle; it is thus formed twice over by the light from the complete annulus. The aberration is most likely to be detected in photographic prints by a fuzzy edge to one side of a narrow object, such as a pole, which stands out strongly against its background, while the other edge appears much sharper. The removal of this aberration is particularly important in photographic lenses on account of the large field of view involved, to which this particular aberration is proportional.

The remaining first order aberrations relate to departures of the image surface from the plane. Two independent constants e, e' occur, so that two aberrations are present, the formulae for the displacements being

$$\frac{2\delta y}{y^2}=\eta(3e+e')$$

and

$$\frac{2\delta z}{y^2}=\zeta(e+e').$$

It can be shown from these expressions that for points on a sphere of curvature proportional to $(3e+e')$ having its vertex in contact with the plane in which the image has been assumed to lie δy will assume zero value, and that similarly δz will vanish for points on a sphere whose curvature is proportional to $(e+e')$. These spheres are obviously the loci of the focal lines of the pencils which form the image. The aberration corresponding to e is called astigmatism, since, if e is finite, the two spheres are distinct, so that no point image exists. The other aberration denoted by e' is called the curvature, since this is the curvature the image surface would have if point images existed in the outer parts of the field of view. The form of the expression shows that it is only when e vanishes that the curvature can be represented by e', the possible range in other cases lying definitely to one side or other of this value, according to the likeness or unlikeness of the signs of e and e'.

The removal of aberrations of this type was for long an obstacle in the way of improvements of photographic lenses, and was not realised until the introduction of novel types of glass had resulted from the work of Abbe and Schott at Jena. These new glasses were of particular importance in enabling e' to be controlled in value. Together with this improvement it is necessary, if e is to receive a satisfactory value, for the optical system to contain lenses appreciably separated from one another.

(iii.) *Aberrations in General.*—In closing this very brief description of the aberrations to which lenses are subject, it is necessary to point out that the values of the constants by which the defects are measured are dependent on the position of the object. It follows that a lens which is corrected for an object in one position will not give so good an image when the object is considerably displaced. The magnitude of the defects depends largely on the size of the lens aperture, so that a lens of large aperture is necessarily less suitable for general work than one in which the aperture is smaller. In particular, if a lens corrected for an object at infinity is reversed and still used for a distant object the image will not be satisfactory unless the aperture is less than a definite value. An indication of this value is afforded by the largest aperture for which

symmetrical objectives are offered for the photography of distant scenes. The advantage to a manufacturer of the symmetrical construction is sufficiently great to ensure his utilising it as far as it can be satisfactory. A lens of this type cannot possibly be thoroughly corrected except for the reproduction of objects on full scale. Actually, such lenses are made for general work up to apertures of $f/5{\cdot}6$. This affords a direct means of finding the standard of accuracy which manufacturers find necessary in their objectives.

It must further be remembered that these first order effects are modified in the parts of the field of view more remote from the axis by the presence of aberrations of higher orders. These may tend in many instances to reduce the evil effects of the aberration of lower orders; for instance, the surfaces containing the focal lines may be caused to depart from the spherical form and made to approach the ideal image plane again. This condition is fulfilled in several modern objectives, the two focal surfaces crossing in or close to this plane near the edge of the useful field of view. Strictly speaking, this is the condition which is held to justify the application of the term "anastigmat" to a lens, though, on the one hand, this usage is far more free than mathematical conceptions warrant, and, on the other hand, the term is also applied by their makers to lenses which do not even attain this limited degree of stigmatism.

The actual appearance of the image in any lens depends upon the combined effect of all the aberrations which are present, and is also modified by the finite wave-length of the light forming the image. The classification of the defects into a number of separate aberrations is entirely artificial, its justification being the convenience of dealing with the defects in the manner described.

§ (9) Types of Lenses.—The most varied forms have been proposed and used for photographic lenses, and it is impossible here to attempt any detailed historical treatment of the subject. Much interesting matter will be found in the writings of von Rohr[1] and Gleichen,[2] which should be consulted by all who desire fuller information. A broad division of the forms in use at the present day may be drawn between the symmetrical and the unsymmetrical classes. The former group may be subdivided into

(*a*) Fully symmetrical;
(*b*) Hemi-symmetrical;
(*c*) Quasi-symmetrical;

and in each of these subdivisions there may be anastigmatic or astigmatic types, combinations built upon cemented or uncemented components, or on still more complex forms.

The unsymmetrical forms may be built from 1, 2, 3, 4, or 5 components, some or all of which may themselves be compound lenses. The cases of most importance are

(*a*) The single lens;
(*b*) The double lens;
(*c*) The telephoto lens, a special case of the double lens;
(*d*) The triple lens.

As practically all lenses of the symmetrical type are obtained by combining together two systems which are themselves unsymmetrical lenses of classes (*a*) or (*c*), it appears the simplest course to consider the unsymmetrical forms first.

§ (10) Unsymmetrical Types. (i.) *The Single Lens.*—This form of lens may be constructed from one or several pieces of glass cemented together. All lenses of this type are used with an aperture stop some distance in front of them, and are meniscus in external form, presenting their concave surfaces to the incident light. This arrangement is adopted to secure a pseudo-flattening of the image by selecting for different parts of the field of view pencils which have been refracted through different regions of the lens. The device is only effective when either central spherical aberration or coma or both are present in the image. The stop must not under these circumstances be large, and as this method of disguising curvature of the field necessarily introduces distortion, systems of this kind cannot be used on large fields containing numerous straight lines which do not lie near the lens axis. It is readily seen from the diagrams (*Figs.* 6 and 7) that the presence

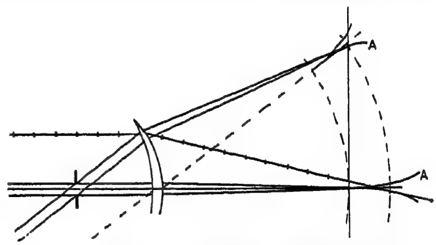

Fig. 6.—Curvature Correction in the Presence of Over-corrected Spherical Aberration.

of coma is of greater assistance than spherical aberration, and that when either is present alone the coma should be under-corrected and the spherical aberration over-corrected. The sign required for the outstanding coma accounts for the use of a lens strongly concave to the incident light.

In some of the more complex modern forms a ruling factor in the design is the presence of at least two cemented surfaces at which the angles of incidence may be large in comparison

[1] *Theorie und Geschichte des photographischen Objektivs.*
[2] *The Theory of Modern Optical Instruments*, trans. by Emsley and Swaine.

with those at other surfaces, one of these two being of positive power and the other of negative power, the system further containing

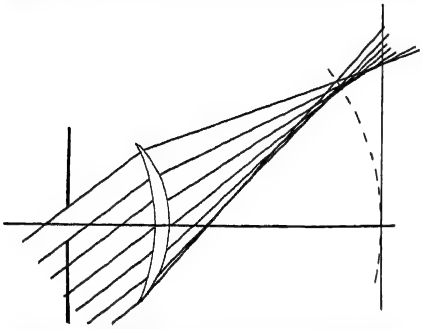

FIG. 7.—Curvature Correction in the Presence of Under-corrected Coma.

at least one lens of barium crown glass which combines a high refractive index with small dispersion. For a fuller account of such lenses reference may be made to the treatise by von Rohr, already mentioned, or to Lummer's *Photographic Optics*, translated by Thompson. The earliest lenses used in photography appear to have been single lenses of one glass of the form devised by Wollaston. The earliest achromatic lenses were of the ordinary telescope form with a double convex crown lens, but at the present time a form with both crown and flint of meniscus shape, and with the crown lens nearer the stop, is invariably used, as it yields more satisfactory images over an extended field.

(ii.) *Systems composed of Two Dissimilar Lenses.*—Such lenses when separated by an appreciable distance comprise one of the most important classes of objective. By far the most celebrated design which has yet been evolved, the Petzval portrait lens (*Fig.* 8),

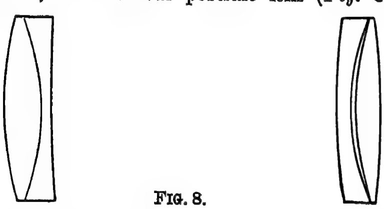

FIG. 8.

belongs to this group. This lens was produced in the very early days of photography, when the need for great rapidity was acute on account of the slowness of the sensitive materials at that time available, and in many respects it has hardly been surpassed by any later designs. In either its original form or in the modification introduced by Dallmeyer (*Fig.* 9) it is extensively used as a cinematograph projection lens at the present day, the relative aperture varying from $f/3{\cdot}5$ to about $f/2$. These lenses are, of course, made with the old silicate glasses.

The form of Petzval's objective generally corresponds to that which would be indicated by basing the design on the conditions for the

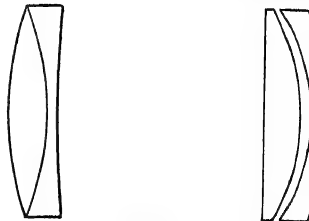

FIG. 9.

removal of first order aberrations as far as this is possible with the glasses available. As any actual design involves a balance between aberrations of different orders which cannot be effected simultaneously, the results given by the expressions for these first order aberrations are subject to considerable modification in the evolution of the final system.

The other members of this class which require special mention are anastigmatic lenses, and so utilise barium crown glasses. They are generally composed of an achromatic combination of the older types of glass, which is over-corrected for central spherical aberration, on one side of a central stop, and an achromatic combination of a light flint with a dense barium crown, which is necessarily under-corrected for central spherical aberration if the surfaces are spherical, on the other side of the stop. Both components are meniscus in external form, and present their concave sides to the stop, the ordinary achromat being of the form usual in single lenses but being placed before the stop, the other lenses resembling in shape the ordinary telescope objective with its flint component next to the stop. Under these conditions the cemented surface of the front component is of negative power and that of the back component of positive power. The need for presenting the concave sides of both components to the stop arises from the conditions for the removal of coma and distortion. Among the best known lenses of this class are the Protars of Messrs. Zeiss (*Fig.* 10). The Aldis lens, which in form is a double objective, is most simply regarded as a special case of a triple objective.

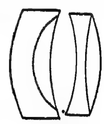

FIG. 10.

(iii.) *The Telephoto Objective.*—This form, as a self-corrected lens in which the components stand in a fixed relation to one another, is of comparatively recent development. The essential feature is that a positive lens is followed at a considerable distance by a

negative lens, which increases the focal length of the system without extending the separation between the front lens and the image in the same proportion. Such a combination of a positive and a negative lens, each corrected for colour, lends itself very readily to the construction of an anastigmatically corrected system Among these systems the large aperture telephoto lens (*Fig.* 11) made by Messrs. Taylor, Taylor & Hobson may be mentioned.

FIG. 11.

Although telephoto lenses made of two single glasses are not employed as an unsymmetrical objective, such systems require mention, as they provide the basis of many symmetrical objectives. In particular, the Gaussian form of telescope objective is used in more than one of these more complex lenses.

(iv.) *Lenses with Three Components.*—Among the early attempts to improve photographic objectives systems consisting of three separated components are of frequent occurrence, the external components being of positive power and the central one of negative power. In most instances each component was achromatised independently. None of these lenses survive to-day, and their present interest is chiefly due to the claim they may have to be considered as forerunners of the Cooke lens (*Fig.* 12), designed by Mr. H. Dennis Taylor of Messrs. T. Cooke & Sons, and made by Messrs. Taylor, Taylor & Hobson. When account is taken of the large number of conditions which have to be satisfied and the simplicity of the means adopted to achieve them, the design is one which must command general admiration. The excellence of its actual performance is sufficiently attested by the reputation of the lens among photographers. The general form of the lens, as in other cases, may be derived by considering aberrations of the first order only.

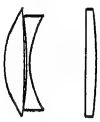

FIG. 12.

Another well-known lens of this type which may be considered a slight elaboration of the Cooke is the Tessar (*Fig.* 13), produced by Messrs. Zeiss. The chief difference between the two lenses is that in the Tessar the back lens of the Cooke is replaced by a cemented doublet. In theory at least the additional degrees of freedom attained by the introduction of one more glass should enable a somewhat larger field of view to be covered with satisfactory definition by the Tessar than by the Cooke: whether in fact the gain, if any, actually achieved, justifies the complication, is debatable. Some indication of the excellent results attainable with the Cooke design is provided by the extensive use of such lenses of large aperture and long focal length by the German army in the war for aeroplane photography. So far as is known to the writer, the Tessar was not used for this purpose. The only serious drawback to lenses of this type appears to be the rapid deterioration in the definition outside the field which the lens is intended to cover, so that the extent to which the lens can be decentered is distinctly small compared with that possible in some of the double symmetrical types when a small stop is used.

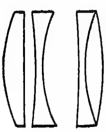

FIG. 13.

The Aldis lens (*Fig.* 14) may be regarded as a modified Cooke, in which the first two lenses are of substantial thickness and are cemented together. The reduction in the number of glass air surfaces which results from this modification is of distinct advantage, but the accompanying restriction in the number of variables at the disposal of the designer greatly increases the difficulty of attaining as high a standard of definition as with a true triple lens. These difficulties have been ably met, and this lens appears to be as close an approach as is possible with spherical surfaces to the highest triple standard.

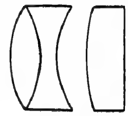

FIG. 14.

Many miscellaneous types of unsymmetrical lenses have been constructed by combining on the different sides of a central stop dissimilar types of double and triple lenses.

§ (11) SYMMETRICAL LENSES. (i.) *True Symmetricals.*—Turning now to lenses of the symmetrical class, the true symmetricals, obtained by combining together two exactly similar lenses of equal focal length in such a manner that one occupies the position of the image of the other in a plane mirror coincident with the central stop plane, may be considered first. Among the simplest of these lenses is one due to Sutton, in which water is the refracting agent, this being enclosed between two thin concentric glass hemispherical shells. The use of such shells enclosing various liquids has been repeatedly suggested, but, though satisfactory pictures have been produced by their means, they have not come into use for obvious reasons. Closely allied to this lens is the Hypergon of Messrs. Goerz (*Fig.* 15), consisting of two very deep positive meniscus lenses of a single glass, so placed that the external surfaces very approximately form a sphere. This lens is used

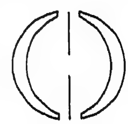

FIG. 15.

with a rotating star stop to equalise the illumination over the plate, and covers an angular field several times as great as is attempted with lenses of other types. For a long period the best lens for general purposes was obtained by using two achromatic meniscus lenses of the type described earlier to form a symmetrical lens. Many names were in use for such lenses (*Fig.* 16), though in essentials they differed very little from one another. The names by which they became best known are the "rapid rectilinear" and the "aplanat," the former describing the characteristic improvement on the single lenses used previously, and the latter description being justified by the improved definition which enabled a larger relative aperture to be employed, though in the modern sense in which aplanatic is used the term is not correct.[1]

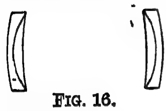

FIG. 16.

Among modern constructions of the anastigmatic types many are of this symmetrical class. The simplest elements from which they can be constructed in the case of cemented components must contain at least three different glasses to yield cemented surfaces whose powers differ in sign. The commonest types have either (*Fig.* 17) a positive

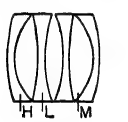

FIG. 17.

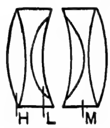

FIG. 18.

H = Highest index.
M = Medium index.
L = Lowest index.

double convex lens cemented between two negative lenses, or (*Fig.* 18) a double concave lens cemented between two positive lenses. In either case the refractive indexes of the glasses form a descending sequence on proceeding from the external medium towards the stop. In another form (*Fig.* 19) a positive meniscus lens

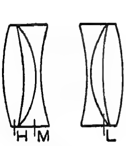

FIG. 19.

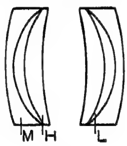

FIG. 20.

of low refractive index is placed between a double convex lens of a dense barium crown and a double concave lens of a light flint, the latter of course being nearest the stop. In a fourth form (*Fig.* 20) the central meniscus lens presents its concave instead of its convex side to the stop, and all the component lenses are meniscus, the negative lenses occupying the extreme positions. Still more complex forms are found if more than three glasses are used, and lenses of this class having four and five glasses to a single component are made.

In another class of symmetrical objective the central lens of the third type of triple cemented component is replaced by a meniscus air lens (*Fig.* 21), each component thus consisting of a double convex dense barium crown lens separated from a double concave lens made from a light flint glass. In a limiting case this type merges into the triple lens of the Cooke class. One further class in which

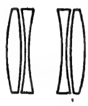

FIG. 21.

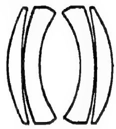

FIG. 22.

an air-gap is used remains, corresponding to a form of triple cemented component which does not appear to have been utilised. In this class the objective may be considered a derivative of the Gaussian objective, consisting of separated positive and negative meniscus lenses. The best known lens of this type is the Homocentric of Messrs. Ross (*Fig.* 22). A more complex lens constructed for reproductive work and available with apochromatic correction is the Planar of Messrs. Zeiss (*Fig.* 23). The cemented lens in

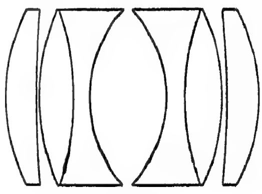

FIG. 23.

this construction is composed of two glasses with different dispersions but approximately equal refractive index.

(ii.) *Theoretical Considerations.*—It has often been claimed for the symmetrical construction that its use automatically removes distortion, coma, and all aberrations of the unsymmetrical class, whatever the position of the object may be. As this question is of very great importance it is worth inquiring what advantages a symmetrical construction does necessarily secure. For this purpose it is quite unnecessary to consider the details of the lens

[1] In earlier writings aplanatic signifies merely freedom from central spherical aberration. Abbe introduced the meaning now generally adopted by imposing the additional condition that the sine condition must be satisfied, so that the term now implies simultaneous correction for central spherical aberration and for coma.

construction, the symmetry itself being the only pertinent factor.

Suppose, then, that C (*Fig.* 24) is the centre of the stop, and thus symmetrically situated with respect to the two components. Any ray through C will strike the components in corresponding points and will be refracted by the separate components into exactly corresponding positions. The incident and emergent rays will thus strike similar and symmetrically situated surfaces in points which also correspond. In particular, if the intersection with the object and image planes for magnification −1 are P and P′, the distances of these points from the axis are equal,

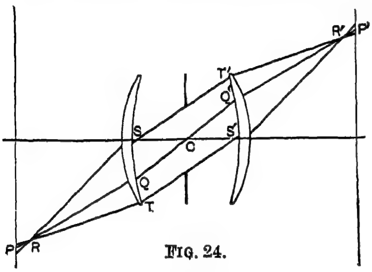

FIG. 24.

and the objective is therefore free from distortion for this particular magnification.

Again consider two parallel rays ST′ and TS′ in the space separating the components, which meet the central stop plane in diametrically opposite points. Symmetry again shows that the incident ray corresponding to ST′ is parallel to and correspondingly situated with the emergent ray belonging to TS′, and *vice versa*. Thus the intersection R of the two incident rays is symmetrically situated with respect to the intersection R′ of the emergent rays. Moreover, the previous result shows that the ray from R through C passes through R′, and the more general case is easily established, that corresponding to any ray through R and R′ another ray through the same two points may be found which is parallel to the former ray in the stop space and meets the stop in the diametrically opposite point. These results are readily interpreted to mean that the lens symmetry automatically secures freedom from all unsymmetrical aberrations when the magnification is −1. It is to be observed that there is no need for the various pairs of rays such as ST′ and TS′ to be parallel in the stop space to QQ′ or to other pairs of rays arising from the same object point, so that the uncorrected character of the half lens is of no consequence. When we proceed to consider conjugate planes for a different magnification the arguments which have served to establish this result for the magnification −1 break down. For example, in the case of distortion, freedom from this aberration evidently involves the absence of aberration in the image of C in a single component. To secure the absence of all chromatic aberration the single component must bring a parallel bundle of rays incident in the stop space to a single focus in the image space, and must also form an image of C in the same place for the different colours.

When coma is considered in a similar way for a magnification other than −1 the rays concerned in the formation of the image of a particular object point which intersect the stop in opposite ends of a diameter do not lie parallel to one another in the stop space, and in the absence of such symmetry conclusions can only be drawn when more is known of the unsymmetrical aberrations for the magnification −1. Algebraic investigation is in this case more simple, and leads definitely to the conclusion that with the symmetrical construction the only magnifications for which the aberrations generally can be removed are +1 and −1, the former corresponding to the stop and the latter to a real image.

With moderate sized stops the fact that a symmetrical objective is free from unsymmetrical aberration when copying full size may be taken to involve small but not zero values for the unsymmetrical aberrations for objects in other positions, but for large apertures the conclusion is unavoidable that this construction is undesirable. The design of a symmetrical objective for copying the same or approximately the same size is particularly simple, since it reduces to the design of a half component which is free from symmetrical aberrations alone for parallel beams incident on the surface presented to the stop, together with the correction of the image of the point in which the stop meets the axis for colour and spherical aberration. The conditions to be satisfied are thus considerably fewer in number than with a complete unsymmetrical objective.

(iii.) *Hemi-symmetrical Objectives.*—These are formed by combining together two components of similar design but of different focal lengths. The position of the stop should divide the space between the inner surfaces in proportion to the focal lengths of the components, and, as in the fully symmetrical systems, the image of the axial point of the stop plane should be free from chromatic and spherical aberrations. The want of symmetry which exists in the paths of other rays shows that we cannot in this case infer absence of unsymmetrical aberrations for the magnification determined by the ratio of the focal lengths of the components, though when these focal lengths are not extremely dissimilar in magnitude considerations of continuity lead us to expect that aberrations of this kind will not be large. Lenses of this type are chiefly used as a variation of the fully symmetrical type to secure a lens of somewhat different focal length at the cost of half a lens, one component only of the fully symmetrical lens being replaced by another of the same design but of different focal length.

(iv.) *Quasi-symmetrical Systems.*—It is evident from the preceding discussion that for the best results for distant objects with large apertures the symmetrical construction is unsuitable. In a number of lenses this difficulty is overcome by introducing slight differences between the two components, as by altering one or two curvatures and possibly a separation also in one component compared with the other. In this way the advantages which the symmetrical construction offers to a manufacturer may in part be retained,

and the design of the lens is also simplified, since each component must be given properties which differ in known directions from those which yield correct images for full-size copying.

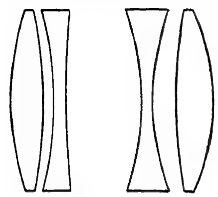

FIG. 25.

Such lenses may be called quasi-symmetrical objectives, and among them may be noted the Celor (*Fig.* 25) made by Messrs. Goerz with an aperture of $f/3{\cdot}5$, while several forms of the Cooke lens and of its variants may be regarded as special cases of quasi-symmetrical lenses. In most of these objectives the outstanding feature of the modification is that the front portion, in comparison with the back, has surfaces more strongly convex to light proceeding from external space to the stop.

PHOTOMETRY AND ILLUMINATION

I. GENERAL PRINCIPLES AND DEFINITIONS

§ (1) GENERAL.—Photometry is that branch of applied physics which deals with the quantitative comparison of light sources and their evaluation in terms of some agreed standard. It will be seen from Part III. on "Photometric Methods" that this comparison or evaluation is always achieved by means of a comparison of the brightnesses of surfaces illuminated by the sources, and this comparison has always to be made by the human eye. There is therefore a natural limit to the accuracy with which two sources of light can be compared, viz. the limit beyond which the human eye is incapable of perceiving differences of brightness. This limit varies with the absolute value of the brightnesses compared, any difference that may exist between their spectral distribution, the state of the eye, and other factors which are discussed elsewhere (see article on "The Eye as an Optical Instrument").

In photometry there is always an ordered sequence of phenomena each of which has to be separately considered. Some object, called a "luminous source," emits radiation which is capable of affecting the retina of the human eye and thereby producing the sensation of light. This radiation, or some portion of it, reaches a given surface and thereby "illuminates" it; the surface reflects some portion of the radiation it receives and then is said to have a certain "brightness."

The consideration of this sequence leads to a system of definitions of photometric terms. These may be based on the luminous power of the source as the primary conception,[1] or alternatively, the rate of flow of radiation (*i.e.* luminous flux) may be regarded as fundamental, all other phenomena, including the source, being referred to this as the primary conception.[2]

§ (2) DEFINITIONS.—The following definitions of the more important photometric quantities may be given. Those marked with an asterisk (*) were adopted by the International Commission on Illumination in 1921.

*(i.) *Luminous Flux.*—It is the rate of passage of radiant energy evaluated by reference to the luminous sensation produced by it.

Although luminous flux should be regarded strictly as the rate of passage of radiant energy, as just defined, it can, nevertheless, be accepted as an entity, for the purposes of practical photometry, since the velocity may be regarded as being constant under those conditions.

It is measured by the quantity of luminous energy falling per second on a surface of unit area placed at right angles to the flow.

*(ii.) *The Unit of Luminous Flux* is the Lumen. It is equal to the flux emitted in a unit solid angle by a uniform point source of one international candle.

(iii.) *A Luminous Source*, or source of light, is one which emits luminous flux.

*(iv.) *The Luminous Intensity* (*candle-power*) of a point source in any direction is the luminous flux per unit solid angle emitted by that source in that direction. (The flux emanating from a source whose dimensions are negligible in comparison with the distance from which it is observed may be considered as coming from a point.)

*(v.) *The Unit of Luminous Intensity* (*candle-power*) is the international candle, such as resulted from agreements effected between the three National Standardising Laboratories of France, Great Britain, and the United States, in 1909.

[1] A. P. Trotter, *Illum. Eng.*, London, 1914, vii. 339.

[2] "Report of the Committee on Nomenclature and Standards of the Illuminating Engineering Society," *Am. Illum. Eng. Soc. Trans.*, 1917, xii. 438.

This unit has been maintained since then by means of incandescent electric lamps in these laboratories which continue to be entrusted with its maintenance.

These laboratories are: the Laboratoire Central d'Électricité in Paris, the National Physical Laboratory in Teddington, and the Bureau of Standards in Washington.

The International Candle is thus an arbitrary standard in terms of which luminous intensity is measured.

* (vi.) *The Illumination* at a point of a surface is the surface-density of the luminous flux at that point or the quotient of the flux by the area of the surface, when the latter is uniformly illuminated.

* (vii.) *The Practical Unit of Illumination* is the Lux. It is the illumination of a surface one square metre in area receiving a uniformly distributed flux of one lumen, or the illumination produced at the surface of a sphere having a radius of one metre by a uniform point source of one international candle situated at its centre.

In view of certain recognised usages, illumination may also be expressed in terms of the following units:

Taking the centimetre as the unit of length, the unit of illumination is the lumen per square centimetre; it is known as the Phot. Taking the foot as the unit of length, the unit of illumination is the lumen per square foot; it is known as "Foot-candle."

1 "foot-candle" = 10·764 lux
1·0764 milliphot.

(viii.) *The Brightness* of a luminous surface in a given direction is the candle-power per unit projected area of the surface in that direction. It is expressed in candles per square millimetre or per square metre.[1]

N.B.—Confusion has been caused in the past by the use of the illumination unit "foot-candle" or its modification "equivalent foot-candle" to express brightness. Brightness should preferably be expressed in terms of candles per unit area.

(ix.) *The Mean Horizontal Candle-power* of a lamp is the average candle-power in the horizontal plane passing through the luminous centre of the lamp.

It is here assumed that the lamp (or other light source) is mounted in the usual manner, or, as in the case of an incandescent lamp, with its axis of symmetry vertical.

(x.) *The Average Candle-power* of a lamp is the average value of the candle-power measured in all directions in space. It is numerically equal to the total luminous flux emitted by the lamp in lumens divided by 4π. This has been generally termed the "mean spherical candle-power," and similarly the term "mean hemispherical candle-power" of a lamp (upper or lower) has been used for the average candle-power of a lamp in the hemisphere considered. It is recommended that for this purpose the name of the hemisphere in question should be added to the term "average candle-power," thus: "average candle-power (upper hemisphere)." In the past the term "Efficiency" has been generally used to denote the performance of a lamp in terms of the watts of electrical power consumed, divided by the luminous intensity in candles. It is recommended that this should be called the "watts per candle" of the lamp.

[1] Normal brightness is the brightness of a surface when viewed in the direction of its normal.

§ (3) Fundamental Relation of Photometry.—From the fact of the rectilinear propagation of luminous radiation it at once follows that, with a uniform point source: (*a*) the flux incident per unit area, on a very small surface normal to the direction of the light, varies as the inverse square of the distance of the surface from the source; and (*b*) the flux incident per unit area, on a very small surface at a given distance from the source, varies as the cosine of the angle between the normal to the surface and the direction of the light. Thus, if the distance between a surface and a luminous source so greatly exceeds the dimensions of both that these may be neglected by comparison, the illumination E of the surface varies (i.) directly as the candle-power J of the source in the direction of the surface; (ii.) inversely as the square of the distance of separation, d; (iii.) directly as the cosine of

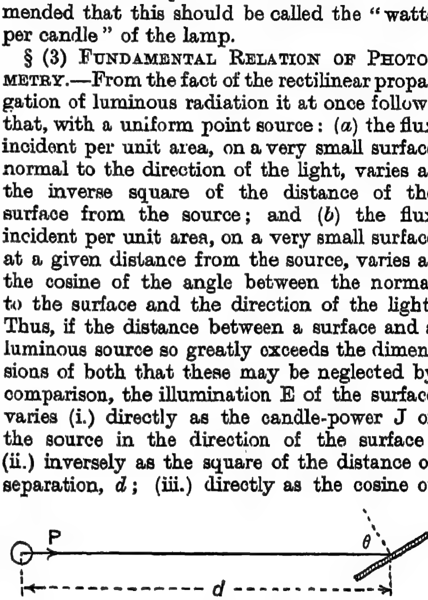

Fig. 1.

the angle θ between the normal to the surface and the line joining it to the source (see *Fig.* 1), or, in symbols,

$$E = J \cos \theta / d^2.$$

The second and third of these laws are known as the "inverse square law" and the "cosine law" of illumination respectively, and it is upon the equation just given that the whole of the science and practice of photometry is based.

II. Photometric Standards

The standards to be dealt with in this article include two groups: (*a*) primary standards, in terms of which the candle-powers of all sources are expressed; and (*b*) secondary standards, for practical use in everyday photometry.

§ (4) Requirements of Primary Standards.—The conditions which a primary standard should fulfil are those required of any physical standard, viz. ease of reproducibility

from specification, maintenance of value over long periods, small correction factors for change of conditions such as barometric pressure, temperature, etc. In addition to these, a standard of candle-power must fulfil, as far as possible, the condition that the spectral distribution of its light shall approximate to that of the light sources measured by comparison with it. This condition is due to the great difficulties introduced into photometry by difference of colour between the lights being compared (see § (102) *et seq.*).

Many suggestions have been made at different times for the production of a satisfactory primary standard of candle-power. None of these fulfils, even approximately, all of the conditions outlined above. Most are difficult to reproduce with sufficient accuracy and are greatly affected by change of exterior conditions. None fulfils the condition as to spectral distribution, the colour of the light being, in every case, much redder than that of the sources of light in common use to-day.

§ (5) Kinds of Standards.—The proposed standards which have so far received any degree of support may be divided into two groups: (i.) flame standards, depending on the candle-power of a luminous flame burning under specified conditions; (ii.) incandescence standards, depending on the candle-power of a specified area of some solid or molten material at a given temperature.

Of the flame standards the most important are the British standard candle, the Vernon-Harcourt Pentane Lamp, and the Hefner Amyl-Acetate Lamp.

§ (6) British Standard.—(i.) The British candle was set up under the Metropolitan Gas Act of 1860 as the official standard for the purpose of testing London gas. It was described as a spermaceti candle weighing one-sixth of a pound, and burning at the rate of 120 grains per hour.

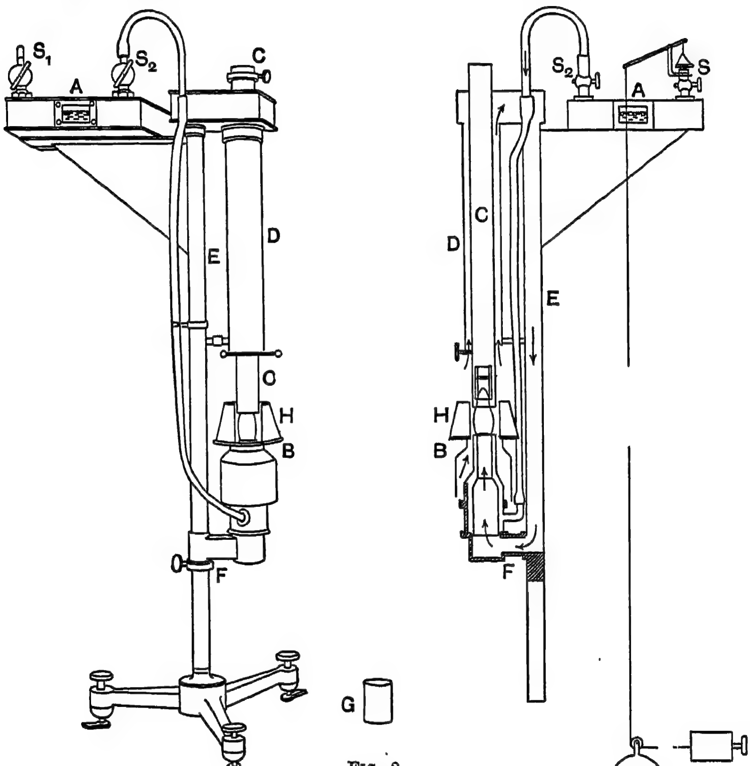

Fig. 2.

(ii.) This standard has now been superseded for practical purposes by the pentane lamp devised by Vernon-Harcourt in 1877. This lamp is shown diagrammatically in *Fig.* 2. The saturator A holds the fuel, liquid pentane, a highly inflammable and very volatile hydrocarbon distilled from petroleum. This saturator is filled to about two-thirds of its capacity before the lamp is lighted. The level of the liquid (observed through the window in the side of the saturator) is never

allowed to fall below one-eighth of an inch when the lamp is in use. The saturator is connected, by means of a wide india-rubber tube, with the burner B, which consists of a steatite ring pierced with 30 holes, and at which the issuing mixture of air and pentane vapour is ignited. The rate of flow of the mixed vapour, and therefore the height of the flame, can be adjusted by means of the stop-cocks S_1 and S_2 on the saturator. The chimney tube CC is furnished near its base with a mica window, upon which is marked a horizontal line 88 mm. above the bottom of the chimney. The chimney is set, by means of a cylindrical wooden gauge G, so that its lower end is exactly 47 mm. above the steatite ring burner. Surrounding the chimney CC is a concentric tube D up which a current of air is drawn by the heating of the chimney, and this heated air passes into the hollow supporting pillar E and so down through F to the centre of the steatite ring where it is used in the combustion of the pentane. It is important that the chimney CC be brought centrally over the burner B, and three screws are provided at the base for the purpose of making this adjustment. H is a conical shade for protecting the flame from draught. When in use, the lamp is set up with the pillar E vertical, and the stop-cocks S_1 and S_2 are so adjusted that the tip of the flame just rises to a level halfway between the bottom of the mica window in CC and the cross bar. (A slight variation in the height of the flame, however, does not affect its candle-power.) The mica window must, of course, be turned away from the photometer head, while H is turned so that the whole of the flame is visible from the photometer, except the portion at the top which is cut off by the lower part of the chimney. The saturator A is at first placed upon its bracket as far from the central column as possible and the lamp is left alight for at least a quarter of an hour before any photometric measurements are made. If it is found at the end of this period that the flame has a tendency to fall in height, the saturator is moved slightly towards the central column. In making photometric measurements all distances are reckoned from the centre of the flame, *i.e.* the geometric centre of the steatite ring.

(iii.) *The Pentane Lamp as Standard.*—When burnt under standard conditions of temperature, pressure, and humidity, the pentane lamp is recognised as having a candle-power of ten international candles. For a more accurate and detailed specification of the lamp, and of the preparation of the pentane, the Notification of the Metropolitan Gas Referees for the year 1916, published by H.M. Stationery Office, should be consulted. A copy of this notification, together with working drawings of the pentane lamp, is deposited at the National Physical Laboratory, and may be there consulted.

The value of the candle-power of the pentane lamp depends on the humidity and barometric pressure of the atmosphere in which it is burning. Several determinations have been made of the effect of these variables on the candle-power of the lamp. The latest is that of C. C. Paterson and B. P. Dudding at the National Physical Laboratory,[1] and for the details of their experiments their original work should be consulted. The result they obtain is given by the formula

$$\text{C.P.} = 10\{1 + 0{\cdot}0063(8 - e) - 0{\cdot}00085(760 - b)\},$$

where C.P. represents the candle-power of the lamp when burning in an atmosphere at a pressure of b mm. of mercury with a humidity of e litres of water-vapour per cubic metre of the moist air. The constants of the above equation agree exceedingly well with those given by Butterfield, Haldane, and Trotter,[2] but Rosa and Crittenden [3] find values for the constants which are notably lower than those given above, viz. 0·00567 and 0·0006. It has been suggested that this difference in the constants may be accounted for on the assumption that the lamp really possesses a temperature coefficient, but that as humidity and temperature are so closely related in any one locality, their separate effects cannot be determined by the usual method of observation. Differences in the relation between these two quantities at Washington and at Teddington might explain the observed differences in the humidity coefficients found at these two places. The values of the constants are obtained from a very large number of comparisons with an electric glow-lamp sub-standard of the same colour, observations being made under all available conditions of pressure and humidity. The most probable values of the constants are then found by the method of least squares. The value for the humidity correction found in 1917 by K. Takatsu and M. Tanaka [4] was 0·00638, and they suggest that the different value found in America may be due to the use of a hood and ventilating duct, if the effect of this is not the same at all humidities.

§ (7) The Hefner Lamp.—The standard of candle-power adopted as legal in Germany and some other European countries is the lamp devised in 1884 by von Hefner Alteneck and shown in *Fig.* 3. It consists of a container C, made of brass, 70 mm. in diameter and 38 mm. high. It holds about 115 c.c.

[1] "The Unit of Candle Power in White Light," *Phys. Soc. Proc.*, 1915, xxvii. 281.

[2] *Journ. of Gas-Lighting*, 1911, cxv. 88.

[4] Electro-Techn. Laborat., Dept. of Communications, Tokyo, Oct. 1917.

of amyl acetate, a specially pure grade of this compound being required for photometric purposes. The liquid should always be

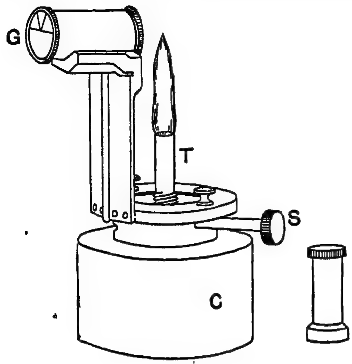

Fig. 3.

emptied out of the container when the lamp is not in use, as otherwise corrosion is liable to take place even though the inside of the container be tinned or nickel-plated. A thin German silver tube T, constructed very accurately to the dimensions of 25 mm. in height, 8 mm. in internal diameter, and 0·15 mm. in thickness of metal, holds a wick of 15 to 20 strands of untwisted cotton which can be adjusted in height by means of the screw S. G is a gauge consisting of a lens and ground glass screen with a horizontal cross-line. The lens forms an inverted image of the flame on the screen, and by this means the tip of the flame can be very accurately adjusted to the correct height of 40 mm. above the level of the tube. The candle-power of the flame depends appreciably on its height, and one of the chief disadvantages of this standard is the fact that the flame is very lambent and sensitive to draught, so that in the absence of any chimney its use is attended with great difficulty for practical measurement.

Liebenthal finds that a variation of 1 mm. in the height of the flame causes 2·7 per cent change in candle-power. The gauge on the lamp may be raised 4 mm. to permit adjustment of the flame to a height of 44 mm., at which height the candle-power has been found to approximate very closely to the unit derived from the pentane lamp.

With the Hefner, as with the pentane lamp, allowance has to be made for pressure and humidity of the air. The formula in the case of the Hefner lamp is

$$\text{C.P.} = 1 + 0{\cdot}006(8{\cdot}8 - e) - 0{\cdot}00011(760 - b),$$

where e and b have the same meaning as before.[1]

§ (8) The Carcel Lamp.—The flame standard officially adopted in France for gas-testing is the Carcel lamp, which is a lamp burning colza oil with an Argand burner and glass chimney. The wick is continually supplied with oil by means of a clockwork pump, and the correct candle-power is obtained when the rate of oil consumption is 42 gm. per hour. In actual use the wick is adjusted to give approximately this consumption, and a correction is applied for the departure from this theoretical value. The actual consumption is obtained by burning the lamp on a form of balance, and noting the time at which the lamp loses ten grammes in weight. The difficulties attending the use of this lamp are very great, and different observers are unable to obtain results either consistent among themselves or in agreement with one another.

§ (9) The Violle Standard.—Of the incandescence standards which have been proposed two require some description, viz. the Violle platinum standard, and the positive crater of the carbon arc. The former, which was proposed in 1881 by Violle, is the light from one square centimetre of a surface of molten platinum at the temperature of solidification. The Violle standard, on account of its obvious theoretical advantages, has been regarded as a promising advance on the existing flame standards, and unsuccessful attempts have been made at various times to place it on a satisfactory practical basis. The most recent careful work on this standard is that of Petavel,[2] who used a semicircular bar of platinum heated by an electric current to such a temperature that the inner core of the bar melted while the outer shell remained solid. The second form of the standard on which he made measurements was an ingot of platinum fused in a crucible of pure lime by means of an oxy-hydrogen blow-pipe. The metal was first completely melted and then heating was stopped and photometric measurements of the brightness were made at 10-second intervals during cooling. The readings when plotted showed a constant value over the region corresponding to the time of solidification, and the mean of the observations at this period was taken as the value required. It was found that the values obtained by this method did not depend on the shape or mass of the ingot, but that the effect of contaminating the platinum with either silica or carbon was very marked. Petavel's final conclusion was that the probable variation in the light emitted by molten platinum under standard conditions was not greater than one per cent, and that with more experimental refinements an even greater accuracy than this might be attainable. It cannot be said, however, that one per cent is sufficient to bring the Violle standard, with its additional disadvantage of redness of light,

[1] E. Ott, *Journ. of Gas-Lighting*, 1915, cxxxii. 378; and *Electrician*, 1915, lxxvi. 227.

[2] *Roy. Soc. Proc.*, 1899, lxv. 481.

into serious competition with the existing standards.

§ (10) LUMMER-KURLBAUM STANDARD.—One other platinum standard which has been proposed, and may be mentioned in passing, is that of Lummer and Kurlbaum. This consists of the light emitted by one sq. cm. of a platinum strip raised to such a temperature that a layer of water 2 cm. in thickness transmits 10 per cent of the total resultant radiation. This ratio is determined by means of a bolometer. Although this standard is used at the Physikalisch-Technische Reichsanstalt for the checking of Hefner lamps, Petavel has found (*loc. cit.*) that the bolometer method of temperature adjustment is not sufficiently exact to enable this apparatus to fulfil the conditions of a primary standard.

§ (11) CARBON ARC STANDARD.—The other incandescence standard, on which a considerable amount of work has been done by Morris, Forrest,[1] and others, is that provided by a square millimetre of the positive crater of a carbon arc operating under conditions designed to ensure steadiness. In the Forrest arc (*Fig.* 4) two negatives are employed, each at an angle of about 100° with the positive. Under these conditions, and using carbons of 8 mm. diameter with a total current of 7 to 10 amperes, it was found that the brightness of the crater was uniform over the whole of its surface, and photometric measurements were made of the candle-power per sq. mm. by inserting in front of the crater at D a small diaphragm of accurately known dimensions. Forrest found that the arc would work quite silently over a considerable range of currents, and that the crater brightness was independent of the current under these conditions. The value he obtained was 172-174 candles per sq. mm., and more recent work on the same lines by Allen[2] has confirmed his general conclusions and gives 176 candles per sq. mm. as the intrinsic brightness of the positive crater of a silent arc.

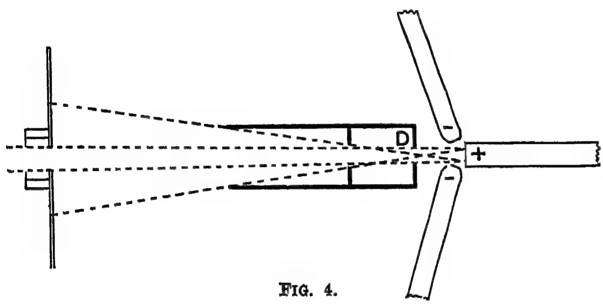

FIG. 4.

An advantage which this standard possesses over any other is that the colour of the light is bluer than that of most present-day sources, a difference which will diminish as the efficiency of practical illuminants increases.

§ (12) BLACK BODY STANDARD.—The proposal to use a definite area of a total radiator (black body) at some definite temperature has been made during recent years,[3] and as early as 1908 Waidner and Burgess suggested the use of one sq. centimetre of a black body at the temperature of melting platinum. The chief difficulty is that, as with all incandescence standards, the light emitted varies as a high power of the temperature of the radiator, so that the accuracy of the temperature measurements needs to be at least ten times as great as the desired accuracy of the light standard.

§ (13) GLOW-LAMP SUB-STANDARDS.—Finally, it is necessary to describe the electric glow-lamp sub-standards which are used for daily work in practical photometry. Specimens of such lamps as used at the National Physical Laboratory are shown in *Fig.* 5, some having carbon and some drawn tungsten filaments. In the case of the latter the filaments are disposed in grid formation so that the plane of the whole filament can be brought accurately over any mark on the photometer bench. Such standards as these can be operated at any given efficiency so that an approximate colour match may be obtained with the source with which they are to be used. Paterson has found[4] that, if not overrun, these lamps will maintain their

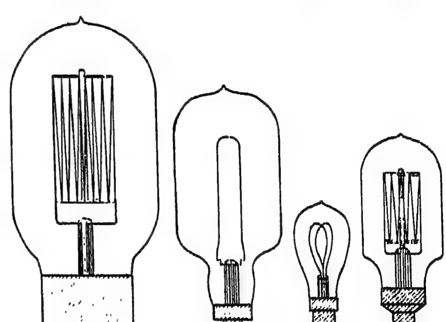

FIG. 5.

candle-power values for many hours of burning, so that if used only for a few minutes each day, they do not need recalibration for long periods. For this reason they have very largely superseded the actual primary standards in everyday photometry, and standards such as these, after comparison with master standards at a National Laboratory, are used in most photometric laboratories for practical work. Since the candle-power of a carbon filament varies as the sixth and that of a tungsten filament as the fourth power of the voltage applied to it, it is necessary to make the electrical measurements with 4 to 6 times the accuracy required of the candle-power measurements. With proper battery supply and potential measuring apparatus, however, this presents little difficulty.

§ (14) Relative Values of the Standards.—The following table summarises the relative values of the different standards above described.

Table I

	Pentane.	Hefner.	Carcel.	Violle.
Pentane .	1	11·1	1·05	0·5
Hefner . .	0·09	1	0·094	0·045
Carcel . .	0·96	10·6	1	0·48
Violle . .	2·0	22	2·1	1

Since 1909 the standard derived from the 10-candle pentane lamp has been adopted by the National Laboratories of France, Great Britain, and U.S.A., and has been subsequently preserved by means of glow-lamp sub-standards. This is now termed the International Candle, and is equal to the old French "Bougie décimale."

III. Photometric Methods

As has already been stated in the section on General Photometric Principles (*q.v.*), the comparison of light sources is always made by comparing the brightness of surfaces illuminated by these sources. Thus every photometer is essentially an instrument for the ready comparison of brightness. Photometers may, however, be grouped in two classes according as they are primarily intended for the comparison of light sources, or for the measurement of illumination at a given position.

In the case of the former class the two sources are generally placed one on either side of the photometer, and their respective distances from the comparison surfaces in the instrument are then adjusted until equality of brightness is obtained. Assuming both the surfaces to have the same reflection ratio, and to be equally inclined to the incident light, this condition gives the distances at which the two sources produce equal illuminations, and hence the candle-powers of the sources (in the direction of the photometer) are in the same ratio as the squares of their respective distances from the photometer surfaces.

§ (15) The Bunsen Photometer.—As a convenient example, the simple form of the Bunsen Grease-Spot Photometer may be described. This consists of a sheet of opaque white paper rendered translucent over a small circular region in its centre by the application of paraffin-wax. This sheet S (*Fig.* 6) is mounted in a box which is blackened on the inside and provided with two mirrors MM by means of which the two sides of the sheet may be simultaneously observed. The box is mounted between two sources of light, the sheet of paper being perpendicular to the line joining them, and is moved to and fro along this line until the observer obtains an identical appearance for the two sides of the paper as viewed in the mirrors. The candle-powers of the sources are then in the ratio of the squares of their distances, d_1, d_2, from the paper sheet in the photometer head, *i.e.* if J_1 and J_2 are the candle-powers of the sources in the direction of the photometer, then

$$\frac{J_1}{J_2}=\frac{d_1^2}{d_2^2}.$$

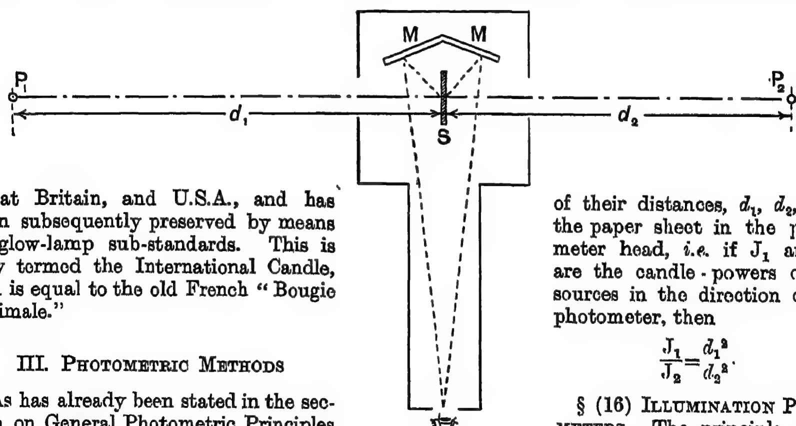

Fig. 6.

§ (16) Illumination Photometers.—The principle of an illumination photometer is somewhat different. This instrument is used for determining the illumination at a given position by placing a matt white surface in that position and measuring its brightness by comparison with that of another surface contained in the instrument. The illumination of this surface is variable at will by the motion

of some part of the instrument, so that, with a scale previously calibrated, the value of the illumination of the outside surface can be at once obtained. *Fig.* 7 shows a typical form of illumination photometer.

P is the photometer case containing L the electric lamp, S_2 the surface whose brightness can be varied by moving L, and E an eyepiece. S_1 is the other surface placed at the point at which it is desired to measure the

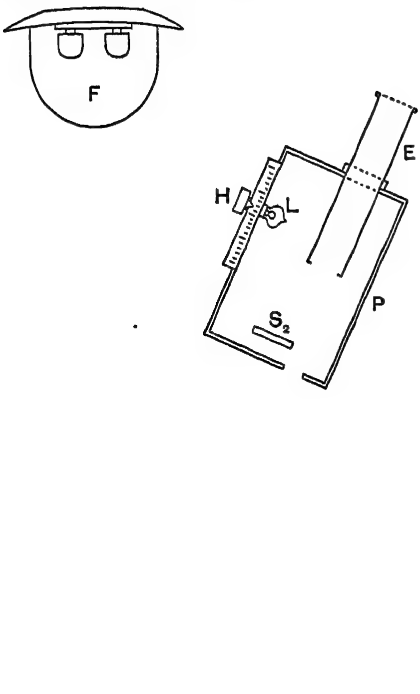

FIG. 7.

illumination produced by lamp F. The surfaces S_1 and S_2 are observed simultaneously through E, and the handle H is moved until S_1 and S_2 appear equally bright. As the movement of the handle regulates the illumination at S_2 each position taken up by it corresponds with some definite illumination. These illuminations are marked on a scale over which moves a pointer attached to the handle, so that when there is equality of brightness the scale reading indicated by the pointer gives at once the value of the illumination at S_1, which was desired.

§ (17) MODERN METHODS OF PHOTOMETRY.—Modern photometry, as far as it is concerned with the comparison of light sourcés, and their measurement in a given direction by comparison with standard sources, depends on the use of a comparison photometer of the most sensitive type available, together with a photometer bench specially designed for the accurate determination of the distances involved.

§ (18) THE LUMMER-BRODHUN PHOTOMETER.—The form of photometer head generally employed for work of the highest accuracy with lights of the same colour is the Lummer-Brodhun contrast type, the first form of which was described in 1889, though it has undergone several improvements since that date. The principle on which the instrument works will be best understood from *Fig.* 8, which shows on the left a plan view of the interior of the photometer head, and on the right an enlarged view of the prism system P. S is a central screen (approximately 4 mm. thick) constructed of white plaster with as matt a surface as can be obtained. The two sides of this screen are respectively illuminated by light from the two lamps to be compared. M_1 and M_2 are total reflection prisms, and by means of these the light from the two sides of the screen is brought to opposite faces of the prism system P.

This system, as may be more clearly seen from *Fig.* 8A, consists of two right-angled prisms placed with their hypotenuses in contact. The hypotenuse of the left-hand prism, however, is sand-blasted with the pattern shown shaded in *Fig.* 8B, and thus the only parts of the two prisms which are in optical contact have the form of the white pattern in that figure. The result is that light passing into prism P_1 is transmitted without change to prism P_2 in the pattern shown white in *Fig.* 8B, while the pattern shown shaded in that figure is the pattern over which total reflection takes place in prism P_2, *i.e.* the pattern over which the light from M_2 is seen by the observer at O. In effect, therefore, the observer at O sees a pattern of this form in which the brightness of the shaded portion is due to light from the right-hand side of S, while the brightness of the white portion is due to light from the left-hand side of S. Clearly, when the two sides of S have the same brightness the pattern will disappear.

Disappearance, however, is not the condition of which the eye is capable of judging most sensitively, and therefore sheets of glass G_1 and G_2 are inserted as shown in *Fig.* 8A, so that the light forming each of the rhomboidal patches is reduced by 8 per cent, and the condition to be arrived at is then equality of contrast between the patch and its background in both halves of the field of view. The observer is provided with a telescope at O, by means of which the pattern of the field is brought into accurate focus for his eye,

as without sharpness of focus it is difficult to obtain accurate settings of the photometer.

The whole of the optical part of the apparatus is mounted rigidly in a brass box which is capable of rotation about a horizontal axis. Further, the screen S can be removed for alignment of lamps on the bench, or for reversal of screen to eliminate differences due to lack of equality in reflection ratio of the two plaster surfaces. The photometer windows are provided with brass shutters, and these should always be kept closed when the instrument is not in use, as otherwise both the plaster screen and the glass surfaces of the prisms become dusty, and the field of view is covered with specks so that the accuracy of the readings is much impaired. With experienced observers, lights of the same colour can be compared with this photometer to an accuracy of 0·1 per cent by taking the mean of a number of observers working on several occasions and using the method of procedure described later in this section.

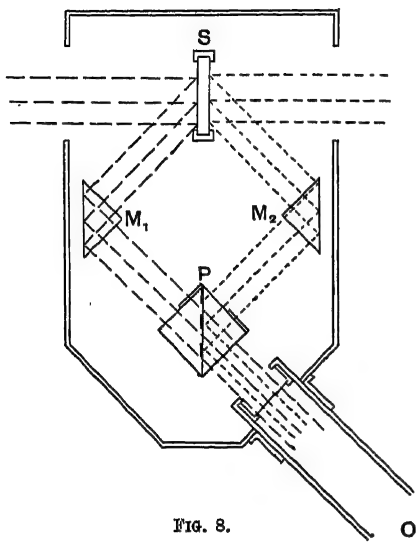

FIG. 8.

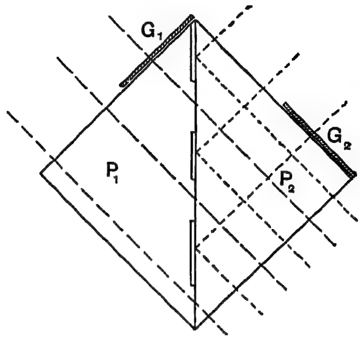

FIG. 8A.

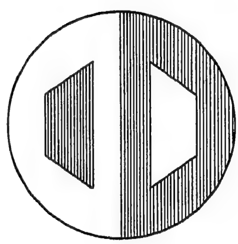

FIG. 8B.

§ (19) THE PHOTOMETER BENCH.—The photometer bench must next be described. The pattern designed and used at the National Physical Laboratory is shown in general view in *Fig.* 9. It consists of two straight steel bars, 3000 to 5000 mm. long, supported rigidly at intervals, the distance between the bars being 300 mm. Carriages, one of which is shown to a larger scale in *Fig.* 10, support the lamps to be compared, and the photometer head. These carriages consist of aluminium base plates B supported on three rollers with V-shaped grooves which run smoothly along the bars of the bench. The centre upright of the carriage has an adjustment for raising and lowering the plate P, and the latter is also capable of rotation about its axis, and carries a scale of degrees, so that it may be brought to any desired position.

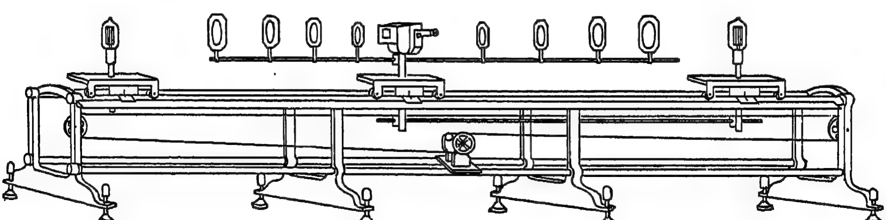

FIG. 9.

Different fittings are attached to the various carriages according to the particular apparatus which they are intended to bear. The speci-

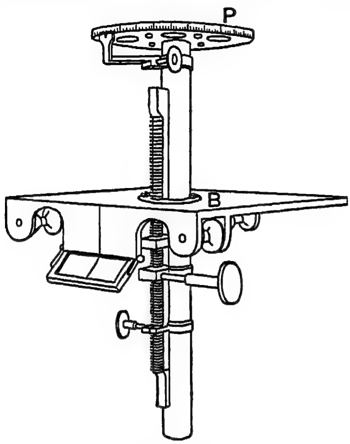

Fig. 10.

men shown in *Fig.* 10 is designed to hold a lamp. Others are adapted for carrying a rotator, apparatus for polar curve measurements, or a photometer head and screening system.

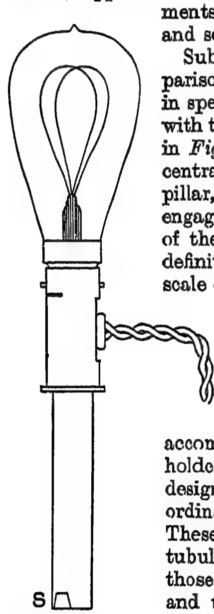

Fig. 11.

Sub-standards and comparison lamps are mounted in specially designed holders, with tubular stems (as shown in *Fig.* 11) which fit into a central hole in the carriage pillar, a slot S at the bottom engaging in a key at the base of the hole, so that when a definite mark on the degree scale of the table is opposite the pointer the lamp is in a definite position with respect to the axis of the bench.

Test lamps are accommodated in special holders which have sockets designed to take lamps with ordinary standard caps. These holders terminate in tubular stems similar to those on the sub-standards, and they are provided with two pairs of leads, both of which are soldered to those parts of the sockets which make the contacts with the lamp cap. One of these pairs of leads is used for supplying current to the lamp, while the second pair is used for voltage measurement. In this way the voltage is measured at points which are as near as possible to the actual lamp contacts, and no allowance has to be made for voltage drop in the supply leads. Each pair of leads is connected at its free end to a special form of ebonite holder, which is designed to facilitate connection with terminals carried on a small ebonite board at the end of the bench (*Fig.* 12).

The carriage bearing the photometer head also carries a steel bar along which are placed,

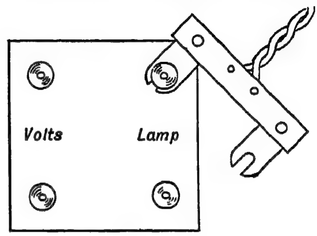

Fig. 12.

at convenient intervals, a number of blackened aluminium screens with varying sizes of apertures. The relative sizes of the screens and their apertures, and the intervals at which they are placed along the bar, are so related that the screen of the photometer head is completely shielded from rays of light proceeding from anywhere but a narrow region surrounding the lamp to be measured (see *Fig.* 13). When the bench is in use black curtains are hung on either side of it throughout its length, and black velvet screens are placed behind the lamps being compared, so that, as far as possible, stray light is completely

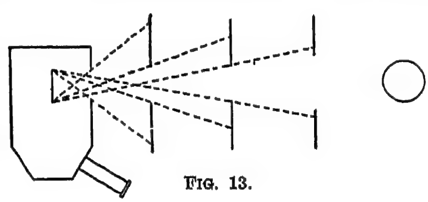

Fig. 13.

prevented from reaching the photometer. One source of stray light which is sometimes found to give trouble is the specular reflection of the light from the lamp by the polished surfaces of the steel rods of which the bench is composed. This may be avoided by ebonising the rods (though even in this case specular reflection still takes place) or, better, by covering the rods at the half-way point with a piece of black velvet. The importance of adequate screening cannot be overestimated in accurate photometric work.

§ (20) Procedure in making a Photometric Measurement.—The photometric procedure adopted at the National Physical Laboratory may be conveniently described by analogy with the double-balance method

of weighing. As in this method the object whose mass is required is first balanced by an unknown mass of sand and is then removed from the scale pan and replaced by weights sufficient to balance the sand again, so in this method of photometry a lamp of unknown candle-power is used on the right-hand side of the photometer bench, and this is termed the "comparison lamp." The carriage holding this lamp is clamped to the carriage holding the photometer head by means of a bar of convenient length, so that the two carriages may be moved as one unit and the illumination on the right-hand side of the photometer head remains constant (see *Fig.* 9).

To adjust this illumination to 10 metre-candles a glow-lamp sub-standard of accurately known candle-power is placed in a carriage at the zero mark on the left-hand end of the photometer bench. The distance of this lamp from the photometer head, which gives an illumination of 10 metre-candles on the screen, being accurately known, the corresponding distance for the comparison lamp (termed its "fixed distance") is found by photometric balance between the two. In actual practice this fixed distance is found as the mean of observations with four or five sub-standards and two or more observers, depending on the accuracy of the work to be undertaken. The distance between the photometer head and the comparison lamp is then fixed, by means of the bar, at the value thus obtained, and the bench is then ready for the measurement of the test lamps.

A test lamp having been placed in the left-hand carriage of the photometer bench, and the axis of its filament (or mean plane of filament when dealing with grid filaments) having been carefully adjusted to be over the zero of the photometer bench, the observer makes a number of settings of the photometer head. An assistant notes these down, and the square of the mean distance in metres multiplied by 10 gives at once the candle-power of the test lamp in the direction of the photometer. It is generally the case that two observers will obtain values for the fixed distance of the comparison lamp differing by several millimetres in 1300 to 1500 (the distance for a lamp giving about 20 candles). It is therefore customary to set the fixed distance at the value found by one observer and to correct the observations of the other observers so as to make these correspond with the fixed distances found by them.

It may be mentioned in passing that the observer at the photometer head never sees his own readings until they are all taken and entered up, so that he has no chance of being unconsciously biassed in one direction or another. For really accurate work, such as the standardisation of sub-standards, where values are certified to an accuracy of a quarter per cent, the procedure above outlined is gone through on three or four separate occasions, as it is found that the relative values obtained by two or more observers will differ slightly from day to day, so that it is desirable to have the mean results of several days' observations.

(i.) *Errors.*—It will be seen that this method of photometry avoids four of the errors to which a simple comparison of test lamp with standard is liable. These errors are: (i.) photometer screen error, (ii.) zero error of photometer head, (iii.) unequal reflections from extraneous objects at the two ends of the bench, and (iv.) observer's personal error. The first of these errors, due to lack of symmetry in the photometer head, as has already been mentioned, can be compensated by reversing the photometer head, but this does not apply to the other errors, which still remain unless a substitution method is employed.

It will be clear that the bench, in addition to its millimetre scale, may bear a "square" scale so graduated that the position of the photometer head, when the illumination is equal to 10 lux, gives the candle-power of the test lamp directly without calculation; for with a reading of n millimetres the candle-power is $(n/1000)^2 \times 10$ candles. It will be noticed that no allowance has been made above for the thickness of the plaster screen of the photometer head. If the distances of the two lamps from the photometer are approximately equal, or even in the ratio of 2 to 1, with distances of 1300 mm. or over, the error introduced by this neglect does not exceed 0·15 per cent. For work at short and unequal distances, however, the semi-thickness should be subtracted from the distance of the test lamp, assuming that the distance of the sub-standard has been given as that necessary to produce an illumination of 10 metre-candles on the actual surface of the photometer screen.

(ii.) *Alternative Method.* — It sometimes happens that the method of fixed distance described above is not practicable, either on account of the high candle-power of the test lamp and insufficient length of the bench, or when measuring a source in a number of positions in which the candle-power varies over a wide range. In this case it is necessary to fall back on actual candle-power measurements of the comparison lamp, and the use of the inverse square law, both lamps being held stationary, while the photometer head alone is moved. In this case, if d is the distance between the two lamps, J the candle-power of the comparison lamp, and x the distance of the photometer head from the test lamp, the candle-power of the test lamp is given by the formula $Jx^2/(d-x)^2$. This method, of course, involves

much more calculation than the fixed distance method.

For the measurement of very high candle-power sources at the National Physical Laboratory, a 3-metre photometer bench is mounted on a table fitted with rollers, which move along a rail track 30 metres in length.

§ (21) BEST ILLUMINATION.—An important factor which has to receive consideration in accurate photometry is the degree of illumination desirable on the photometer screen. It seems to be generally agreed that an illumination of between 5 and 20 metre-candles is that at which the eye is capable of giving the best results with the Lummer-Brodhun photometer head. Outside these limits the accuracy of judgment of equality begins to diminish.

(i.) *Absorbing Screens.*—In the case of very high candle-power sources of light it is sometimes inconvenient or impossible to place these sufficiently far from the photometer to give the desired degree of illumination, and various methods have been proposed for reducing the intensity in a determinable ratio. One such method, the use of a neutral-tinted glass plate (or double-wedge), placed in the path of the light, has the disadvantage that truly neutral glass is unobtainable, so that in practice it is necessary to determine the transmission ratio of a given specimen of glass absorber by means of light of exactly the same colour as that with which it is intended to be used. An alternative is that proposed by Ives and Luckeish,[1] and elaborated by Krüss.[2] This consists of two glass plates ruled with fine opaque black lines, exactly equal in breadth to the spaces between them. These two plates slide one behind the other, and so a variation in transmission of 50 per cent to zero can be obtained.

(ii.) *The Sector Disc.*—The most generally used apparatus for the purpose, however, is the sector disc in one of its many forms. The pattern devised and used by Abney is shown in *Fig.* 14, and possesses the advantage that the angle of the sector openings can be varied while the disc is in motion. The disc is placed so that its upper portion alternately intercepts and transmits the beam of light which it is proposed to reduce. The shaft carries near one end a grooved pulley driven at any desired speed by an electric motor. At the other end is a disc A, of which three equal sectors have been removed, except by the shaft and the rim. A second, exactly similar, disc is placed behind this one, and is rigidly attached to a flange fixed to a sleeve which slides on the shaft, and has a pin engaging in a spiral groove cut in the shaft. Thus, the longitudinal position of the sleeve along the axis of the shaft controls the relative positions of the two discs, and so the width of the sector openings is capable

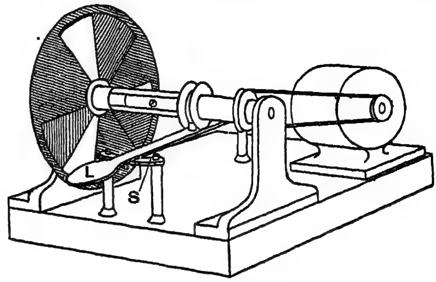

FIG. 14.

of control by means of a grooved wheel attached to the sleeve and acted upon by a pin in a lever L, which moves over a divided scale S. It has been shown by E. P. Hyde[3] that the transmission ratio of a disc of this kind, if due precaution be taken to avoid stray light, is accurately the same as the ratio of the total angle of opening to 360°. Of course, the smaller the opening the more the accuracy of the transmission ratio depends on the accuracy with which the sectors are cut, and for this reason it is not generally advisable to use openings smaller than 10° with a disc of ordinary construction. The speed of rotation has to be adjusted until all flicker of the field disappears, and therefore needs to be higher the smaller the transmission ratio.

§ (22) ERROR DUE TO SIZE OF SOURCE.—An important consideration in the photometry of sources of light of large dimensions, or where the candle-power is so small that the distance from the photometer has to be made comparable with the dimensions of the source, is the limit at which the inverse square law may be taken to apply with the necessary accuracy. This law is, of course, only strictly applicable to a point source of light, and in the practical case of a source of finite dimensions, the illumination of the photometer screen is the sum of the partial illuminations due to all the elementary portions of which

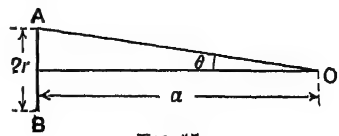

FIG. 15.

the source is composed, the inverse square and cosine laws being applied to each such elementary portion separately. Thus, in the case of a circular disc AB (*Fig.* 15), the illumina-

tion of an elementary surface at a point O along the axis of the disc, due to an element of the disc of area a situated at its centre, is aI/a^2, where I is the normal brightness of the disc. If the disc is a perfect diffuser, the amount of flux it emits in any direction is proportional to the cosine of the angle which that direction makes with the normal to the surface. The illumination produced by a similar element at A, therefore, is only $aI\cos^2\theta/AO^2$, for the amount of flux emitted by the disc per unit area in the direction of AO is $I\cos\theta$, and since this meets the surface at O at an angle θ with the normal to that surface, the illumination is again subject to the factor $\cos\theta$. Hence the illumination at O due to A is $aI\cos^4\theta/a^2$. By integrating this expression over the whole disc it is found that the illumination at O due to the whole disc is $r^2E/(a^2+r^2)$, where r is the radius of the disc and E is the illumination calculated on the assumption that the size of the disc is negligible in comparison with its distance from O. Similarly it may be shown that for a single straight filament of length $2l$ the illumination at an elementary surface distant a from its centre is $E/2[a/l\tan^{-1}l/a+a^2/(a^2+l^2)]$, where E has the same meaning as before. Clearly, in these two particular examples, if the error is not to exceed 0·2 per cent, then in the first case r/a must not exceed 4·5 per cent, and, in the second case, l/a must not exceed 4 per cent. In *Fig.* 16 are given graphs of the percentage errors introduced by assuming discs or lines of various dimensions to behave as absolute point sources. These graphs give therefore the dimensions of the largest sources for which the inverse square law may be assumed to hold to any desired degree of accuracy.
